The current through the input resistor is thus easily computed because all node voltages are now known. Furthermore, by Kirchhoff's current law this current must equal that through the feedback resistor R_F since we have assumed that no current flows into the input terminals of the op-amp proper. Thus,

$$i_1 = i_F \rightarrow v_1/R_1 = -v_{\text{out}}/R_F, \tag{2}$$

so that

$$v_{\text{out}}/v_1 = -R_F/R_1, \tag{3}$$

that is, this circuit provides a voltage amplification factor (or gain) that is equal to $-R_F/R_1$, with the minus sign indicating that this circuit also provides an inversion.

Figure 2(b) shows how this circuit may be extended to provide an output that is a weighted sum of any number of inputs. The analysis is simplified by observing that the current i_F is simply the sum of the currents through the input resistors, and that the output voltage is simply the product of this total current and the feedback resistor (with a minus sign). Thus,

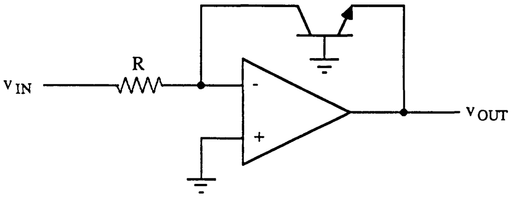
$$v_{\text{out}} = -R_F\left(\frac{v_1}{R_1} + \frac{v_2}{R_2} + \cdots + \frac{v_n}{R_n}\right). \tag{4}$$

By appropriate choices of the various resistors, this circuit can compute a variety of linear functions of the inputs, including the average of n input signals, as well as the special case of a pure sum.

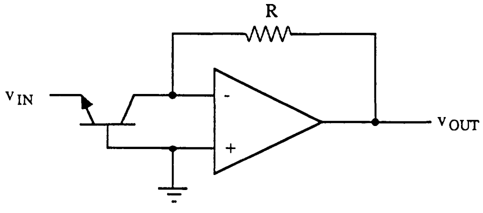
Figure 2(c) shows how a noninverting amplifier may be realized. Note that negative feedback is still employed, but that the input signal is now applied to the noninverting input of the op-amp. Proceeding as before, observe that the voltage at the inverting terminal is simply

$$v_- = v_{\text{out}}\left(\frac{R_2}{R_1 + R_2}\right). \tag{5}$$

Since we have assumed an infinite differential voltage gain, $v_+ = v_-$ as before. Further-



a) Logarithmic Amplifier



b) Exponentiator

FIG. 3. Nonlinear op-amp circuits.

more, because v_+ is equal to the input voltage, one finds that

$$\frac{v_{\mathrm{out}}}{v_{\mathrm{in}}}=\left(\frac{R_1+R_2}{R_2}\right). \tag{6}$$

With the addition of nonlinear elements (those whose current-voltage characteristics are not expressible in linear form), operational amplifiers can perform a rich variety of functions. As an example, consider the circuits, shown in Fig. 3, that combine transistors with op-amps. Although transistors will be discussed in detail in Sec. 3, assume for present purposes that a transistor obeys the following relationship at a fixed value of collector-base voltage:

$$i_C=I_S\exp(qv_{\mathrm{BE}}/kT), \tag{7}$$

where i_C is the collector current, I_S is a parameter known as the saturation current, q is the magnitude of the electronic charge, k is Boltzmann's constant, and T is the absolute temperature. Although this relation is an approximation, well-made devices conform to it within a few percent over more than seven or eight decades of collector current.

With this exponential $i_C - v_{\mathrm{BE}}$ relationship it is trivial to show that the circuit of Fig. 3(a) is a logarithmic amplifier. By virtue of the negative feedback connection, the inverting terminal is a virtual ground. Therefore the current through the input resistor is simply v_{in}/R. This current is also the collector current, and the base-emitter voltage is logarithmically related to the collector current. The output voltage is $-v_{\mathrm{BE}}$, whose value is readily computed as

$$v_{\mathrm{out}}=-v_{\mathrm{BE}}=-\frac{kT}{q}\ln\left(\frac{v_{\mathrm{in}}}{RI_S}\right). \tag{8}$$

From this last equation we see that as long as the temperature is held constant, the output voltage is proportional to the natural logarithm of the input voltage. It should be noted that there are modifications of this basic circuit that reduce greatly its temperature dependence.

The exponentiator of Fig. 3(b) can be analyzed in an exactly analogous way. The exponentiator can combine with summers and log-takers to permit multiplication entirely in the analog domain.

The computational power of op-amp circuits increases greatly as soon as energy-storage elements such as capacitors (and infrequently, inductors) are used since such elements provide some memory of past history. As an example consider the circuit shown in Fig. 4. This connection realizes an electronic integrator, that is, a circuit whose output is proportional to the integral of the input voltage (or current).

Analysis of the integrator is straightforward. Recall that charge (Q) and voltage are related in the following manner:

$$Q=CV. \tag{9}$$

Furthermore, note that the capacitor current i_C is simply the time integral of the capacitor charge. Finally, note that the negative feedback connection once again guarantees that the current through the input resistor is equal to that through the capacitor and that

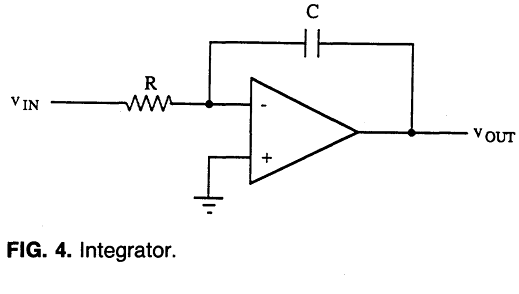


FIG. 4. Integrator.

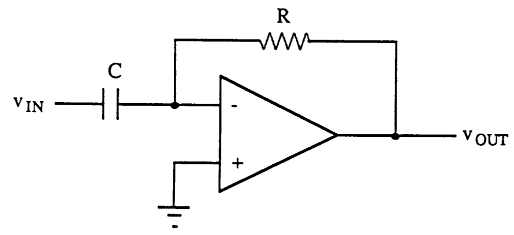

FIG. 5. Differentiator.

the capacitor voltage is the negative of the output voltage. Hence,

$$Q(t)=\int_0^t i_C\,d\tau=\int_0^t \frac{v_{\text{in}}}{R}\,d\tau \qquad (10)$$

$$\rightarrow v_{\text{out}}(t)=\frac{-Q(t)}{C}=-\frac{1}{C}\int_0^t i_C\,d\tau$$

$$=-\frac{1}{RC}\int_0^t v_{\text{in}}\,d\tau. \qquad (11)$$

The foregoing equation implicitly assumes that the capacitor possesses no initial charge. Any initial voltage across the capacitor merely adds to that computed by the integral term.

The differentiator of Fig. 5 exploits the relationship between capacitor current and voltage in a complementary manner by placing the capacitor in the input circuit, rather than in the feedback circuit.

Note that the integrator and differentiator may operate on several input signals simultaneously, so that integrals or derivatives of sums can be computed by these circuits. Additionally, a number of integrators and summers can connect to simulate a variety of differential equations (see Fig. 6 for an example).

One may perform a great many mathematical operations by combining these various building blocks in appropriate ways, and indeed the term "analog" traces its origin to the use of such circuits to construct electronic analogs of physical processes. Even though digital computers have all but completely replaced analog ones, there remain important classes of problems (such as voice and image recognition) which have resisted solution by digital means despite decades of effort. That biological systems (which are essentially analog in character) have successfully solved many of these problems has recently sparked a resurgence of interest in analog computation [e.g., in the form of so-called "neural networks" (*q.v.*)].

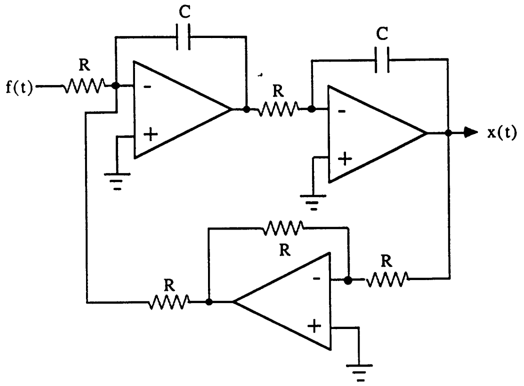
2. REVIEW OF LINEAR SYSTEM THEORY

The foregoing review of operational amplifiers glibly ignores the important issue of stability; there is no guarantee, *a priori*, that a feedback system will be stable. We now review the properties of systems with a focus on feedback structures and stability.

This discussion strictly applies only to linear systems, that is, those that obey superposition. Thus doubling the amplitude of excitation doubles the amplitude of response in linear systems. Although virtually every system exhibits nonlinearities if the excitation is made sufficiently large, many systems are approximately linear over some suitably restricted range. The development that follows assumes that excitations are within this linear range.

Recall that the input-output behavior of a linear system is completely characterized by either the time response to an impulse excitation (i.e., to the Dirac delta "function") or by the total frequency response (magnitude and phase over all frequencies) of the system to sinusoidal excitation.

The link between the time-domain and frequency-domain descriptions of a linear system is the Laplace transform. Let us denote by $h(t)$ the impulse response of a system, and by $H(s)$ the complex frequency response (also



$$\frac{d^2x}{dt^2}=\frac{1}{(RC)^2}[f(t)-x(t)]$$

FIG. 6. Example of an analog computer.

called the system function or transfer function) of the linear system. Then,

$$H(s) = \int h(t)e^{-st}\,dt, \qquad (12)$$

where appropriate limits of integration are chosen depending on the situation. In general, one employs the unilateral Laplace transform if the system is *causal*, that is, if the system produces no output to any excitation (e.g., an impulse) before the excitation is applied. In such cases the limits of integration are 0 and ∞.

The steady-state response of a system to sinusoidal excitation at a frequency of ω rad/s is found by setting $s=j\omega$ in the expression for $H(s)$. The magnitude of $H(j\omega)$ is the magnitude of the gain and the phase of $H(j\omega)$ is the phase angle of the output relative to the input.

The values of complex frequency s that result in infinite values of $H(s)$ are the poles of the system, while those that result in a zero value are known, appropriately enough, as the zeros. Because $H(s)$ is a generalized (complex) gain and therefore is the ratio of Laplace transforms of the output and input, an infinite value of $H(s)$ necessarily implies that no input signal is required to produce a nonzero output signal at a pole frequency. Poles are thus also known as the *natural frequencies* or *eigenvalues* of the system, and their values determine whether a system is stable. Correspondingly, no output results when a system is excited with complex exponentials at the frequencies of its zeros.

Definitions of stability abound, each with its own subtle nuances. This article employs the *bounded-input, bounded-output* (BIBO) definition of stability, which states that a system is stable if every bounded input always produces a bounded output. It may be shown formally that a linear system is stable in the BIBO sense if the real parts of all of the poles of $H(s)$ are negative in sign.

This stability criterion makes intuitive sense since complex exponentials of the form e^{st} are eigenfunctions of linear systems. Thus natural frequencies with negative real parts correspond to components in the output that decay, rather than grow, with time.

In designing systems (particularly feedback systems), simply achieving BIBO stability usually is not sufficient. For example, the response to a particular bounded input may be undesirably large while remaining bounded. Thus one may imagine *degrees* of stability, a notion we shall quantify after examining feedback systems in detail.

Figure 7 is a general block diagram of a feedback system. It comprises a forward path [some functional block whose transfer function is denoted by $a(s)$], a feedback path denoted by $f(s)$, and a summing junction or error comparator. Because most feedback systems employ negative feedback, the requisite minus sign is customarily absorbed by the summing junction, as shown. With negative feedback, the intent is to respond to a perturbation in a manner that tends to reduce the influence of the perturbation. A familiar example is a thermostatically controlled heater, which responds to a drop in temperature by turning on. Hence the response of the system is in a direction that opposes the perturbation.

After a little algebraic manipulation the overall input-output transfer function of our general block diagram is readily found to be (see Fig. 7)

$$H(s) = a(s)/[1+a(s)f(s)]. \qquad (13)$$

With this expression in hand we are now in a position to explore some of the properties of feedback systems. Note that the poles of $H(s)$ are the roots of the denominator polynomial, $1+a(s)f(s)$. The denominator polynomial is also known as the *characteristic equation* or the *desensitivity*. The product $a(s)f(s)$ is the negative of a quantity known as the *loop transmission*. The loop transmission is found by setting all inputs to zero, cutting the loop anywhere, injecting a signal into one end (preserving the direction of signal flow that prevails in normal operation), and observing what emerges from the other end. The ratio of the output to the input in this experiment is defined as the loop transmission. The reason this quantity is important is that it determines

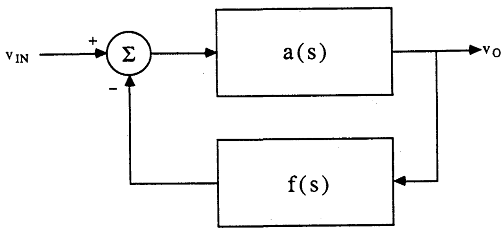


FIG. 7. Feedback system.

the roots of the characteristic equation of $H(s)$ and hence the natural frequencies of $H(s)$.

The loop transmission is an important quantity for reasons other than the control it exerts on the dynamic properties of the system. Let us consider the behavior of $H(s)$ when the magnitude of the loop transmission is large compared to unity. In this case,

$$H(s) \approx 1/f(s). \tag{14}$$

We see that the overall input-output behavior of a feedback system is largely *independent* of the characteristics of the forward path as long as the loop transmission magnitude is large compared to unity. Hence the forward path element may (and typically does) exhibit nonlinearities, temperature dependence, drifts in parameters with time, and a whole host of other undesirable properties without deleteriously affecting the overall system as long as the loop transmission magnitude (or desensitivity) remains large. In many instances, $f(s)$ is realized with linear, passive components whose characteristics are relatively stable with time and temperature so that $H(s)$ also possesses these desirable characteristics.

Let us also consider the other extreme, that is, very small loop transmission magnitudes. In this case the overall system function becomes

$$H(s) \approx a(s). \tag{15}$$

When the loop transmission magnitude is small compared with unity, we see that the system function is approximately equal to the forward path transfer function. Thus any desirable properties of $f(s)$ are *not* conferred upon $H(s)$ in this case.

Recognizing that large loop transmission magnitudes are desirable from the standpoint of greatly suppressing the dependence of overall loop behavior on any indiscretions of $a(s)$, it would appear that one should provide as much amplification in the loop as possible. Unfortunately, stability considerations preclude applying with abandon any such remedy. The reason, of course, is that the loop transmission also controls the natural frequencies and thus affects the dynamic behavior of the loop.

To illustrate this sort of problem consider a three-pole loop transmission of the following form:

$$-a(s)\, f(s) = -a_0\, f_0/(\tau s+1)^3, \tag{16}$$

where f_0 is a purely scalar quantity whose value we shall vary. The characteristic equation associated with this loop transmission is

$$P(s) = 1 + a_0\, f_0/(\tau s+1)^3 \tag{17}$$

and has two roots that acquire positive real parts as $a_0\, f_0$ increases. In fact, the system is unstable in the BIBO sense for any $a_0\, f_0$ equal to or greater than 8. Thus, obtaining large loop transmission magnitudes is at odds with stability considerations.

Even though this conclusion appears strictly to apply only to this particular example, the result is in fact general. The reason is that all physical systems are essentially *low-pass* in nature, at least ultimately so. As a consequence there are always additional poles in the loop transmission that will eventually cause trouble for a large enough magnitude of $a_0\, f_0$. Loop transmission magnitudes cannot be made arbitrarily large as a consequence.

Fortunately, the tradeoff between stability and desensitivity can be made less severe by a number of compensation methods. To understand how these compensators function, let us explore the frequency response of a system that is nearly unstable. Specifically, consider a system in which $a(j\omega)f(j\omega)$ is nearly -1 over some range of frequency ω and that this frequency range is relatively narrow in span. It follows that the magnitude of $H(j\omega)$ will be quite large over a similar frequency range compared with its magnitude elsewhere. We regard this large peaking in the frequency response as a sign of encroaching instability.

Appropriate modification of the magnitude and/or phase behavior of the loop transmission can help the product $a(j\omega)f(j\omega)$ avoid ever getting close to a value of -1. Stated in greater detail, satisfactory operation is obtained as long as one avoids the simultaneous occurrence of a unit magnitude and $-180°$ phase shift of $a(j\omega)f(j\omega)$.

Quantitative measures of stability based on these ideas are the gain margin and phase margin. These are defined as follows:

$$\text{Gain margin} \equiv \frac{1}{|a(j\omega_{-180})f(j\omega_{-180})|}, \tag{18}$$

Phase margin

$$\equiv 180° - \angle a(j\omega_{\text{unity}})f(j\omega_{\text{unity}}), \tag{19}$$

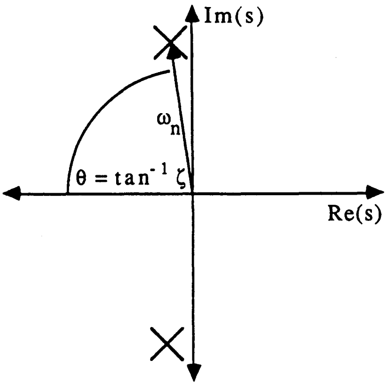

FIG. 8. Complex pole parameters.

where ω_{-180} is the frequency at which $a(j\omega)f(j\omega)$ has a phase shift of $-180°$, and ω_{unity} (also known as the crossover frequency) is the frequency where the loop transmission magnitude is unity.

These quantities have the following interpretations. The gain margin is the factor by which the loop transmission magnitude may be increased before instability results. The phase margin is the amount of additional (negative) phase shift the loop can tolerate at the crossover frequency before becoming unstable. Generally, a gain margin greater than or equal to about three, coupled with a minimum phase margin of approximately 30°–60°, will yield satisfactorily stable performance.

Use of these stability measures is attractive because only the frequency response (magnitude and phase) of the loop transmission needs to be determined. Since one can usually measure the frequency response with relative ease, application of these stability criteria is generally a straightforward exercise in practice.

Unfortunately, no simple general expression relating these measures to parameters such as overshoot (in response to a step excitation) or frequency response peaking exists. However, if the system is dominated by a complex pole pair (as is common), and if $H(s)$ is never zero for any finite values of s, then $H(s)$ may be approximated as

$$H(s) \approx \frac{K}{(s^2/\omega_n^2) + (2\zeta s/\omega_n) + 1}, \qquad (20)$$

where K is some constant factor (the dc gain of the closed-loop system) and ω_n and ζ (known as the damping ratio) are defined as shown in the *s-plane* plot of Fig. 8, where the poles are represented by ×'s.

For this two-pole case the maximum step-response overshoot P_0, measured as the ratio of the maximum value to the final value, is

$$P_0 = 1 + \exp[-\pi\zeta(1-\zeta^2)^{-1/2}], \qquad (21)$$

and the maximum peaking M_p in the frequency response, measured as the ratio of the maximum magnitude of $H(j\omega)$ to its magnitude at low frequencies (e.g., dc), is

$$M_p = (2\zeta)^{-1}(1-\zeta^2)^{-1/2} \quad \text{for } \zeta < 2^{-1/2}. \qquad (22)$$

Note that there is no peaking in the frequency response for values of ζ greater than 0.707 in an all-pole second-order system.

Having presented some measures of stability, we may now discuss several strategies for improving system stability at a given value of $a_0 f_0$. As one might suspect, compensation methods center around either modifying the magnitude of the loop transmission near frequencies where the phase shift of $a(j\omega)f(j\omega)$ is near $-180°$, or modifying the phase characteristics of $a(j\omega)f(j\omega)$ near the crossover frequency, or both.

A lag compensator (Fig. 9) reduces the magnitude of the loop transmission above a certain frequency that may be controlled by design (consider the low- and high-frequency asymptotic gains of this network). Because this type of compensator reduces the crossover frequency, the speed of the system is reduced at the same time the stability is improved. Furthermore, the lag compensator introduces a phase lag (hence its name) over some range of frequencies. Care must be taken in the design of the compensator to guarantee that only a small amount of this negative phase shift remains at the crossover frequency. A general rule of thumb is to place the zero of the lag compensator at least a

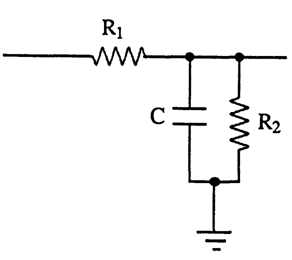

FIG. 9. Lag network.

factor of 10 below the crossover frequency to avoid this problem.

The lead compensator shown in Fig. 10 functions by adding a positive phase shift (a leading phase) to the loop transmission. There also is an attendant increase in magnitude that forces the crossover frequency to increase as well. While a higher crossover frequency increases the speed of the system, care must be taken not to push out crossover too far since many loop transmissions exhibit a rapid increase in negative phase shift as frequencies increase. Hence an excessive increase in crossover frequency may conceivably result in a net degradation in stability rather than the anticipated improvement. A general rule of thumb is to place the zero of the lead compensator at about the anticipated crossover frequency. Some iteration usually is required for a satisfactory design.

While the notion of phase margin has formed the primary focus for this discussion on stability and compensation, it must be noted that there are some pathological cases in which phase margin may not be defined. For example, it is possible for a loop transmission to exhibit multiple crossover frequencies; it is even possible not to have an explicit crossover frequency at all (at least mathematically). In these cases one must resort to the Nyquist stability criterion (Roberge, 1975) as the final arbiter of the question of stability. As with gain and phase margin, the Nyquist criterion requires only frequency response information and thus may operate on experimentally derived data. While gain and phase margin essentially attempt to decide the stability question by noting the behavior of the loop transmission at only two discrete frequencies (and primarily one, the crossover frequency), the Nyquist criterion examines the loop transmission at all frequencies and is able to determine stability in all cases. Because the Nyquist criterion is somewhat cumbersome to apply, the gain and phase margin criteria (primarily the latter) are most widely used. Fortunately, the gain and phase margin ideas presented here are adequate in nearly all cases of practical interest, and one must resort to use of the Nyquist criterion only rarely.

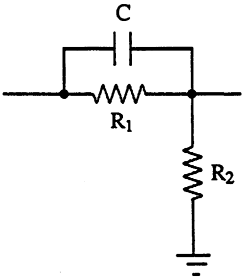

FIG. 10. Lead network.

3. DEVICE PHYSICS AND CIRCUIT MODELS

The two broad classes of active devices presently in most common use are the bipolar transistor and the field-effect transistor (FET). We will briefly review operation of the bipolar transistor and the metal-oxide-semiconductor FET (MOSFET) with an eye toward the development of linearized circuit models of these devices. This linearization is necessary because of the significant mathematical barriers that attend any effort to analyze exactly an aggregation of elements as nonlinear as transistors. Although machine computation may always be employed, useful design insight rarely emerges from such an exercise. Thus simulation is best used as a final, verification tool rather than as a primary design tool. The focus of this section is on the development of models that are more helpful in circuit design as well as in initial analyses.

3.1 Bipolar Transistors

An *npn* bipolar transistor is depicted in simplified form in Fig. 11 along with its schematic symbol. A *pnp* device is constructed similarly, although with materials of the opposite doping type. The schematic symbol for a *pnp* transistor is the same as that for an *npn* device except that the emitter arrow points in the other direction.

In normal operation (known as "forward active" operation) the potential at the base terminal of an *npn* transistor is made more positive than that at the emitter. Additionally, the collector potential is made greater than that at the base. Under these conditions the collector current is related to the base-emitter voltage as follows:

$$i_C = I_S\,[\exp(qV_{BE}/kT) - 1], \qquad (23)$$

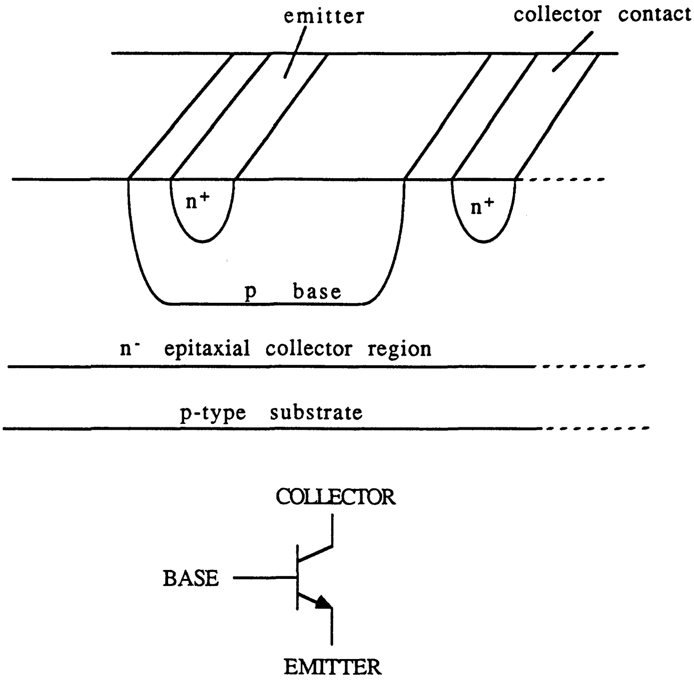

FIG. 11. *npn* transistor.

where I_S is known as the reverse saturation current, q is the magnitude of the electronic charge, k is Boltzmann's constant, and T is the absolute temperature in kelvins. Practical devices conform to this relationship over several decades of collector current if the collector-to-emitter potential is held fixed. Additionally, the exponential term dominates over the -1 term to such an overwhelming extent at all practical currents that the -1 term is often omitted.

The base current is typically a small fraction (ideally zero) of the collector current. The ratio of collector current to base current is denoted by β and is typically on the order of 100, although it can range from a few tens to several thousand depending on the details of device fabrication. The value of β depends greatly on temperature, processing, and operating current levels and is thus by no means constant, even for devices of nominally the same type. For example, it is not uncommon to observe a 2 or 3 to 1 change in β as the temperature changes from −55° to 125 °C (β increases with temperature). Hence care must be taken to avoid designs that are overly sensitive to β.

As noted earlier the highly nonlinear dependence of collector current on base-emitter voltage makes exact analysis of transistor circuits somewhat difficult. Linearized models, valid only over some restricted operating range, are typically used instead. In this case the exponential relationship is approximated by a linear one, centered about some *operating point* value.

Figure 12 illustrates this approach to linearization. The operating point on the i_C-v_{BE} curve is simply some value about which one performs a Taylor-series expansion of the true exponential relationship. Only the linear term in the expansion is preserved. As a consequence all variables may be considered the sum of two components, an operating point value (also known as the bias point, dc point,

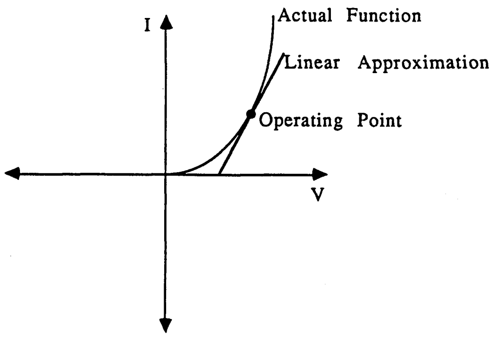

FIG. 12. Linearization.

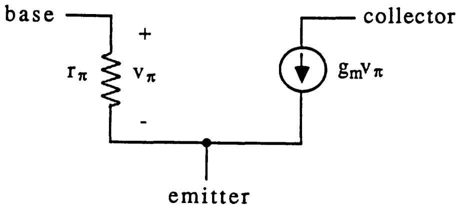

FIG. 13. Hybrid-π model.

or quiescent point) that is assumed constant, and an incremental or small-signal component. The incremental quantities thus represent small perturbations about the operating point and are linearly related to one another.

A combination of upper- and lower-case variable names and subscripts is customarily used to denote the various quantities. A dc point is represented by an upper-case variable with upper-case subscripts, while lower-case variables with lower-case subscripts denote small-signal quantities. The sum of a dc and incremental quantity is known as a *total variable* and is represented by a lower-case variable with an upper-case subscript. Thus as an example

$$i_B = I_B + i_b. \tag{24}$$

With these formalities out of the way it is a straightforward exercise to verify that Fig. 13 is a small-signal model of a bipolar transistor. This model, known as the *hybrid-π* model for historic reasons, employs a dependent current source (also known as a *transconductance*), with a value g_m, to represent the linearized relationship between a change in collector current and a change in base-emitter voltage. The resistance from base to emitter, traditionally called r_π, accounts for the signal-dependent base current that flows. The values of g_m and r_π are given by the following equations:

$$g_m = qI_C/kT, \tag{25}$$

$$r_\pi = \beta/g_m. \tag{26}$$

The quantity kT/q occurs frequently enough that it is often referred to as V_T, the "thermal voltage," and has a value of about 25 mV at (warm) room temperature.

Although the model of Fig. 13 is adequate for the analysis of static circuit behavior in many cases, there are instances where its limitations become particularly significant. As an example, consider the incremental model of a circuit known as a common-emitter amplifier shown in Fig. 14. The voltage gain of this amplifier is easily found by noting that the input voltage is equal to the voltage v_π and that the output voltage is (minus) the product of the transconductance and the output load resistance R_L. Thus,

$$\text{gain} = -g_m R_L. \tag{27}$$

This last expression suggests that the gain may be increased without limit simply by increasing the effective load resistance. However, the gain per stage in practice is typically limited to values of a few thousand because of a phenomenon called *base-width modulation*, also known as the Early effect. Since the collector-base space-charge layer (SCL) has a voltage-dependent width, variations in collector potential cause variations in the effective base width. An increase in collector voltage causes the SCL to extend further into the base, effectively narrowing it. Because β is a critical function of base width, the base current then decreases at the same time the collector current increases. These effects are modeled as additional resistances as shown in Fig. 15.

The base-width modulation factor η is typically in the range of 10^{-5}–10^{-3}. Sometimes a quantity known as the Early voltage (denoted V_A) is specified instead. The ratio of the thermal voltage V_T to the Early voltage is equal to η.

The model as presented so far has at least one important deficiency—it fails to represent any dynamic limitations of the transistor. This oversight is readily corrected with the improved model of Fig. 16. Capacitances are added across the base-emitter and collector-base junctions since each junction has a capacitance associated with the space-charge layer. The junction capacitances are depen-

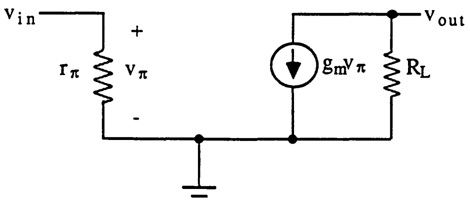

FIG. 14. Incremental model of a common-emitter amplifier.

dent on junction voltage as well as on doping levels and geometries and generally behave as follows:

$$C_j = \frac{C_{jo}}{(1 - V_J/\Psi_o)^m}, \tag{28}$$

where C_{jo} is the capacitance at zero bias, V_J is the dc voltage across the junction, Ψ_o (the *contact potential*) is a doping-level- and temperature-dependent "constant" on the order of a volt, and m is a doping-profile-dependent constant, usually between 0.2 and 0.5. The small-signal junction capacitance associated with the collector-base region is usually denoted by C_μ while that associated with the base-emitter region is usually denoted by C_{je}.

In the case of the base-emitter junction in forward bias (base voltage greater than the emitter voltage in an *npn* device) there is an additional capacitive component due to the minority carriers present in the base region under such a condition. Because a change in base-emitter voltage changes the amount of charge injected (and thus present) in the base region, and since this change requires the flow of base current, there is a *current*-dependent capacitance, known as the *diffusion capacitance*, denoted by C_b. The sum of the two base-emitter capacitances is known as C_π.

With this more elaborate model one may compute quantities such as the bandwidth of an amplifier provided that the various device parameters are known.

As a last comment on the hybrid-π model, it should be noted that even the augmented model is not valid over an infinitely wide frequency range. Owing to implicit assumptions of quasistatic device operation, the model eventually breaks down when the frequencies involved are high enough to invalidate these assumptions. In general, the model is valid as long as the frequencies are at least a factor of 3–5 lower than a value denoted as ω_T (sometimes called the current gain-bandwidth product), defined as

$$\omega_T = g_m/(C_\pi + C_\mu). \tag{29}$$

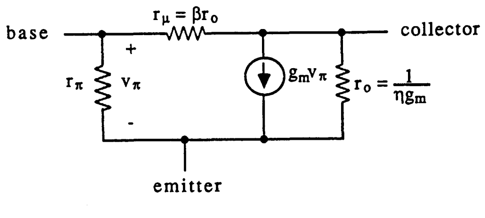

FIG. 15. Augmented hybrid-π model.

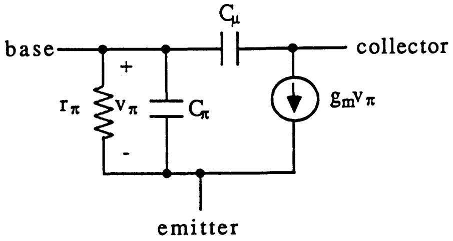

FIG. 16. Dynamic hybrid-π model.

3.2 MOSFETs

A typical *n*-channel MOSFET is shown in Fig. 17, along with two of its commonly used symbols. From the figure it is clear that a MOSFET is actually a four-terminal device. The fourth terminal, the substrate or body, is not always explicitly shown (e.g., as in one of the schematic symbols). If one ignores the substrate, the drain current of the *n*-channel MOSFET behaves in the following manner on a static basis:

$$i_D = \frac{\mu C_{\text{ox}} W/L}{2}(v_{GS} - V_T)^2, \quad v_{GS} - v_{DS} < V_T, \tag{30}$$

$$i_D = \frac{\mu C_{ox} W/L}{2}[2(v_{GS} - V_T)v_{DS} - v_{DS}^2], \quad v_{GS} - v_{DS} > V_T. \tag{31}$$

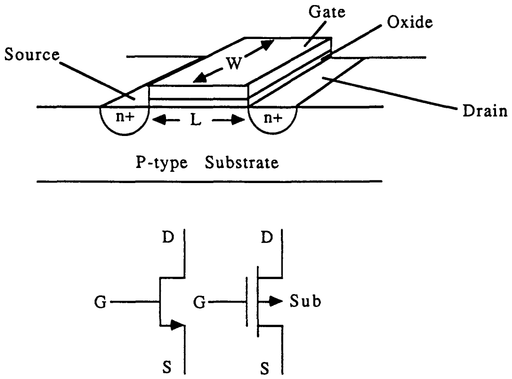

FIG. 17. *N*-channel MOSFET.

The condition $v_{GS} - v_{DS} < V_T$ defines the *saturation* or *pinch-off* region of operation while $v_{GS} - v_{DS} > V_T$ defines the *Ohmic* or *triode* region of operation. The saturation region is the usual operating regime of the MOSFET, where its behavior is similar to that of a bipolar transistor in the forward active region of operation. Two important differences, however, are that the gate current is practically zero independent of the drain current, and that the relationship between drain current and gate-source voltage is square law, not exponential.

An incremental model for the MOSFET in saturation, including capacitances, is shown in Fig. 18. This model also includes an additional resistance between the drain and source to account for the effects of *channel-length modulation,* a phenomenon analogous to the Early effect in bipolar transistors.

Figure 19 shows a simplified incremental model for a MOSFET in the triode region of operation. Note that the device simply acts as a voltage-controlled resistor at frequencies where the capacitances may be ignored.

3.3 The Charge-Control Model

So far we have examined only the small-signal behavior of transistors. We now consider the development of a model that will permit us to analyze the large-signal dynamic behavior of the bipolar junction transistor (BJT) in all regions of operation. This model is the "charge-control" model, and provides a tremendous amount of insight that is especially valuable in the design of switching (e.g., digital) circuits.

We will initially ignore the effects of space-charge-layer capacitances (the large-signal counterparts of C_{je} and C_{μ}). Furthermore, we will focus at first on the forward-active (normal) mode of operation, since the charge-control equations for reverse-active (i.e., roles of collector and emitter interchanged) operation can be written by analogy.

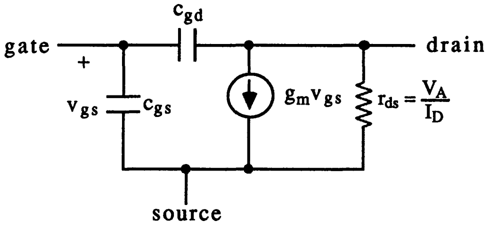

FIG. 18. Incremental model of MOSFET in the saturation region.

$r_{ds} = \frac{L}{W}\left(\frac{1}{K(V_{GS} - V_T)}\right)$
drain
source

FIG. 19. Incremental model of MOSFET in the triode region.

Also, since saturation involves forward bias on both the base-emitter and base-collector junctions, we will write the charge-control equations for the saturation region simply by adding the equations for the forward-active region of operation to those for the reverse-active region. Although the resulting set of equations will appear imposing, we will find that a greatly simplified set of equations will often suffice to describe device behavior in saturation. In all that follows, the subscript "*F*" will denote those quantities pertaining to the forward-active mode of operation, while the subscript "*R*" will denote quantities pertaining to reverse-active operation.

After deriving the basic charge-control equations we will relate charge-control and hybrid-π model parameters to underscore the relationship between small-signal and large-signal behavior. We will then examine several examples of how to use the model to carry out actual calculations. We will conclude by augmenting the model to include SCL capacitances, and by making some observations about the validity and accuracy of the charge-control model.

To begin the development of our model, recall that a "typical" static excess-carrier distribution for an *npn* transistor looks as shown in Fig. 20. The excess-carrier concentration at the base-emitter SCL edge, $n_b'(0)$, is equal to $n_{bo}[\exp(v_{BE}/v_T) - 1]$, where n_{bo} is the equilibrium minority-carrier concentration in the base. Assume that this relationship holds over essentially infinite bandwidths.

If we may neglect recombination, the distribution will be a perfect triangle, and the total amount of excess charge in the base can be computed readily as $qAWn_b'(0)/2$, where W is the base width and A is the area of the emitter junction. Hence the total excess charge

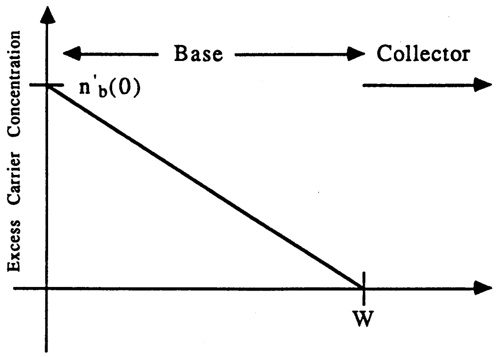

FIG. 20. Minority-carrier distribution in the base region in the foward-active region.

in the base varies exponentially with the applied junction voltage.

Recall that charge transport in the base region is dominated by diffusion so that the slope of the excess-carrier distribution at the base-emitter SCL edge is proportional to the emitter current and the slope of this distribution at the collector-base SCL edge is proportional to the collector current. Since we are neglecting recombination at this point, these two slopes are equal. Because the total excess charge in the base region, q_F, is proportional to the slope of the excess-carrier distribution (via a simple geometrical consideration, that is, that the area of a right triangle is proportional to the slope of the hypotenuse), we may write

$$i_C=q_F/\tau_F, \tag{32}$$

where the constant of proportionality τ_F possesses the dimensions of time.

We need a second charge-control equation to account for the base current. In actual fact, the base current consists of three components. One is proportional to q_F and supports recombination of carriers in the base region. Another component results from the reverse injection of holes from the base into the emitter, and is also proportional to q_F. The third component accounts for currents that support *changes* in q_F. Thus this last current is proportional to dq_F/dt. Consequently, one may express the base current as follows:

$$i_B=q_F/\tau_{BF}+dq_F/dt, \tag{33}$$

where the proportionality constant τ_{BF} also possesses the dimensions of time.

Finally, the emitter-current charge-control equation is readily derived by applying Kirchhoff's current law:

$$-i_E=i_C+i_B. \tag{34}$$

If we now consider operation of the BJT in the reverse-active region, that is, with the roles of emitter and collector reversed, we can write the three relevant charge-control equations by analogy with the forward-active case:

$$i_E=q_R/\tau_R, \tag{35}$$

$$i_B=q_R/\tau_{BR}+dq_R/dt, \tag{36}$$

$$-i_C=q_R(1/\tau_R+1/\tau_{BR})+dq_Rdt. \tag{37}$$

The six equations presented in the foregoing development describe completely the large-signal dynamic behavior of bipolar junction transistors in all regions of operation, neglecting the influence of space-charge-layer capacitances. As we shall see, operation of the BJT even in the saturation region can be analyzed by combining the equations for the forward- and reverse-active modes.

Before proceeding further, recognize that the charge-control model must be compatible with the small-signal model. Let us now turn to the task of relating hybrid-π model parameters to those of the charge-control model. This exercise is not purely pedagogic; transistor data sheets rarely provide charge-control parameters in any useful form, so that one is usually forced to derive them from the small-signal parameters that *are* usually given.

One would hope that the charge-control and small-signal models converge for small-signal dynamic analyses. In fact, we will *require* this convergence and exploit this requirement to relate charge-control parameters to hybrid-π model parameters. For example, consider the forward-active region collector-current and base-current charge-control equations. In the steady state, the ratio i_C/i_B is equal to τ_{BF}/τ_F. The hybrid-π model tells us that this ratio is β_F. Hence, one relationship we have discovered is

$$\tau_{BF}=\beta_F\tau_F. \tag{38}$$

Similarly, for the reverse-active region,

$$\tau_{BR}=\beta_R\tau_R. \tag{39}$$

Thus the base and collector time constants are simply related by the respective β.

Now consider τ_F itself. Perhaps the most expedient way to relate it to hybrid-π parameters is to equate base currents in the limit of infinite frequency (while continuing to neglect SCL capacitance terms). In the charge-control (CC) model, the base current approaches

$$i_b=dq_F/dt, \tag{40}$$

while in the hybrid-π model the base current approaches

$$i_b=C_b\,dv_{be}/dt. \tag{41}$$

Now recall from elementary device physics that we may express the diffusion capacitance C_b as follows:

$$C_b=g_mW^2/2D_n=g_m\tau, \tag{42}$$

where g_m is the transconductance, W is the effective base width, and D_n is the diffusivity of electrons (recall that we are considering *npn* transistors here). Equating the expressions for base current and substituting for C_b, we find that

$$q_F/\tau=g_mv_{be}. \tag{43}$$

Noting that g_mv_{be} is simply the collector current so that

$$i_c=q_F/\tau, \tag{44}$$

we conclude that τ is simply equal to τ_F by comparing this equation with the collector-current CC equation. Thus, we have discovered an important link between CC and small-signal model parameters, namely, that τ_F is equal to C_b/g_m.

In many circuits, the drive levels are high enough to saturate the transistor. In saturation, both transistor junctions are forward biased. Since both the base-emitter and base-collector junctions consequently inject excess carriers into the base region, we need to sum the reverse- and forward-active CC equations to model the combined effects of these two sources of charge. Thus the relevant charge-control equations are

$$i_C=\frac{q_F}{\tau_F}-\frac{dq_R}{dt}-q_R\left(\frac{1}{\tau_R}+\frac{1}{\tau_{BR}}\right), \tag{45}$$

$$i_B=\frac{dq_F}{dt}+\frac{q_F}{\tau_{BF}}+\frac{dq_R}{dt}+\frac{q_R}{\tau_{BR}}, \tag{46}$$

$$-i_E=i_B+i_C. \tag{47}$$

At this point, it is best to consider a picture of the charge distribution in the base region under conditions of saturation (Fig. 21). The form of the charge distribution in the base region in saturation has the general shape of a trapezoid. This shape in turn may be regarded as the result of summing two triangular distributions, one of which corresponds to q_F and the other of which corresponds to q_R. The areas of the triangles are proportional to their respective charge components, but be aware that the constants of proportionality are *not* the same for the two components. Thus one cannot simply solve the problem purely graphically. The primary virtue of this picture is that it allows us to rethink the problem of describing the dynamic behavior of transistors in the saturation region.

Let us call the amount of q_F necessary to put us at the edge of saturation q_{BO}. The additional base charge in saturation will then be some mixture of forward and reverse charge. Denote the additional amount of forward charge as q_{FS} and let the reverse charge be q_R. It is also useful to lump these last two components together in a single quantity called q_S, the saturation charge. Hence the total base charge may be expressed as

$$q_B=q_{BO}+q_{FS}+q_R=q_{BO}+q_S. \tag{48}$$

Now, from Eq. (46), we can develop a relationship between the amount of reverse charge and the amount of excess forward charge in saturation. It can be demonstrated that there is a wide separation in natural frequencies of the saturation charge control

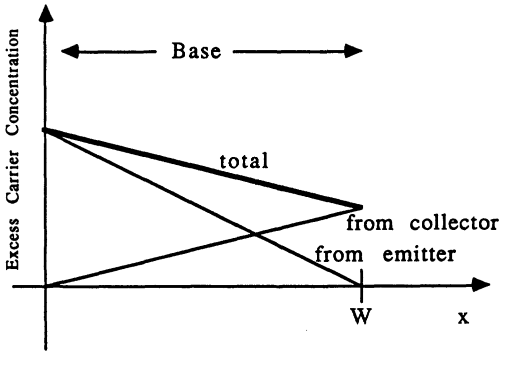

FIG. 21. Minority-carrier distribution in the base region in saturation.

equations and thus we may neglect the d/dt term in Eq. (46) to obtain

$$\frac{q_{FS}}{\tau_F}=q_R\left(\frac{1}{\tau_R}+\frac{1}{\tau_{BR}}\right). \tag{49}$$

This last equation is a key equation, since it tells us that only two of q_R, q_{FS}, or q_S are independent. Thus one can rewrite Eq. (46) in terms of just q_S, for example. If this is done, one obtains the following expression for the base current in saturation:

$$i_B=\frac{dq_S}{dt}+\frac{q_S}{\tau_S}+\frac{q_{BO}}{\tau_{BF}}. \tag{50}$$

Recognize that the last term of this equation is simply the base current necessary to put the transistor at the edge of saturation. Calling this current i_{BO} allows one to write

$$i_B-i_{BO}=\frac{dq_S}{dt}+\frac{q_S}{\tau_S}, \tag{51}$$

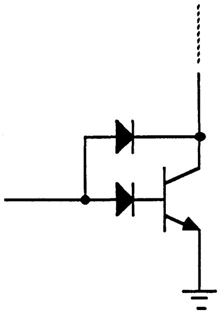
where the time constant is

$$\tau_S=\frac{\tau_{BF}(\beta_R+1)+\beta_F\tau_{BR}}{\beta_F+\beta_R+1}. \tag{52}$$

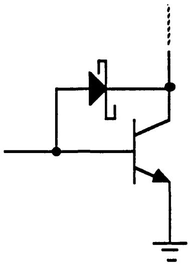
Notice that the dynamics in saturation are first order in nature. Additionally, the driving "force" behind changes in the saturation charge is simply the difference between the applied base current and the amount of base current necessary to put the device at the edge of saturation. Furthermore, these changes take place with a characteristic time constant that is a particular weighted sum of the forward and reverse time constants.

These equations reveal an important insight. Since both junctions are in forward bias in saturation, the base-emitter and base-collector voltages are essentially fixed. However, base charge continues to build (as long as the base current exceeds i_{BO}), and the transistor cannot be returned to a nonconducting state until this charge is removed. Hence, saturated transistors are slow to turn off. This property is particularly troublesome for digital circuits, where rapid transitions between off and on states are always desired.

One way to increase switching speed in such cases is to avoid saturation in the first place. Two methods for accomplishing this end are shown in Fig. 22. Both of these circuits employ diode clamping to prevent significant forward bias of the collector-base junction. In Fig. 22(a) (known as a "Baker clamp"), the upper diode turns on as the transistor approaches saturation. Any additional base current diverts through this diode rather than causing increases in base charge, thus preventing saturation.



(a) Baker Clamp



(b) Schottky Clamp

FIG. 22. Antisaturation circuits.

The circuit of Fig. 22(b) employs a single Schottky diode to perform the same function. A Schottky diode may be formed at the interface of a metal with a lightly doped semiconductor, and has a relatively small forward voltage (e.g., 0.3 V) in the conducting state, compared with the 0.6–0.7 V that is typical of standard junction diodes. Hence, the Schottky clamp allows the collector-base junction to be forward biased, but only weakly so. Because of its simplicity and efficacy, Schottky clamping is employed in the fastest families of TTL (transistor-transistor logic) digital circuits (see CIRCUITS, DIGITAL).

It may be shown that SCL capacitances can control switching speed in many cases, just as they can control bandwidth in the small-signal realm. Thus we need to augment our CC model and equations to reflect this reality. With the addition of the capacitances and their associated charges, q_{VE} and q_{VC}, come associated terms in the CC equations. These SCL currents are

$$i_B=\frac{d(q_{VE}+q_{VC})}{dt}, \tag{53}$$

$$i_C=-\frac{dq_{VC}}{dt}, \tag{54}$$

$$i_E=-\frac{dq_{VE}}{dt}. \tag{55}$$

These terms need to be added to the CC equation previously derived, and would seem to increase to unpleasant levels any analyses we would wish to carry out, especially since the charge terms are nonlinearly related to the junction voltages. However, note that not all of the terms in the equations are important in all regions of operation.

In the cutoff region, which we shall arbitrarily define as associated with less than a 0.4-V forward bias on the base-emitter junction, only the SCL terms are important since there is essentially no q_F in such a case.

In the forward-active region (FAR), the base-emitter voltage is roughly constant, so we can often neglect the base-emitter SCL capacitance. Finally, in the saturation region, all of the terminal voltages are constant so that one may neglect all of the SCL capacitances (there are no d/dt's). Thus the additional complexity imposed by the SCL terms is actually quite modest.

Both the hybrid-π and charge-control models assume that the base charge can be represented by a single "lump." However, as frequencies approach f_T $(=\omega_T/2\pi)$ one must take the true distributed nature of the base charge into account. Recall that a consequence of this neglect is the inability of the hybrid-π model to give us accurate answers for frequencies near f_T. A similar limitation applies to the CC model—it simply cannot provide any reliable predictions on time scales comparable to, say, τ_F (for the FAR). Thus while it is true that the CC model allows us to analyze the large-signal dynamic behavior of switching circuits over all regions of operation, CC analysis does not evade the fundamental frequency limitations of the hybrid-π model.

4. AMPLIFIER DESIGN

4.1 The Three Basic Amplifier Topologies

The three fundamental bipolar transistor amplifier topologies are the *common-emitter, common-base,* and *common-collector* (more commonly known as the *emitter follower*), as shown in Fig. 23. Analogous structures realized in MOS form are obtained by recognizing that the base terminal corresponds to the gate, the emitter to the source, and the collector to the drain.

The incremental model for the common-emitter amplifier is repeated in Fig. 24(a) (ignoring capacitances for the moment). As noted earlier, the voltage gain of this amplifier is $-g_mR_L$ (the minus sign indicates that the amplifier inverts the signal). From the figure it is also easy to see that the input impedance is simply r_π while the output resistance is R_L. At a collector bias current of 1 mA, r_π is about 2.5 kΩ at a temperature of 300 K. This value of resistance is considered neither particularly high nor low, and the input impedance of the common-emitter amplifier is thus considered moderate.

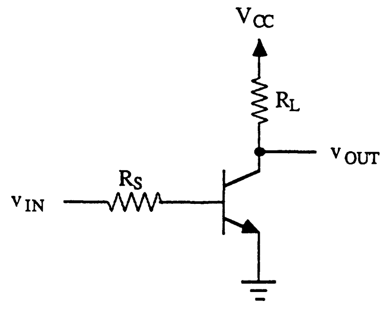
The incremental model for the common-base amplifier is shown in Fig. 24(b). It is straightforward to show that the input impedance of this amplifier is

$$z_{\text{in}}=\frac{r_\pi+R_S}{\beta+1}\approx\frac{r_\pi}{\beta}+\frac{R_S}{\beta}=\frac{1}{g_m}+\frac{R_S}{\beta}. \tag{56}$$

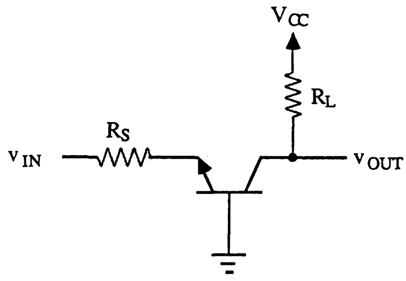
At a collector current of 1 mA, the reciprocal of transconductance is approximately 25 Ω while β is generally a fairly large number (e.g., a couple of hundred). As a consequence the input impedance of the common-base amplifier is considered low.

Both the output resistance of this amplifier and the voltage gain magnitude are the same as for the common-emitter amplifier with the important difference that the common-base amplifier does not invert.

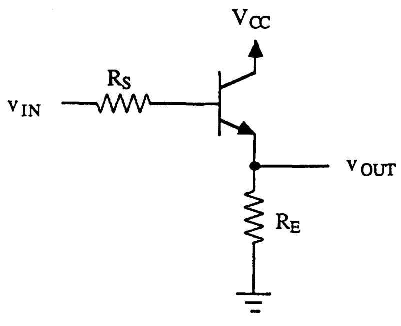
The emitter follower's incremental model



(a) Common-Emitter



(b) Common-Base



(c) Emitter Follower

FIG. 23. The three basic amplifier topologies.

is shown in Fig. 24(c). The voltage gain is readily found as

$$\text{gain} = \frac{(\beta+1)R_E}{(\beta+1)R_E + R_S + r_\pi} < 1, \tag{57}$$

while the input impedance is

$$z_{\text{in}} = (\beta+1)R_E + r_\pi \tag{58}$$

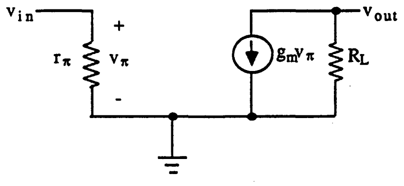
and the output impedance is

$$z_{\text{out}} = \frac{R_S + r_\pi}{\beta+1} \| R_E \tag{59}$$

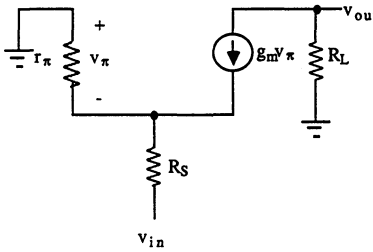
where the symbol "$\|$" denotes a parallel resistance combination $[a\|b = ab/(a+b)]$.

Examination of these expressions reveals that the input impedance of the emitter follower can be quite large, because of the multiplicative factor $\beta+1$, while the output impedance can be quite small, because of the appearance of the same factor in the denominator. Thus the emitter follower can drive relatively heavy loads while not appreciably disturbing whatever stage is driving the follower. For this reason the follower is also known as a buffer, and this action reveals the value of the amplifier even though its voltage gain is unity at best.

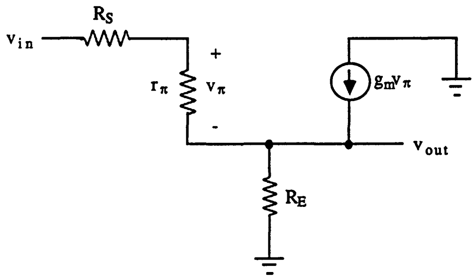
These three topologies are often combined in a variety of ways to exploit the various advantages of each. As an example consider



(a) Common-Emitter



(b) Common-Base



(c) Common-Collector (Emitter Follower)

FIG. 24. Incremental models of amplifier topologies.

the *differential amplifier* of Fig. 25. For perfectly differential (antisymmetric) input signals this amplifier may be regarded as a pair of common-emitter amplifiers. This connection has value because all practical amplifiers exhibit a variety of drifts with time and temperature. Drifts (and noise) that affect both devices in the same way are effectively suppressed by taking the output differentially. With some care thermal drifts referred to the input of approximately 1 μV/°C are routinely achievable, and with extraordinary care 50 nV/°C has been achieved. This performance is a substantial improvement over the basic −2 mV/°C drift that a typical common-emitter amplifier exhibits by itself. For these reasons the differential amplifier forms the core of a great many practical circuits, including the first stage of almost every operational amplifier.

4.2 Biasing

Implicit in much of the discussion thus far is some means to establish an operating point. This function is explicitly provided by bias circuitry, and takes a number of forms as shown in Fig. 26. In Fig. 26(a) bias is established by a voltage divider whose tap drives the base terminal, and by a resistor inserted in the emitter circuit. In practice the quiescent voltage at the emitter is often chosen a minimum of 2 or 3 V to suppress variation in collector current with base-emitter voltage variation. The resistors in the voltage divider at the base are chosen low enough in value to avoid modulation of the base voltage by variations in base current (such as might be caused by β variation), but high enough in value to avoid excessive loading of the previous stage.

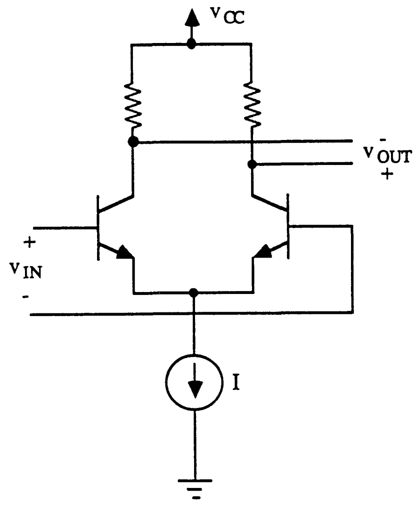


FIG. 25. Differential amplifier.

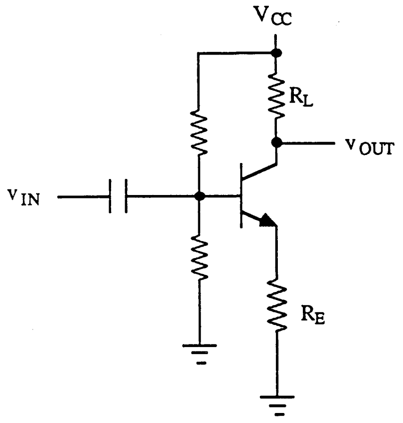
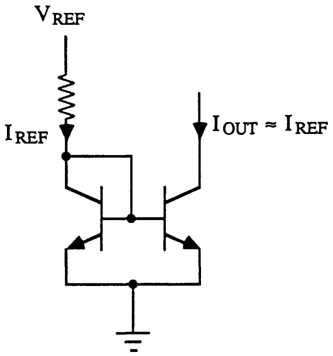


a) Classic Bias Scheme



b) Current Mirror

FIG. 26. Bias circuits.

When this type of bias circuit is used, coupling capacitors are generally required in series with the input and output (the differential amplifier is a notable exception to this rule). These capacitors are necessary to prevent the upset of bias voltages that may occur if stages were directly connected together. Coupling capacitors necessarily block dc, and such a bias circuit is thus not suitable for dc amplifiers. Additionally, since the required capacitances are usually many orders of magnitude larger than can be realized in integrated form, alternative means must be employed in integrated circuits (ICs).

The bias circuit shown in Fig. 26(b) is known as a current mirror and exploits the matched characteristics of two transistors on a given integrated circuit. If such matching is assumed then it follows that the two collector currents are equal since the base-emitter voltages are forced to be equal. Such a current mirror may be employed as a current source for a differential amplifier, for example.

4.3 Bandwidth Considerations

The explicit computation (by hand) of the 3-dB bandwidth of an arbitrary network is generally impractical for all but the simplest systems. For example, finding the bandwidth of a network comprising just four independent energy-storage elements may require finding the roots of a fourth-order equation. Considering that the incremental model for a transistor includes two capacitances, we see the difficulty in extracting these roots if we use more than, say, just two transistors in a circuit.

While it is certainly true that machine computation can circumvent this limitation in the analysis of networks, it is less helpful in their design.

The method of open-circuit time constants (OCTs) allows one to estimate the bandwidth of a system almost by inspection, although at the expense of some accuracy. Because this method often yields useful answers with relatively little effort one is often willing to accept the approximate nature of those answers. Most importantly, and unlike typical circuit simulation programs, OCTs identify which elements are responsible for bandwidth limitations. The great value of this property in the design of amplifiers hardly needs expression.

To begin development of this method, consider all-pole transfer functions only. Such system functions may be written as follows:

$$\frac{V_o}{V_i}(s)=\frac{a_o}{(\tau_1 s+1)(\tau_2 s+1)\cdots(\tau_n s+1)}, \tag{60}$$

where the various time constants may or may not be real.

Multiplying out the terms in the denominator leads to a polynomial we shall express as

$$b_n s^n+b_{n-1}s^{n-1}+\cdots+b_1 s+1, \tag{61}$$

where the coefficient b_n is simply the product of all of the time constants and b_1 is the sum of all of the time constants. (In general, the coefficient of the jth term is computed by forming all unique products of the n time constants taken j at a time and summing all $n-j+1$ such products.)

Now, near the -3-dB frequency, the first-order term typically dominates over the higher-order terms so that (perhaps) to a reasonable approximation

$$\frac{V_o}{V_i}(s)\approx\frac{a_o}{b_1 s+1}=\frac{a_o}{(\sum_{i=1}^{n}\tau_i)s+1}. \tag{62}$$

The bandwidth of the original system in radian frequency as estimated by this first-order approximation is then simply the reciprocal of the effective time constant:

$$\omega_h\approx\frac{1}{b_1}=\frac{1}{\sum_{i=1}^{n}\tau_i}. \tag{63}$$

It may be shown that this bandwidth estimate is conservative in the sense that the actual bandwidth will always be at least as high as estimated by this method.

So far, it has only been shown that a first-order estimate of the bandwidth is possible if one is given the sum of the pole time constants. Unfortunately, such information is almost never available in this explicit form.

This limitation can be circumvented by relating the desired time-constant sum to (more or less) easily computed network quantities. Specifically, consider an arbitrary linear network comprising only resistors, sources (dependent or independent), and m capacitors. Compute the effective resistance R_{jo} facing the jth capacitor with all of the other capacitors removed (open-circuited), then form the product $t_{jo}=R_{jo}C_j$ (the subscript "o" refers to the open-circuit condition). Finally, sum all such "open-circuit" time constants. Remarkably, this sum is in fact *precisely* equal to the sum of the *pole* time constants used earlier. Thus at last, we have

$$\omega_{h,\mathrm{est}}=\frac{1}{\sum_{j=1}^{m}R_{jo}C_j}. \tag{64}$$

The method of OCTs is relatively simple to apply because each time-constant calculation involves the computation of a single pure resistance, although one must be wary of the impedance-modifying potential of dependent sources (such as the transconductance of a transistor model). In any event, the amount of computation required is typically substantially (indeed, often even fantastically) less than that needed for an exact solution.

The greatest value of the technique lies in its identification of those elements implicated in bandwidth limitations, that is, those elements whose associated open-circuit time constants dominate the sum. This knowledge can guide modifications to circuit values or even suggest wholesale topological changes. In contrast, typical simulators only provide a numerical value for the bandwidth while conveying little or nothing about what can be done to alter performance in a desired direction.

The origin of this property of OCTs may be regarded intuitively as follows. The reciprocal of each *j*th open-circuit constant is the bandwidth that the circuit would exhibit if that *j*th capacitor were the *only* capacitor in the system. Thus each time constant represents a local bandwidth degradation term. The method of OCTs effectively states that a linear combination of these individual, local limitations yields an estimate of the total bandwidth. The design value of OCTs derives directly from the identification and quantification of the local bandwidth "bottlenecks."

One must be careful not to place too much faith in the ability of OCTs to provide accurate estimates of bandwidth, however. This situation should hardly be surprising in view of the rather brutal truncation to first order of the denominator polynomial. However, there are numerous conditions under which OCT estimates are fairly reasonable.

It should be clear that an OCT bandwidth estimate is, in fact, *exact* for a first-order network since no truncation of terms is then involved. Similarly, OCT estimates will be quite accurate if a network of higher order happens to be dominated by one pole (that is, one pole is much lower in frequency than all of the other poles). There are many systems of practical interest, such as operational amplifiers, that are designed to have a dominant single pole.

Unfortunately, there are so many conditions under which OCTs give terribly pessimistic estimates that some caveat is necessary. For example, complex poles quite commonly arise in the design of wideband multistage amplifiers. The presence of complex poles upsets OCT estimates because OCTs effectively ignore the imaginary part of the pole time constants since complex poles must appear in conjugate pairs. The act of summing as required by the OCT method thus leaves only the real part. However, the true bandwidth of systems *does* depend on both the real and imaginary parts. The larger the imaginary part of the time constant, the greater the actual bandwidth and the greater the error. In fact, it is not uncommon for OCTs to estimate bandwidths that are one-half (or less) that actually observed.

Since it is generally not possible to tell by inspection of a network if complex poles are going to be an issue, one must always keep in mind that the primary value of OCTs is in identifying those portions of a circuit that control the bandwidth, rather than in providing accurate bandwidth estimates. Circuit simulators take care of the latter task.

Although application of open-circuit time constants is reasonably straightforward, there are one or two final issues that deserve consideration. An extremely important idea is that not all capacitors in a network belong in the OCT calculations. We have seen that the method of open-circuit time constants is an extremely valuable tool for designing amplifiers for good dynamic performance mainly because of its ability to identify the problem areas of the circuit. Because of the tremendous insights gained with extremely modest effort we are generally willing to overlook its quantitative limitations such as the often highly conservative nature of the estimated bandwidth. As long as we take care to apply the method only to models that apply to the high-frequency regime, we are assured of reasonable answers.

Concluding, the method of open-circuit time constants is an indispensable guide in the design of amplifiers. With it one can design intelligently and confidently to satisfy a given bandwidth specification. To be sure, the method has its quantitative shortcomings, but the valuable intuition provided is usually more than sufficient compensation.

5. DATA CONVERTERS

As technology moves increasingly toward digital representation of data, one is confronted with the fact that the world is analog in nature. In this section we examine analog-to-digital (A/D) and digital-to-analog (D/A) converters.

5.1 Analog-to-Digital Converters

Without question A/D conversion is more difficult than D/A conversion. The tradeoffs among complexity, resolution, and conversion speed tend to be somewhat severe, certainly more so than in D/A conversion. The great variety of A/D converter topologies is a consequence of this situation.

Since an analog signal spans a continuum of amplitudes, and since a digital representation is necessarily finite, an A/D converter maps a continuous range of signal amplitudes into a discrete digital representation. Given that this action thus irrevocably discards certain information about the amplitude of the original signal, one must determine how many bits are sufficient from a consideration of the requirements at hand. Additionally, we need to develop a criterion that identifies required conversion speeds.

One can derive some rough guidelines regarding resolution if certain simplifying assumptions are made. Referring to Fig. 27, we see that the quantization error has a uniform probability density function (PDF) for a ramp input (Δ is the size of the minimum quantum the converter can resolve). If we assume that this PDF also applies for a sine-wave input, the root mean square (rms) signal-to-noise (S/N) ratio thus becomes $(6N+1.8)$ decibels (dB), where N is the number of bits used in the representation. Hence, an eight-bit A/D converter can provide a nearly 50-dB rms S/N ratio.

There is a theorem due to Nyquist that determines how fast one must sample a wave form. Consider a signal that is band limited (i.e., its spectrum has zero energy beyond some frequency). Nyquist's sampling theorem states that one must sample the signal at more than twice the frequency of the highest-frequency component of the signal. If this sampling is performed with infinite amplitude resolution, the original wave form can in principle be recovered perfectly using an ideal, interpolating ("brickwall") filter. Thus a signal that possesses energy up to, say, 4 MHz (e.g., a broadcast television signal) must be sampled at least at an 8-MHz rate. Furthermore, since ideal filters are unrealizable, one must actually sample at a somewhat higher rate (e.g., 10 MHz) to accommodate this lack.

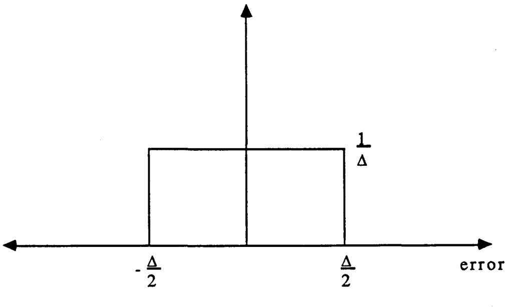


FIG. 27. PDF of error for ramp input.

Although various exotic technologies exist for performing high-speed analog-to-digital conversion (e.g., electrooptical and electron-beam methods), this review concerns circuit techniques only.

In principle, the fastest A/D conversion method is the parallel or "flash" method (Fig. 28). To perform an N-bit conversion, the analog input is presented simultaneously to an array of $2^N - 1$ comparators. The threshold of each comparator is derived from a voltage divider driven by a reference voltage. Thus the output of the comparator whose threshold is set just below the value of the input signal is high, as are the outputs of all the comparators underneath. The resulting "thermometer code" is sent to a digital encoder to provide an N-bit binary output.

This converter is fast because of its parallel nature. The conversion time is simply the sum of the delay of a single comparator and the delay of the encoding logic. Comparators with six-bit resolution and speeds in excess of 400 MHz are available, illustrating the high speeds attainable with this method. The greatest resolution achieved so far is 10–11 bits.

Unfortunately, the exponential dependency of the number of required comparators on the value of N limits the practicality of this approach for N larger than about 10. In addition, the substantial and nonlinear input capacitance associated with such a large number of comparators presents a nontrivial drive problem.

When greater resolution is required than can comfortably be provided by flash converters, a number of techniques can be used, most of which also ameliorate the drive problem.

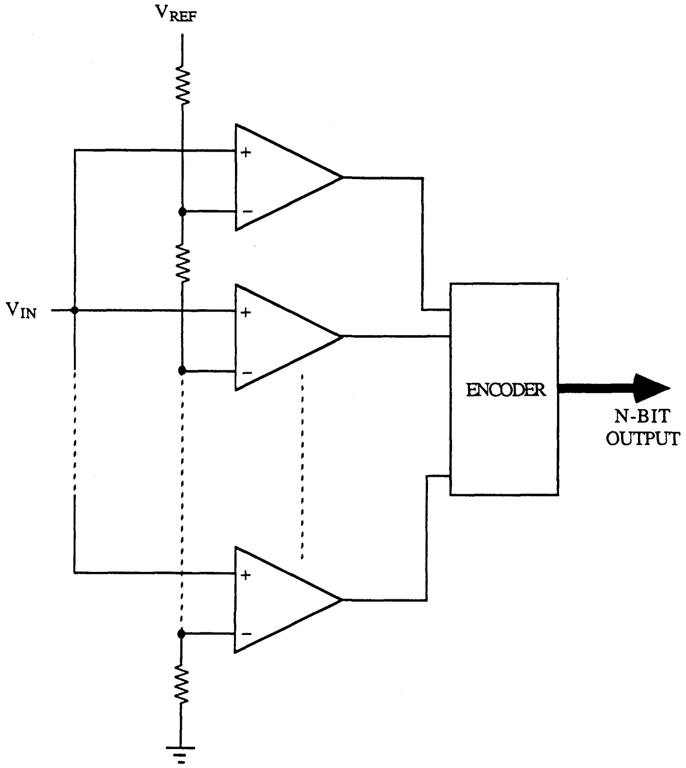

FIG. 28. Flash converter.

Many of these methods employ flash converters as components within the overall converter, and these consequently can digitize at high speeds. One such method, the dual-rank or subranging technique, is illustrated in Fig. 29. Here two flash converters of relatively low resolution combine to realize a system possessing higher resolution than either of the two-component A/D converters alone. The first-rank converter coarsely digitizes the input signal to M bits. This M-bit output feeds an N-bit DAC (digital-to-analog converter) which possesses at least the accuracy desired of the overall converter (N bits). The analog output of the DAC is subsequently subtracted from the input, and this residue (the "subrange") is converted by the second-rank ADC, which possesses $(N-M+1)$-bit resolution. The outputs from both internal ADCs are then combined to yield the final N-bit output.

A practical conversion system employing this type of converter generally requires the use of a sample-and-hold (S/H) stage to guarantee that the input signal remains stable during both steps of the conversion. Although a S/H stage is critical for the dual-rank converter, it also reduces conversion errors in virtually all other converters as well.

If somewhat lower conversion speeds can be tolerated, the successive approximator (S/A) shown in Fig. 30 can be used. As can be seen, the S/A converter comprises a comparator, a DAC, and some specialized digital logic known as a successive-approximation register (SAR).

Upon receipt of a "start convert" command, the SAR makes an initial estimate by setting the most-significant bit (MSB) high and all other outputs low. The comparator output remains high if this guess is less than the digital equivalent of the input. The MSB is then known to be high and remains on; otherwise it is turned off. The other bits are tested in succession in this manner. An end-of-conversion (EOC) signal is asserted upon completion of the procedure, signaling to the external world that the digital output of the SAR is valid. In general, then, we see that at least N clock cycles are required to complete an N-bit conversion using the S/A method.

Clearly, the input must remain stable during the conversion interval or gross errors will

result. Hence, a S/H stage must precede the converter proper.

In some instances the analog input signal varies quite gradually over a conversion interval. In such cases the tracking or servo A/D converter shown in Fig. 31 may be used. Here,the difference between the analog input and an analog version of the digitized value is quantized to one bit with a comparator. An up/down counter is either decremented or incremented depending on the sign of the comparator's output.

The tracking converter performs well as long as the input changes by less than one least-significant bit per clock pulse, but fails miserably if the input signal changes by a large amount. In the worst case, $2^N - 1$ clock cycles are required to catch up to a full-scale

step change in the input signal. Hence, even though this converter provides faster tracking performance than the S/A converter, the worst-case performance is much worse.

When high speed is not critically important, but high resolution is, the dual-slope A/D converter shown in Fig. 32 is widely used. In this method, a unipolar input signal is connected to a previously zeroed integrator for some fixed amount of time. Then a reference of the opposite polarity is connected to the integrator at the same time a counter is enabled. The counter is stopped as soon as the output of the integrator crosses zero. The counter's value is proportional to the input signal.

Because the same components (particularly the resistor and capacitor) are used in both the up and down portions of the integration, they only need to be stable over one conversion cycle; slow drifts in the characteristics of these elements can be tolerated. With the addition of special circuitry to compensate for inevitable system offsets, resolution in excess of 12–16 bits is routinely achievable. It is primarily for these reasons that digital

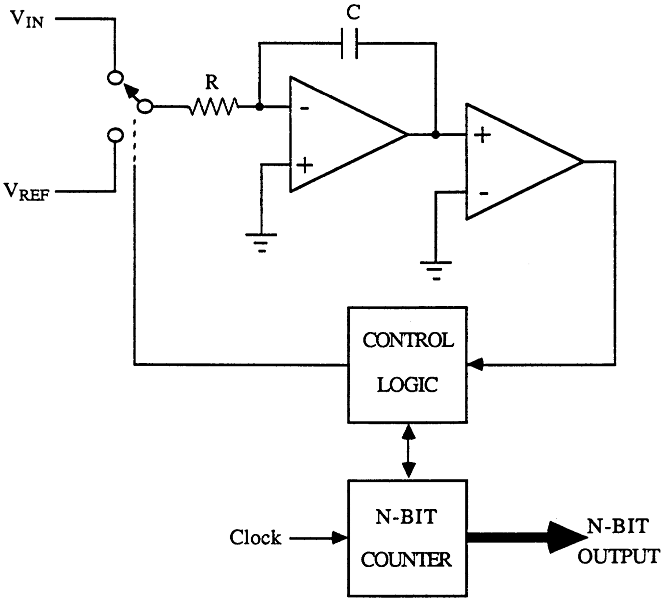

FIG. 32. Dual-slope converter.

voltmeters use this technique almost exclusively, although the conversion speeds tend to be quite slow (e.g., 100 Hz or less).

Another attractive property of this type of converter is that frequencies at integral multiples of $1/T$ are rejected. Thus by a judicious choice of the integration time T, the influence of certain periodic interfering signals (e.g., 60-Hz power line noise) can be greatly reduced.

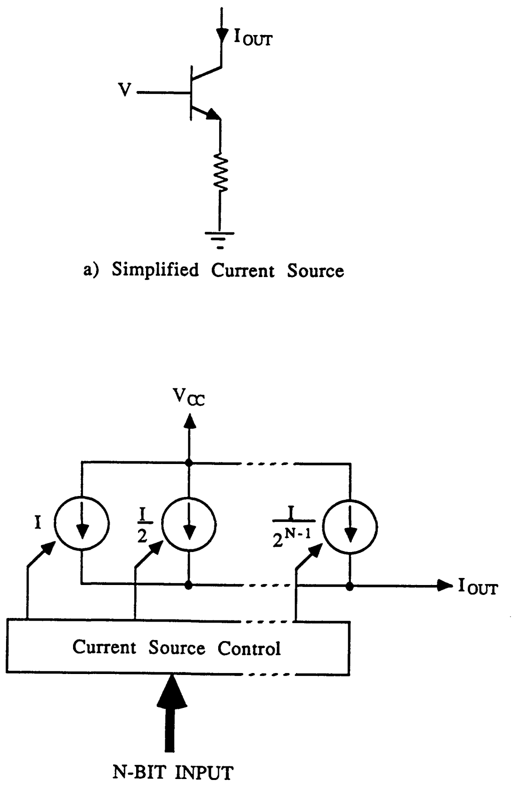
5.2 Digital-to-Analog Converters

Virtually all modern DACs depend on the controlled summation of binary-weighted current sources. If a voltage output is desired (as is often the case) this current is simply made to flow through a suitable resistance.

Figure 33(a) shows how a transistor may be connected as a current source. By establishing a voltage on the base, the emitter voltage is also roughly fixed. Since the emitter voltage is the voltage across the resistor, the emitter current is fixed. Finally the collector current and emitter current are nearly equal if the transistor possesses a high value of β.

Figure 33(b) shows one popular method of combining current sources in a binary-weighted fashion. Under the control of the digital input, the various current sources are activated or deactivated as appropriate, providing an output current proportional to the digital input. This particular realization is amenable to realization in integrated circuit form because only current sources weighted in integer ratios are required. Thus one may exploit the excellent matching of components that monolithic construction offers.

A substantial side benefit of implementing DACs in a current mode is that the conversion speeds can be quite impressive. Because speed is usually limited in most electronic systems by parasitic capacitances rather than inductances, switching currents rather than voltages results in high-speed operation. As an example, many current-mode DACs offer conversion times as low as a few nanoseconds, while the best voltage-mode DACs require 100 ns or more.



a) Simplified Current Source

b) Simple DAC

FIG. 33. Current-mode DAC.

6. MISCELLANEOUS APPLICATIONS

Because analog circuit design spans such a vast area it is simply not possible to provide anything resembling a representative sampling of applications. In this section we examine just three types of circuits that have not been covered earlier in this article.

Figure 34 shows a *switching power supply* in a general form. Switching supplies are used when it is necessary to convert voltages (or currents) from one value to another with high efficiency. The key to this topology's efficiency is the use of a switch to perform the actual modulation of power from source to load. Since a perfect switch does not dissipate energy when it is open (because the current is zero) or closed (because the voltage across it is zero), modulating the time the switch is on allows power to flow to the load without loss.

Practical realizations of this type of power supply employ transistors as the switching elements. Although transistors are not ideal switches, conversion efficiencies in excess of 90% are routinely achievable in many cases.

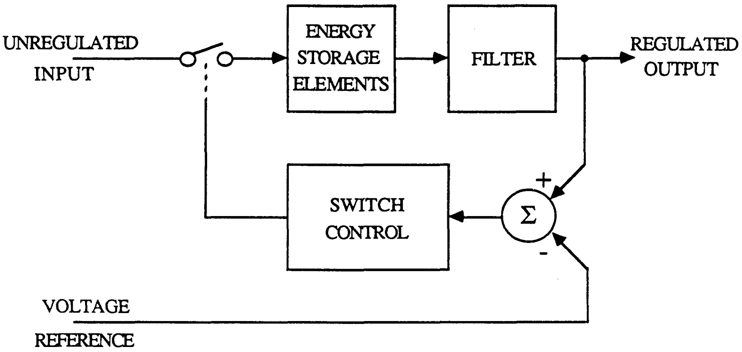


FIG. 34. Switching converter model.

Figure 35 shows a method for exploiting the temperature dependency of bipolar transistors. If one assumes that the two transistors are identical but are operated at a precisely known ratio of currents, then one may compute the difference in base-emitter voltages as follows:

$$\Delta V_{\mathrm{BE}}=\frac{kT}{q}\ln\left(\frac{I_1}{I_2}\right). \qquad (65)$$

Thus this circuit provides an output voltage that is proportional to absolute temperature (PTAT). With care practical circuits of this type readily conform to this law over a wide temperature range [e.g., (−55)–125 °C] to within tenths of a percent.

The last example, shown in Fig. 36, is a *band-gap voltage reference.* Such a circuit is useful for generating a stable, temperature-independent, known voltage for a variety of applications. Its operation exploits the detailed nature of I_S, the saturation current. A quasiempirical expression for the saturation current is

$$I_S=ABT^r\exp\left(-qV_{Go}/kT\right), \qquad (66)$$

where A is the base-emitter junction area, B is some constant, r is a process-dependent constant (usually between 2 and 5), and V_{Go} is the band-gap energy, extrapolated to 0 K, expressed in volts. With this expression one may show that the base-emitter voltage of a transistor operated at constant collector current exhibits a nearly constant temperature coefficient of about −2 mV/°C. When such a negative-temperature-coefficient voltage is combined in the right proportion with a positive-temperature-coefficient voltage (such as that produced by the thermometer circuit of Fig. 35) a stable voltage results. It may be shown that this voltage is nearly the band-gap voltage (roughly 1.2 V for silicon devices).

In Fig. 36, Q_1 and Q_2 are operated at a constant 2:1 ratio of collector currents by action of the op-amp and associated feedback

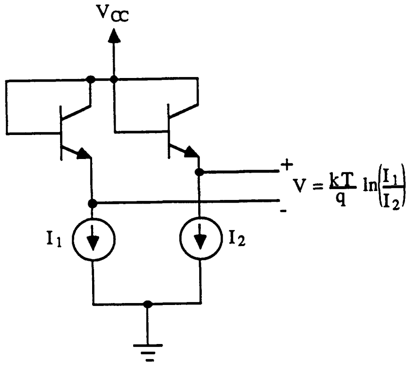

FIG. 35. Thermometer.

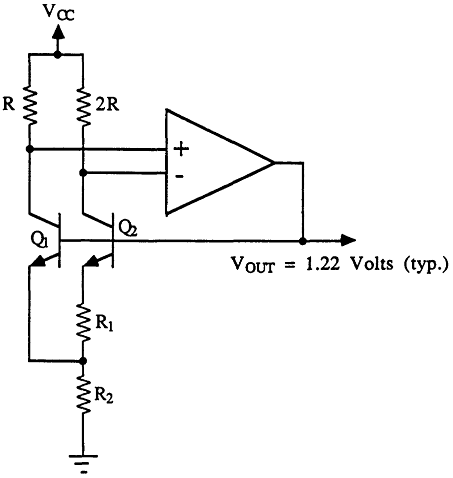

FIG. 36. Band-gap voltage reference.

loop. Hence their base-emitter voltages possess a PTAT component. The current through the resistors in the emitter legs is thus PTAT, and this PTAT voltage drop is added to the base-emitter voltage in just the right proportion so that the two temperature coefficients cancel. The output voltage is typically 1.22 V, and usually varies less than a few millivolts over a range of (−55)–125 °C.

GLOSSARY

BIBO Stability: A system is said to be stable in the bounded-input, bounded-output (BIBO) sense if every bounded input produces a bounded output.

Characteristic Equation: The denominator of the transfer function $H(s)$ whose roots are the poles of $H(s)$.

Crossover Frequency: The frequency at which the negative of the loop transmission [that is, $a(s)f(s)$] of a feedback system has a phase of $-180°$.

Desensitivity: The factor by which any incremental changes in the forward path are suppressed at the output. It is equal to $1 + a(s)f(s)$.

Frequency Response: The magnitude and phase of a transfer function $H(j\omega)$ under steady-state sinusoidal excitation at an angular frequency ω.

Gain Margin: The factor by which the loop transmission may be increased before unstable behavior results.

Incremental Model: One which relates *changes* in excitation to *changes* in response, rather than their absolute values.

Loop Transmission: The gain around a feedback loop. It is equal to $-a(s)f(s)$.

Phase Margin: The amount of negative phase shift that may be added to the loop transmission at the crossover frequency before unstable operation results.

Pole: Any value of complex frequency s that results in an infinite value for a transfer function $H(s)$. These frequencies are also known as natural frequencies or eigenvalues.

Thermal Voltage: The energy kT expressed as a voltage $(=kT/q)$. It has a value of about 25 mV at 300 K.

Zero: A value of complex frequency s for which the transfer function $H(s)$ is zero.

INTRODUCTION

The processing of information by digital circuits and systems has become ubiquitous, primarily because the manipulation of information in digital form offers computational repeatibility and freedom from distortion during transmission and replication, in contrast with the relatively noise-, distortion-, and otherwise error-prone behavior that is typically associated with analog systems. Furthermore, the existence of mathematical formalisms for the design of digital circuits allows algorithmically based automated design of such circuits and systems, while automated design of analog circuits remains largely an elusive goal.

This article provides an overview of digital electronics and begins with a summary of the rules of Boolean algebra in Sec. 1, followed by a survey of a variety of "combinational" logic functions in Sec. 2. Section 3 then examines an important class of circuits that possess memory, while Sec. 4 focuses on the memory elements themselves. Following this macroscopic examination, Sec. 5 presents the electrical (as opposed to logical) characteristics of a number of common logic "families." A survey of representative applications follows in Sec. 6, and Sec. 7 concludes the article with a discussion of some of the fundamental issues associated with digital computation.

1. BOOLEAN ALGEBRA

Digital, or "logic," circuits process information according to rules of mathematical logic developed by Augustus De Morgan (1806–1871) and George Boole (1815–1864). In particular, Boole's *An Investigation of the Laws of Thought on Which are Founded the Mathematical Theories of Logic and Probabilities*, published in 1854, defines rules by which logical statements, expressed in an abstract symbolic form, can be manipulated. These rules comprise what is now known as Boolean algebra.

Boole's accomplishment went largely unnoticed for quite some time. In fact, nearly sixty years elapsed before Alfred North Whitehead and Bertrand Russell proved the essential equivalence of mathematics and logic in their *Principia Mathematica* (1910–1913), acknowledging Boole's significant contribution to this end.

Boolean algebra subsequently was adopted as a tool primarily by semanticists. It was not until 1937 that then-MIT graduate student

Claude Shannon recognized that the discrete nature of electrical relay circuits was particularly suited to analytical treatment by Boolean methods. His ground-breaking paper, "A Symbolic Analysis of Relay and Switching Circuits," introduced symbolic logic into the domain of electronic engineering and thus may be said to mark the birth of digital electronics.

We define *Boolean functions* as those that map n binary input variables into a single binary output. Common practice is to assign values of "1" and "0" (or "true" and "false" or "high" and "low") to these variables. As a consequence of the finite, discrete nature of the mapping, any Boolean function can be completely defined by a table (known as a "truth table") which specifies this mapping. Since each variable can only take on a finite number of values (two), there is only a finite number of possible truth tables, and thus there is only a finite number of distinct Boolean functions of a particular number of variables. Consider Boolean functions of two variables, for example. There are four possible combinations of input variables, and there are therefore 2^4 possible output mappings. Generalizing from this example we see that a Boolean function of m variables possesses $n=2^m$ possible input states and that there are therefore 2^n possible Boolean functions of these n states. We call digital circuits that implement Boolean functions *combinational* circuits.

Some Boolean functions occur so frequently (and are fundamental in some sense) that they have been given mnemonic names. One such function is the AND function, which has the property that its value is 1 only if all of the inputs are 1. We will represent this function in operational form as follows: $Y=AB$, which means "the output Y is 1 only if inputs A *and* B are both 1."

Another common and useful function is the OR function, $Y=A+B$ ("the output Y is 1 if either input A *or* input B is a 1"). It is somewhat unfortunate that the plus sign denotes both the logical OR function as well as common addition, but this usage is standard.

Yet another useful function is the (unary) NOT function, whose output is the logical inverse (or complement) of the (single) input. The NOT function is usually denoted by an overbar ($\bar{A}$).

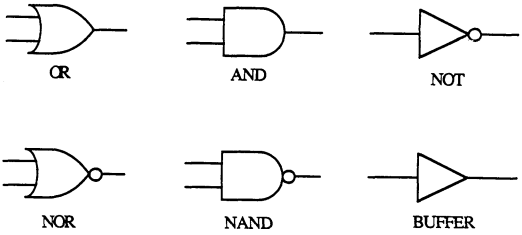

FIG. 1. Basic logic gates.

The circuit symbols for the AND, OR, and NOT operators are shown in the top row of Fig. 1. Note that the addition of a small circle to either input or output is a schematic shorthand notation for inversion—it is equivalent to adding a NOT function at the indicated node, so that the three lower symbols represent NOR (NOT+OR), NAND, and buffer (output=input) functions.

The following list is a collection of axioms, postulates, theorems, and otherwise useful properties of Boolean algebra:

Commutativity:

$$AB=BA, \tag{1a}$$

$$A+B=B+A. \tag{1b}$$

Associativity:

$$ABC=(AB)C=A(BC), \tag{2a}$$

$$A+B+C=(A+B)+C=A+(B+C)\ . \tag{2b}$$

Distributivity:

$$A(B+C)=AB+AC, \tag{3a}$$

$$A+BC=(A+B)(A+C). \tag{3b}$$

(Logical) Sums:

$$A+0=A. \tag{4}$$

$$A+A=A. \tag{5}$$

$$A+\bar{A}=1. \tag{6}$$

$$A+1=1. \tag{7}$$

$$A+AB=A. \tag{8}$$

$$A+\bar{A}B=A+B. \tag{9}$$

(Logical) Products:

$$A0=0. \tag{10}$$

$$AA=A. \tag{11}$$

$$A\bar{A}=0. \tag{12}$$

$$A1=A. \tag{13}$$

$$A(A+B)=A. \tag{14}$$

$$A(\bar{A}+B)=AB. \tag{15}$$

DeMorgan's Theorem:

$$\overline{A+B}=\bar{A}\,\bar{B}. \tag{16a}$$

$$\overline{AB}=\bar{A}+\bar{B}. \tag{16b}$$

With the use of these identities (which clearly are not all independent) it is possible to express *any* Boolean function as either a (logical) sum of (logical) products or as a product of sums. Thus the OR, AND, and NOT functions are sufficient to express any Boolean function. Actually, we can make an even stronger statement since DeMorgan's theorem shows that the AND and OR operators are not independent; one can be derived from the other (with a suitable number of inversions). As a consequence, one can implement any Boolean function using only NOT and either OR or AND functions.This observation is more than simply of purely pedagogic value. The computers of the Apollo spacecraft were implemented entirely with only NOR circuits ("gates"), and this single type of gate was sufficient to get the astronauts to the Moon and back.

2. KARNAUGH MAPS

Although a truth table provides a complete description of a combinational logic function, it does not always present this information in a form that may be amenable to easy synthesis by available building blocks (e.g., AND or OR gates). The Karnaugh ('kar-no) map can aid synthesis by rearranging the truth table in a particular manner that allows one to write down, almost by inspection, a sum-of-products (or product-of-sums) Boolean equation for the logic function. It is then a straightforward (although not necessarily trivial) matter to devise a circuit to implement this desired equation.

The use of a Karnaugh map is best illustrated with a practical example. Let us suppose that we wish to design a circuit that performs arithmetic addition (as opposed to logical addition). Such a module takes three binary arguments (two addends and possibly a "carry in" signal from another like module) and produces two outputs (a sum and carry out). By connecting an appropriate number of such modules together, one can add two binary numbers of arbitrary length.

The truth table for this addition module is as follows:

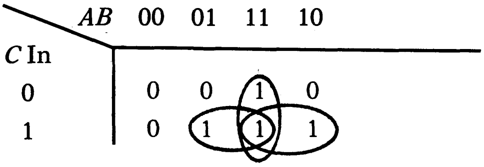
Carry in	*A*	*B*	Sum	Carry out
0	0	0	0	0
0	0	1	1	0
0	1	0	1	0
0	1	1	0	1
1	0	0	1	0
1	0	1	0	1
1	1	0	0	1
1	1	1	1	1

Now, to construct a Karnaugh map for, say, the carry output, we rearrange the truth table for this function so that the input variables are represented along two axes, and so that only one input variable changes at a time in going from one entry to an adjacent entry:

AB *C* In	00	01	11	10
0	0	0	1	0
1	0	1	1	1

To form a sum-of-products expression from this map, we organize the cells that contain 1's into groups of rectangles that are as large as possible. Since only one input variable changes as we go from one cell to the next, any pair of adjacent cells (either vertically or horizontally) corresponds to a term in which one of the variables is irrelevant (missing). For example, the two cells in the third column of our map correspond to $A=B=1$ and $C=1$ or 0, that is, to the term AB. In general, any rectangle containing 2^n cells corresponds to a term in which n variables are missing from the Karnaugh map. By identifying the largest such rectangles comprising 1's in our map, we can rapidly read off a sum-of-products expression.

In our case we find three such rectangles (here identified with ellipses, as is common), each of which is 1 by 2 in size:



C In \ *AB*	00	01	11	10
0	0	0	1	0
1	0	1	1	1

We see that the cells identified in our map correspond to the terms *AB*, *BC*, and *AC*, where C=Carry In. Since the desired function is the union of all such terms, the corresponding Boolean equation is found by logically summing the terms corresponding to these rectangles. Thus, we may write the following expression for the carry output:

$$\text{Carry Out}=AB+BC+AC. \tag{17}$$

The advantages of using a Karnaugh map to simplify the identification of logical equations is limited in practice to systems of four or fewer input variables since the map becomes a volume (then a hypervolume, and so on) beyond four variables. One generally employs computational design aids for the more complex situations.

There are a few other fine points associated with the use of these maps. When trying to identify the largest rectangles containing 1's, recognize that the boundaries of the map are logically connected. Thus, 1's in the leftmost and rightmost columns (or top and bottom rows) would actually be part of one large rectangle.

Often in constructing these maps, one encounters situations in which there are irrelevant values for certain input combinations. These "don't care" states may be handled as 1's to encourage formation of the largest rectangles. However, one should not add extra logical terms in the sum-of-products expression simply to accommodate the added states; the "don't care" states should be used only to simplify the resulting maps. Thus these states should be marked with X's and treated as 1's at one's discretion.

It should also be clear that the resulting Boolean equation is not necessarily unique; one may choose to group the terms in several different, though logically equivalent, ways.

Finally, although the foregoing discussion has only mentioned the sum-of-products formulation of Boolean functions, one could just as well identify rectangular blocks of contiguous 0's. Such blocks represent the result of OR operations so that one can form a product-of-sums expression that is logically equivalent to the sum-of-products formulation.

3. COMBINATIONAL CIRCUITS

Since Boolean functions expressed in a sum-of-products (or product-of-sums) form explicitly use only AND, OR, and NOT operations, they do not necessarily lead one directly to practical circuit implementations. As can easily be imagined, the design of complex digital systems would be quite cumbersome if only those three primitive functions were available (the decision to use only NOR gates in the Apollo computer was the result of reliability considerations). Fortunately, the design of digital circuits is simplified by the great variety of logic functions available in integrated circuit form, some of which we now survey.

The least sophisticated of these functional blocks are simple combinations of the basic gates. An example (see Fig. 2) is the exclusive-OR (XOR) function. This function produces a high output only if the inputs differ, and thus the XOR can form the core of modules that perform addition.

Multiplexers (Fig. 3) route one of n signal inputs to a single output under the command of a control input. For convenience, many multiplexers offer both an output and its inverse. Aside from the conventional routing

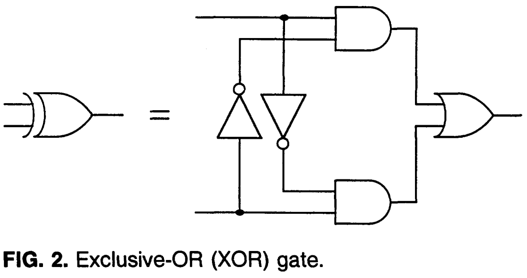


FIG. 2. Exclusive-OR (XOR) gate.

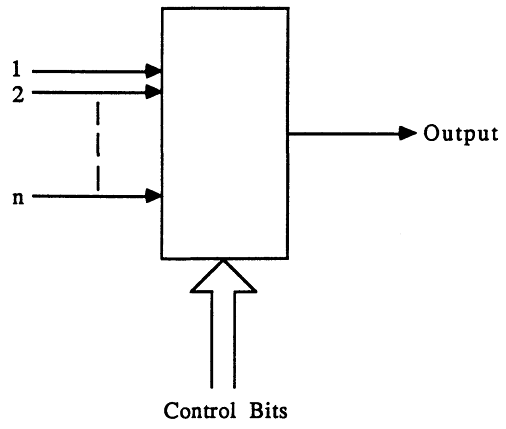

FIG. 3. Multiplexer.

capabilities, an *n*-input multiplexer can synthesize any Boolean function specified by a truth table of *n* entries (even of 2*n* entries, with the addition of, at most, one inverter), if one treats the control signals as the input variables. By connecting the conventional inputs to appropriate high or low states, arbitrary Boolean functions of the control inputs are realizable.

Demultiplexers (Fig. 4), also known as decoders, perform the complementary operation—they take a single input and route it to one of *n* outputs, again under the command of some control bits. Depending on the particular implementation, the unselected outputs may either assume a high-impedance state that approximates an open circuit, or they may be placed in some arbitrary inactive default state (e.g., high). In many cases the input is not an explicit one; the selected output simply assumes its active default state (e.g., low).

Priority encoders (Fig. 5) rank inputs and provide a binary output whose value corresponds to that of the highest-valued input that is asserted. In the example shown in Fig. 5, input number five of the 8-input encoder is the highest-valued input that is asserted (in this particular case, assume that "asserted" means "high"). Thus, the output of the encoder is five in binary form (101).

The priority encoder is particularly valuable in "interrupt-driven" systems in which several entities may vie for a processor's attention. By conveying the priorities associated with these various requests, the encoder allows the processor to order the sequence in which these interrupts will be serviced.

Parity generators/checkers are used in simple forms of error detection. When used as a parity generator, this circuit counts the number of 1's in the input bits, and provides two outputs, either of which may be used. One output, the "even" parity output, is high if there is an even number of 1's in the input, while an odd number of input 1's produces a high state on the "odd" parity output. One of these parity outputs is then sent out along with the original input bits. At the receiving end, an identical parity circuit computes the parity of the incoming data. This computation is compared with the parity bit that was transmitted with the original data. If an odd number of corruptions has occurred (the most likely distortion presumably being a single-bit error), the transmitted parity and that computed at the receiver will disagree, signaling the presence of an error so that one may then take appropriate action.

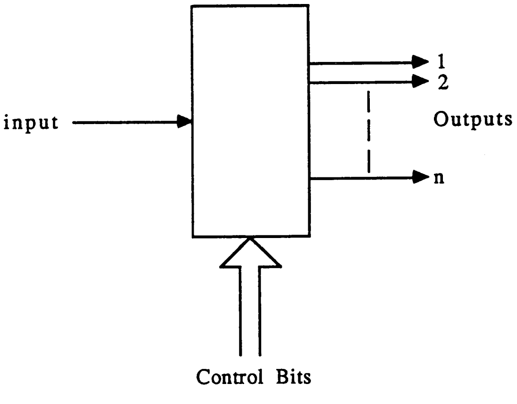

FIG. 4. Demultiplexer.

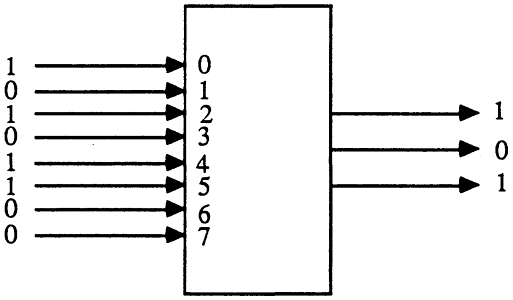

FIG. 5. Priority encoder.

Another important class of combinational circuits consists of those that perform arithmetic operations. *Adders* that typically take two 4-bit arguments and produce their arithmetic sum are available. Furthermore, an arbitrarily large number of these circuits may be combined to handle addends of arbitrary size.

Integrated *multipliers* are also available. These typically accept two 8-bit or 16-bit arguments and generate their arithmetic product.

Magnitude comparators take two arguments and provide outputs either indicating equality or identifying which is greater. As with adders and multipliers, these modules are expandable to permit comparison of inputs of arbitrary size.

Arithmetic logic units (ALUs) can perform a variety of arithmetical and logical operations. Arithmetic functions include addition, subtraction, and magnitude comparison, while logical functions include AND, OR, XOR, and inversion. Because of this smorgasbord of functions, ALUs are found at the heart of virtually all computers (including microprocessors). Finally, ALUs are expandable as well.

Read-only memories (ROMs) and *programmable logic arrays* (PLAs) allow the user to implement custom logic functions. Although ROMs will be discussed shortly in greater detail, it suffices to note that a ROM has m inputs (*address* lines) and n outputs (*data* lines), and that each of the n data outputs can be made an arbitrary Boolean function of the m address inputs. Thus ROM implementations can be superior to those of other combinational circuits, especially when the desired logic function possesses little structure. Furthermore, since n is typically greater than one (e.g., eight), a ROM can simultaneously provide several Boolean functions of a common set of input variables. This attribute is often significant.

It is sometimes necessary to realize a function that involves a greater number of input variables than ROMs can comfortably accommodate. Note that a large number of input variables can be problematic for ROMs since the number of memory cells required grows exponentially with m. In these instances PLAs and their variants (known variously in several commercial versions as PALs, for programmable array logic, or GALs, for generic array logic, etc.) are attractive alternatives. These devices provide custom sum-of-products implementations of one or more Boolean functions of a set of inputs.

In their most general incarnation, PLAs possess the structure shown in Fig. 6. An array of AND gates known as an *AND plane* allows the formation of the individual product terms via programmable interconnections, while a programmable *OR plane* similarly allows the formation of the sum terms. If there are recurrent product terms in the desired sum-of-products expression this structure may afford some economies over a ROM-based implementation because each product term needs to be computed only once.

Programming is accomplished with a special device and typically involves the blowing of microscopic integrated fuses to define the AND and OR connections. Once programmed in this way, such a PLA cannot be "unprogrammed." In other cases, programming relies on tunneling phenomena or hot-electron injection to transport charge onto/into the insulating control electrodes of transistors whose function is analogous to that of fuses in the previous case. Depending on the particular type of device, either tunneling or photoexcitation via ultraviolet light can return the electrons to their original state, allowing reprogramming. Permanent programming can also be performed at the time of manufacture of the integrated circuit. This last option is the most practical one for high-volume production.

As a final comment on this class of circuits, note that there are many PLAs offering a great

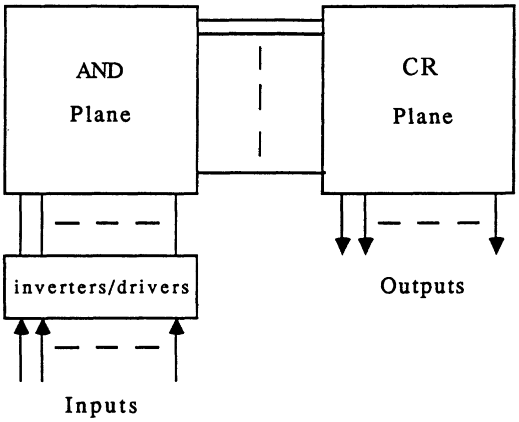

FIG. 6. Internal structure of a PLA.

variety in the number of inputs and outputs as well as in the internal architecture.

Up to now, we have implicitly assumed that logic circuits respond instantaneously. However, clearly all physical systems require some time to respond to changes in the values of input variables, with typical delay times on the order of one to ten nanoseconds for modern computational elements. The logic designer must allow for these delays, even for those associated with interconnecting wiring (approximately one nanosecond per foot of conductor is typical) as well.

Although physical circuits based on the methods described thus far will eventually produce the correct output after the inputs have remained stable for some suitable amount of time, it is quite possible to observe spurious outputs on a transient basis when and if the inputs change. These "glitches" may be harmful by themselves, or they may cause malfunctions in the circuits to which they may be connected. These undesired (and hopefully temporary) outputs are known as *hazards*, and their frequency of occurrence can be eliminated or at least reduced greatly by guaranteeing that all adjacent 1-filled rectangles of the Karnaugh map share terms; that is, that there are overlaps among the rectangles. Unfortunately, this remedial measure is not readily applicable to all forms of combinational logic. In particular, it is difficult to eliminate hazards in purely ROM-based combinational circuits since it is usually impractical to anticipate the many possible intermediate states through which the output may traverse. As will be seen in the next section, however, this problem may be solved quite easily by using an array of flip-flops on the outputs of the ROM. The outputs of the flip-flops are commanded to change only after the outputs of the ROM have settled, thus shielding the external world from hazards.

4. SEQUENTIAL CIRCUITS

The foregoing discussion of combinational circuits has necessarily concerned only functions whose present value is dependent solely on the present values of inputs; there has been no explicit mention of any temporal aspects of computing, except in the context of hazards and related practical issues.

By virtue of their time-invariant nature, combinational circuits lack a property that is crucial to the functioning of computers and virtually all other important systems—that of memory. The ability of a circuit to keep track of past inputs (and decisions) is directly responsible for the great variety of powerful behavior that computational devices (both digital and analog) exhibit.

Of necessity, digital circuits possessing memory cannot be constructed *as* combinational circuits. Interestingly, however, they can be constructed *from* combinational elements. We now consider *sequential* circuits, which can exhibit such behavior.

The crucial difference is the presence of feedback. As an example, consider the block diagram of Fig. 7. A set of signals (state variables) defines the present state of the circuit and is fed back to the input of the combinational circuitry. The combinational logic uses the old state information and the present value of the inputs to compute the next state.

As a practical example consider the circuit shown in Fig. 8 . The lower drawing emphasizes the similarity of this circuit, known as a reset-set (RS) *flip-flop*, to the model of Fig. 7. To analyze this circuit, note that if $R=1$ the output Q will be 0 independent of S or X. By symmetry, if $S=1$, then X will always be zero. As a consequence, Q will equal $\overline{R}$; the output is the inverse of the R input in this case.

If $S=R=0$, then $Q=\overline{X}$, that is, the present output equals the inverse of the state. Under this set of conditions, the output Q can be *either* 0 or 1. The actual value of Q cannot be determined by examining the static solutions to these Boolean constraints.

To deduce the output of this circuit when $S=R=0$, assume initially that $X=1$ and $Q=0$. If S subsequently changes to 1, X will change to 0 as noted earlier, and Q will change to 1. The set of conditions $R=X=0$ and $Q=1$ is

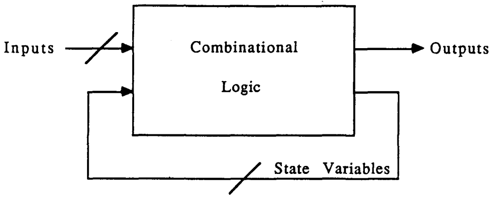

FIG. 7. Asynchronous sequential circuits model.

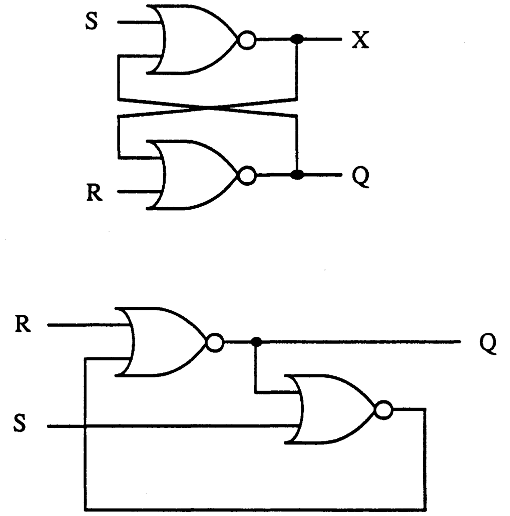

FIG. 8. RS flip-flop.

stable; no further changes will take place, even if S returns to 0.

Now assume that R changes to 1 while $S=X=0$ and $Q=1$ initially. The output Q will change to 0, causing X to change to 1. Again, the output does not change, even if R returns to 0. From these observations we conclude that the circuit remembers which of S or R was most recently in the high state. If S was high more recently, then Q will be 1 (set). If R was high most recently, then Q will be reset to 0. Finally, if $S=R=1$, Q takes on a value of 0 until S changes to 1 and $R=0$.

From the verbosity of the foregoing description, it is clear that there is a need for a more efficient means of describing the behavior of sequential circuits. The state transition diagram of Fig. 9 completely specifies the behavior of the RS flip-flop in a particularly economical way.

Let us define a state as some subset of stable (on a static basis) solutions to the Boolean constraints imposed by the gates and the associated connections, and represent it as a circle on our diagram. The equations inside each state circle define the outputs as Boolean functions of the inputs, while the labels on the arcs (which denote transitions) are the Boolean functions which define the conditions under which transitions take place.

In the RS flip-flop example shown in Fig. 9, there are two states, defined by the value of Q. When $Q=1$, it will remain so until R changes to 1. When $Q=0$, it will remain so until $S\bar{R}=1$.

In addition to the RS flip-flop, there are several other types of flip-flops (shown in Fig. 10). The *D flip-flop* has a single data input, a *clock* input (denoted by the wedge in the symbol), and often two outputs (Q and its inverse, as shown). When the clock input makes a transition (usually from low to high), the output assumes the value of the input at that time, and remains there until the next activating transition of the clock. This type of flip-flop is commonly used to "deglitch" the outputs of ROMs, as discussed earlier.

The *JK flip-flop* has two data inputs and a clock input. If the J and K inputs are inverses of each other, the output after an activating clock transition (e.g., high to low) is equal to the value of J at the time of the transition. If both inputs are low, the output does not change after a clock transition. If both inputs are high, the next output is the inverse of the present one.

A *latch* has a data input and a latch-enable input. As long as the enable signal is low, the output follows the input. When the enable is high, the output stays at whatever state pre-

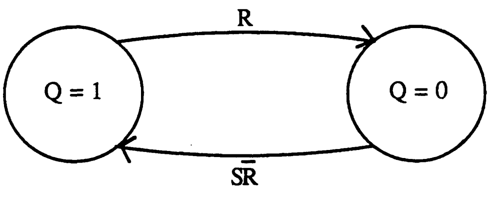

FIG. 9. State diagram for RS flip-flop.

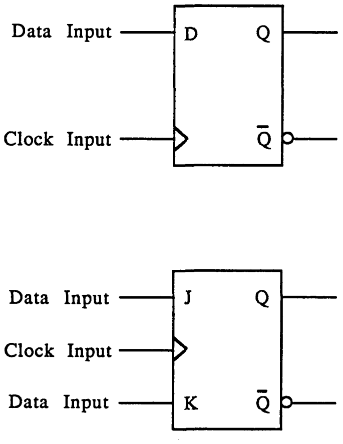

FIG. 10. Other flip-flops.

vailed at the time the enable signal made the transition from low to high.

The particular paradigm for sequential circuits shown in Fig. 7 is sometimes called the primitive or fundamental mode model, and is fraught with difficulties of a subtle nature. Note, for example, that state changes may take place whenever any input signal changes. Hence, state changes occur at unpredictable times, and may even be triggered spuriously by noise (from whatever source) on the input signals.

To reduce the susceptibility of digital systems to such noise-induced errors, and to enforce a discipline that encourages the design of systems that are amenable to tractable analysis, a modified sequential circuits model is almost universally used. Shown in Fig. 11, this model explicitly separates the storage of state information from the combinational logic. State information is stored in some memory (e.g., an array of flip-flops) at intervals controlled by an external clock. Because the state memory updates its contents only at times controlled by the clock, independent of the behavior of the inputs at other times, the likelihood of noise-induced errors is greatly reduced.

The design of such *synchronous* systems is straightforward, and begins with the construction of a state diagram appropriate to the function desired. Combinational logic is then designed to produce the desired outputs given a particular state and inputs, in addition to computing the next state and presenting this information to the input of the state memory. When the clock next updates the state memory, this new information is presented to the combinational logic, and on it goes.

Rounding out a survey of sequential circuits are *counters* and *shift registers*. Some counters can count both up and down, and both decimal and binary moduli are available. Many counters are also presettable so that counting may start from values other than zero.

Shift registers are merely collections of flip-flop chains. Inputs and outputs can be in serial or parallel form, depending on the particular type of shift register. The example in Fig. 12 shows, in simplified form, a serial-in/parallel-out type of shift register. Input data are clocked through a cascade of flip-flops, and the output data are taken as a group of *n* bits every *n* clock cycles. Such a circuit thus converts data in a serial format to data in a parallel format.

5. MEMORY CIRCUITS

The previous section examined a class of digital circuits that exhibit or employ memory. In this section, we survey some of the many types of circuits whose sole function is that of providing memory.

The two broad classes of memory circuits are *random-access memories* (RAMs) and *read-only memories* (ROMs), with various taxa within these two classes. The key distinction is that RAMs typically require power to retain their data while ROMs do not.

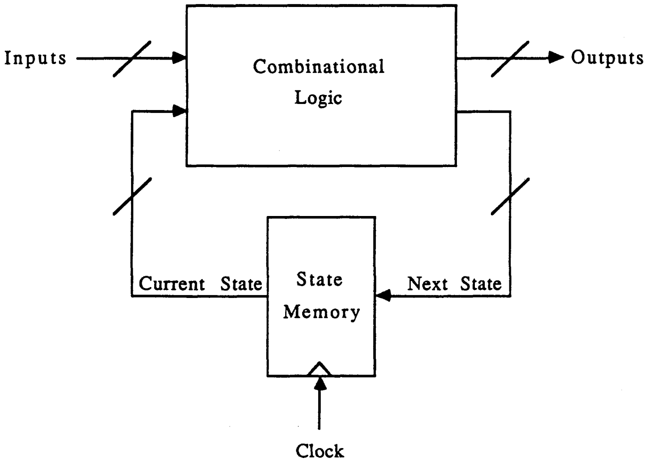

FIG. 11. Synchronous sequential circuits model.

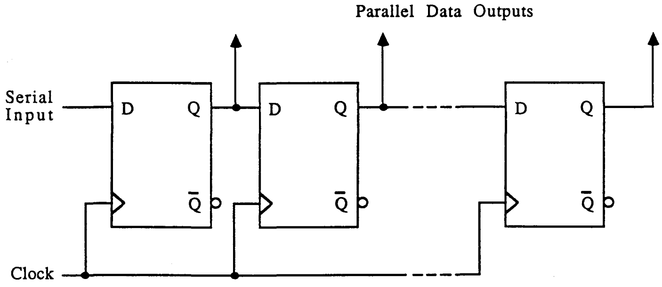

FIG. 12. Shift register.

As the basic static RAM's (SRAM's) memory cell is essentially a flip-flop (each usually comprising four to six transistors), they retain their data as long as power is applied; no further intervention is required. On the other hand, dynamic RAMs (DRAMs) typically represent data as charge stored on an array of capacitors. Because of unavoidable leakage effects, the stored charge cannot persist indefinitely. Thus DRAMs require periodic "refreshing" (e.g., every 2–4 ms) to restore the charge to full value. Despite this need, DRAMs are attractive because their simple internal structure (only one transistor and one capacitor is required per cell) permits a denser packing of memory cells than is possible with SRAMs. However, the need to charge and discharge substantial capacitances makes DRAMs somewhat slower than SRAMs.

Nonvolatile RAMs (NVRAMs or NOVRAMs) may employ magnetic materials to store data and are exceptions to the power requirement rule. These "bubble memory" devices are considerably slower (typically by approximately three orders of magnitude) than their purely electrical counterparts, however. Ferroelectric NVRAMs (and DRAMs) are making a tentative egress from the laboratory, though, and may provide performance that is significantly superior to that of bubble devices.

Read-only memories are found in greater variety than RAMs. *Mask-programmed ROMs* are factory-programmed memories intended for mass production and whose contents cannot be altered once the devices are fabricated, while the cells of *fuse-link PROMs* (programmable ROMs) can be programmed only once since the fusible links that determine the contents of the cells cannot be repaired once they are blown.

Ultraviolet-erasable programmable ROMs (UV-EPROMs) depend on tunneling or hot-electron injection for programming and UV exposure for erasure. The erase process is necessarily not selective since the UV radiation illuminates all cells simultaneously through a transparent window on the device.

Electrically erasable programmable ROMs (EEPROMs) typically exploit tunneling phenomena both to store and to remove charge, permitting completely electrical programming and erasure. Erasure is global in some EEPROMs (known as "flash" EEPROMs), while others allow the erasure of individual cells or groups of cells without disturbing the contents of other cells. Programming/erasure cycle times are steadily decreasing so that EEPROMs are suitable for use as NVRAMs in an increasing number of situations.

6. A SURVEY OF DIGITAL LOGIC FAMILIES

The presentation so far has concerned primarily the global issues associated with digital circuits. To extend the discussion to a more detailed level, we now survey the electrical characteristics and basic underlying circuitry of the dominant logic families.

6.1 Transistor–Transistor Logic (TTL)

The oldest surviving family of digital integrated circuits is TTL, named for the fact that all logic functions are performed entirely with bipolar junction transistors. This family of devices operates from a 5-V power supply, and recognizes any input voltage from 0 to 0.8 V as a valid 0, and any input from 2.4 to 5 V as a valid 1.

Figure 13 is a schematic diagram of the earliest TTL NAND gate. The most distinctive feature of this circuit is the use of a dual-emitter transistor. When a voltage within the valid low range is applied to either emitter, Q_1 turns on, withdrawing charge from the base

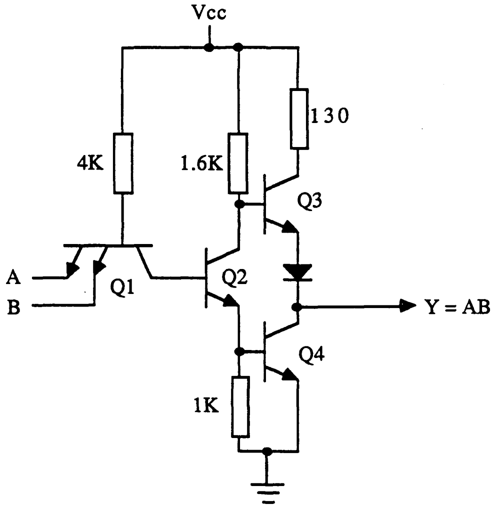

FIG. 13. Classic TTL NAND gate.

of transistor Q_2, causing that transistor to turn off. Transistor Q_2 is known as a phase-splitter since the voltages on its collector and emitter are 180° out of phase. As a consequence, Q_3 turns on while Q_4 turns off, causing the output to go high.

If both inputs are high, the base-collector junction of Q_1 allows current to flow into the base of Q_2 (conventional current is assumed) from the power supply through the 4-kΩ resistor. Since Q_2 is then turned on, Q_3 turns off while Q_4 turns on. The result is a low output. Since we have already deduced that a low at either input causes a high output, we see that this circuit in fact performs the NAND function.

Note that the source that drives the inputs must *sink* current (about 1.6 mA in the original TTL family). Because of the finite current-handling capability of TTL devices (approximately 16 mA), each standard TTL output can drive ten inputs. Beyond this level of loading, the outputs are no longer guaranteed to produce valid logic levels.

Improvements in circuit design and fabrication techniques have spawned a number of TTL subspecies. The use of Schottky clamps (see CIRCUITS, ANALOG) to improve speed significantly without requiring an increase in power is employed in all of the newest TTL devices. Schottky diodes prevent the buildup of excessive base charge when a bipolar transistor is on. Since less excess charge must subsequently be removed, the transistor can turn off much more quickly.

Typical propagation delay times for one type of simple TTL gate are now approximately 3 ns, with power requirements of roughly 4 mW/gate, while another TTL subspecies offers 1–2 ns delays and 10 mW/gate power "dissipation." In both cases, the product of delay and power (conventionally known, in defiance of dimensional considerations, as a speed–power product) is about the same (10–20 pJ/gate). Yet another version of TTL parts requires only 1 mW/gate while switching in about 4 ns, for a 4-pJ product. To the extent that the speed–power product is a figure of merit, smaller numbers are clearly desirable.

As one last comment on this logic family, it should be noted that Schottky (metal-semiconductor) diodes take the place of double-emitter transistors for reasons of speed in modern "TTL" devices.

6.2 Metal-Oxide-Semiconductor (MOS) Logic

Metal-oxide-semiconductor field-effect transistors (MOSFETs) do not require any expenditure of power to maintain their state (i.e., on or off). In principle, then, digital circuits using such devices could drive an infinite number of like gates and would require no power on a static basis.

As with bipolar transistors, MOSFETs are found in two broad classes, termed *n* channel and *p* channel for the polarity of the current-carrying charge. Figure 14 shows the commonly used shorthand symbols for MOSFETs. Where more than one symbol is shown for a particular type of MOSFET, all are equivalent for analyzing digital circuits at this level. Note that all integrated MOSFETs are in reality four-terminal devices. The fourth terminal, the substrate, is shown explicitly in only some of the symbols of Fig. 14, and is almost universally connected to the source terminal in digital circuits and may thus be ignored for the most part. Also, as far as digital circuits are concerned, MOSFETs behave essentially as switches. The on state is characterized by a low (ideally zero) resistance between the drain and source terminals, while the off state is a nearly infinite resistance between these terminals. The state of the device is primarily

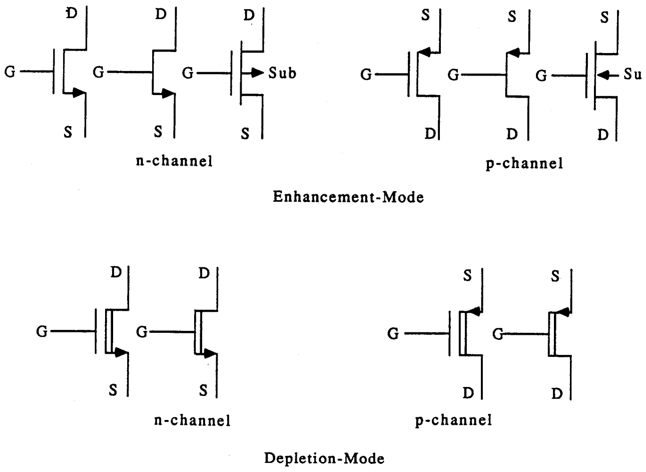

FIG. 14. Shorthand MOSFET symbols.

controlled by a voltage between the gate and source terminals.

In addition to differences in the polarity of the current-carrying charge, MOSFETs are either enhancement-mode or depletion-mode devices (again, see Fig. 14). In enhancement-mode devices, the transistor is constructed so that it is normally off, and thus requires the application of a nonzero gate-to-source voltage to turn it on. This voltage is positive for *n*-channel devices and negative for *p*-channel devices.

In depletion-mode devices, the transistor is normally on and a nonzero gate voltage must be applied to turn it off (negative for *n* channel and positive for *p* channel).

Figure 15 shows a NAND gate realized with *n*-channel devices. To a first approximation, the depletion-mode device may be thought of as a resistor (although a very nonlinear one). Thus the output will be high unless both inputs to the enhancement-mode devices are high.

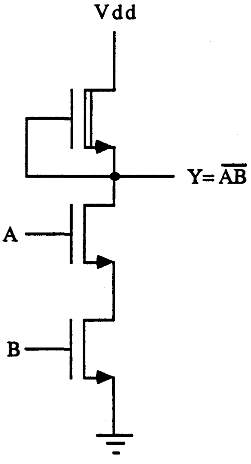

FIG. 15. NMOS NAND gate.

Although a completely analogous circuit can be constructed with *p*-channel devices, *n*-channel realizations are generally favored because electron mobility in silicon is significantly greater than that of holes, leading to superior operating speeds.

A drawback of this enhancement-/depletion-mode combination is that current always flows whenever the output is low; the circuit thus consumes energy in that state. Since the gates of MOSFETs themselves require no current on a static basis, the idling current in the low state represents a significant waste.

This problem can be solved by combining enhancement-mode *n*- and *p*-channel devices to create complementary MOS (CMOS) logic circuits, as shown in Fig. 16. Whenever the inputs are valid logical levels, *n*- and *p*-channel devices are never on simultaneously. In the NAND circuit example shown in Fig. 16, the output is taken to the low state only when both M_1 and M_2 are simultaneously on; that is, only when both inputs are high. When any input is low, either M_3 or M_4 is on, forcing the output to the high state. Since there is thus never a conducting path from the supply to ground (only from supply to output or from ground to output), no energy is consumed on a static basis, with the exception of that due to negligible leakage currents.

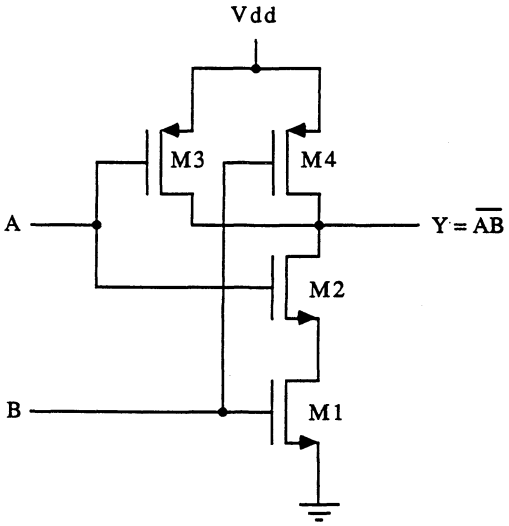

FIG. 16. CMOS NAND gate.

Although CMOS circuits are somewhat less area-efficient than purely *n*-channel ones because of the need to accommodate two transistors of opposite polarity, its vanishingly small static power requirements (typically the order of 10 nW) have led CMOS to dominate MOS logic technologies. Furthermore, the greater power requirements of *n*-channel technologies (or of any technology not using complementary devices) imposes a packing-density limitation because of thermal problems. Hence, CMOS is supplanting all other MOS technologies as densities increase.

To maintain compatibility with established TTL logic circuits, most CMOS devices possess characteristics that are sufficiently similar to TTL in most respects that they may be considered roughly equivalent. Older CMOS devices, however, can function with supply voltages ranging from 3 to 15 V, while newer CMOS devices impose a maximum of 5–7.5 V, compared with the narrow 5% supply voltage tolerance of TTL.

One other attribute of CMOS devices deserves discussion. Since MOS transistors are essentially electronically controlled switches, the outputs of CMOS gates swing within millivolts of the supply and ground, while TTL outputs are typically a maximum of about 3.5 V (out of 5) and a minimum of roughly 0.35 V. Thus CMOS devices can tolerate somewhat more noise than can TTL devices. On the other hand, CMOS devices can generate a great deal more noise than TTL devices because there can be a conducting path from supply to ground through the transistors on a *transient* basis, when perhaps both *n*- and *p*-channel transistors are momentarily on simultaneously. If the impedance of the power supply distribution wires is not sufficiently low, some unintended modulation of the power supply local to the devices can occur with attendant negative consequences. As with all high-speed circuits, this problem is overcome by the liberal use of *bypass capacitors* connected from power supply to ground as close to the device as practical.

6.3 Emitter-Coupled Logic (ECL)

Emitter-coupled logic was developed around the same time as TTL. Recall that early TTL devices were unnecessarily slow because the transistors were allowed to go into saturation, causing excessive buildup of base charge, with attendant reductions in speed.

The philosophy underlying ECL is to avoid saturation and to separate the 0 and 1 states by a smaller voltage than in TTL so that faster switching results for a given maximum rate of change of voltage.

Figure 17 shows an ECL OR/NOR gate in simplified form. Note that the outputs are "open-emitter," meaning that external resistors must be supplied to provide a current path for the output stage. This arrangement allows the outputs of several gates to be wired together, effectively providing an OR function at the common node.

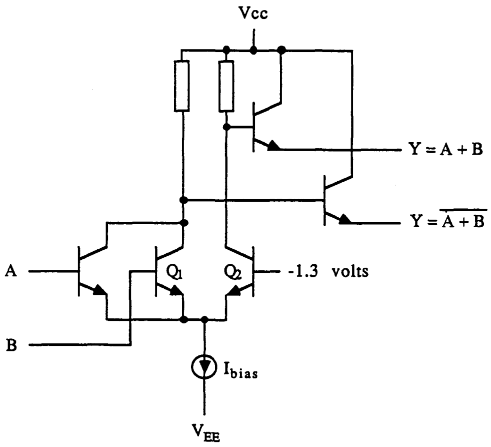

FIG. 17. ECL OR/NOR gate (simplified).

In contrast with TTL and CMOS circuits, the most positive supply in ECL circuits is usually ground, while a negative supply of approximately -5.2 V is normally used, although most ECL circuits will accommodate negative supplies from -4 to -6 V.

The fundamental property on which ECL devices rely is the fact that an emitter-coupled pair of transistors such as Q_1 and Q_2 cannot saturate in the connection shown. Furthermore, base voltage differences of only several kT/q (where k is Boltzmann's constant in joules per kelvin, T is the absolute temperature in kelvins, and q is the magnitude of the electronic charge in coulombs) are required for one of the pair to conduct nearly all of the current I_{bias}. Since kT/q at room temperature is about 25 mV, far smaller voltage differences are required to separate 1 from 0 in ECL circuits than in TTL. With ground and -5.2 V at the supply connections, a valid input 0 is anything lower than approximately -1.475 V, while a valid input 1 is anything greater than about -1.105 V.

By avoiding transistor saturation and by employing small voltage swings, ECL circuits achieve high speeds, with typical propagation delays of 0.5–2 ns for simple gates.

By virtue of the current source I_{bias} (which can be a simple resistor), the current drawn from the supplies is relatively constant, even during switching, since the current merely steers from one transistor of the emitter-coupled pair to the other. Thus not as much power-supply noise generation occurs as with CMOS. However, since the logic swings are smaller, there is less room to accommodate noise in the first place.

Another attractive attribute of ECL circuitry derives from the symmetry of the input stage. Since the collector voltages of the emitter-coupled pair are 180° out of phase, two outputs that are logical inverses of one another are available if both collector outputs are used, as in the example of Fig. 17. Because of the topological symmetry, these two outputs will have essentially no skew in time with respect to one another. This consideration can be particularly important as one pursues extremely high-speed operation.

Unfortunately, the relatively high power requirements (e.g., 10–20 mW/ gate) have limited the density of ECL circuitry because of thermal considerations. Thus only a relatively narrow range of functions is available in ECL form. Nevertheless, ECL offers the highest operational speeds of any silicon-based logic family.

6.4. Gallium–Arsenide (GaAs) Logic

Primarily because electron mobilities in GaAs materials greatly exceed those in silicon, *n*-channel GaAs field-effect transistors (FETs) exhibit substantially faster switching speeds. While this much has been known for quite some time, various impediments primarily of a materials-processing nature have forced a slow development of integrated circuits employing these transistors. For example, the lack of a high-quality insulating oxide has prevented the realization of GaAs MOSFETs. Instead, MESFETs (metal-semiconductor FETs) must be used. Additionally, the tendency of arsenic to evaporate from the crystal during processing has hindered the use of annealing to repair the crystal damage caused by ion-implantation of dopants.

Despite these difficulties, GaAs logic circuits are available and offer speed–power products as small as 15 fJ/gate at 0.1 mW/ gate. At 1 mW/gate, delays of 75 ps are not atypical. Such miserly power consumption means that thermal considerations will not set the bound on attainable density as it does in silicon logic families, although inhomogeneities in processing do limit wafer sizes at present.

Because of the greatly inferior mobility of holes in GaAs, complementary circuits are impractical. Consequently, all logic operations must be carried out with *n*-channel transistors of the type mentioned earlier, the depletion-mode MESFET. An example of a two-input NOR gate is shown in Fig. 18, and is somewhat reminiscent of *n*-channel depletion-mode silicon circuits.

In this circuit, M_1 may be treated as a resistor for purposes of this discussion. As we saw in the silicon case, use of depletion-mode transistors as resistors exacts a penalty in power consumption. It is therefore remarkable that GaAs circuits use as little power as they do. In any event, transistor M_2 is normally off in the absence of any inputs, or when both inputs are low, because of the action of M_1. Transistor M_3, which again may be treated as a resistor, thus pulls the output high.

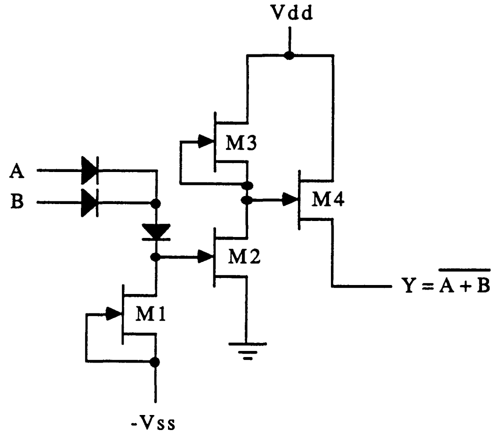

FIG. 18. GaAs NOR gate.

If any input is high, M_2 turns on, pulling the output low. Hence, we see that this circuit does perform the NOR function. Furthermore, any number of arguments can be accommodated simply by adding more diodes to the input stage.

7. SOME REPRESENTATIVE APPLICATIONS

Figure 19 is a collection of some applications of digital circuits. Figure 19(a) shows how a flip-flop may be used as a frequency divider. At each rising edge of the input clock (possessing a frequency "fclk"), the flip-flop output changes state by virtue of the feedback. Thus the output signal is one-half the frequency of the input clock. Many such stages can be chained to yield division factors of any integer power of 2, and these divider chains are integral parts of digital watches, for example. In this application, a master clock frequency of 32 768 Hz ($=2^{15}$ Hz) is often used. A chain of 15 divide-by-two stages thus produces one pulse per second. These pulses in turn drive stages which handle the counting in modulo-12 (or 24) and modulo-60. Finally, subsequent circuitry translates the counter outputs into signals that drive a display.

Figure 19(b) shows how a counter may be used to provide integer divide factors that are not necessarily powers of 2. Most counters have a provision for allowing the preloading of a count value; that is, counting can begin from some arbitrarily set value. Furthermore, many counters provide a separate indication (here, available as signal "Max/Min") of when the output is either a maximum or minimum value. In the circuit of Fig. 19(b), the value of the divide factor is supplied to the preload inputs. At each tick of the input clock the counter decrements toward zero, at which point the Max/Min line goes high. Assuming synchronous preloading, the next tick of the clock results in a return to the preset count value (because the "load" line has been asserted) and the cycle repeats. The Max/Min output is used as the divided output, as shown. Note that the output does not spend equal amounts of time in the high and low states, in contrast with the pure flip-flop divide-by-2^n case.

Figure 19(c) is a sum-of-products implementation of the "carry out" function ($=AB + BC + AC$) of the adder example studied in

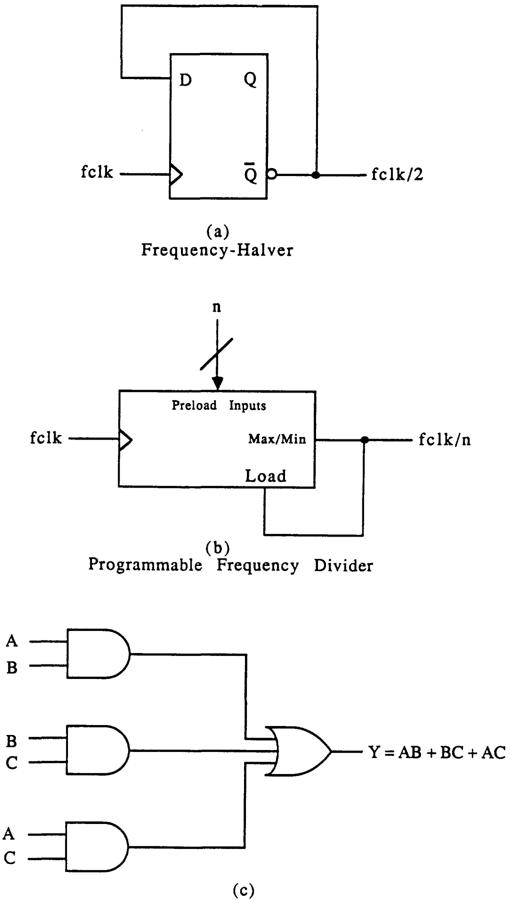

FIG. 19. Miscellaneous applications.

Sec. 3. Recall that, in principle, any Boolean function can be expressed in a sum-of-products form so that only a single level of AND gates and a single level of OR gates is needed. Since signals only propagate through two levels of circuitry, such implementations are capable of exhibiting high-speed performance.

As one last example, Fig. 20 is a simplified block diagram of a microprocessor. Even though all microprocessors are not identical, this diagram is representative of "typical" architectures.

The arithmetic logic unit (ALU) is the heart of the microprocessor, and can perform a wide variety of arithmetic and logical operations as described in Sec. 4. The instruction decoder converts instructions stored in external memory into signals that will initiate appropriate operations in the ALU as well as elsewhere in the system.

The locations of program instructions are identified with a collection of bits known collectively as an address, and the program counter holds the address of the next instruction to be executed. While program execution normally proceeds in a linear sequence, this flow may be interrupted or otherwise modified conditionally on the outcome of operations. The program counter's contents are then altered as necessary.

The accumulator stores the arguments and results of operations, while the condition code register provides information about the status of operations, such as overflow resulting from the addition of overly large numbers.

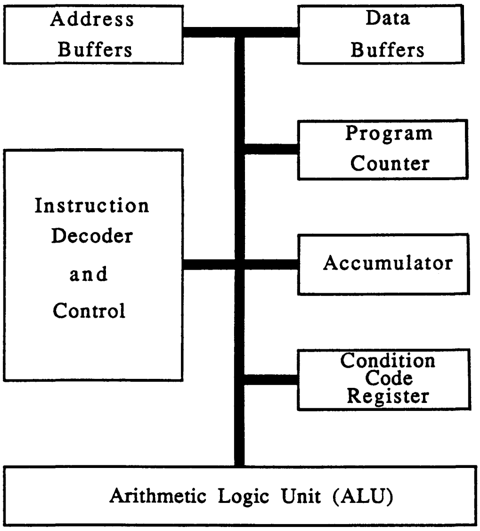

FIG. 20. Microprocessor block diagram.

Finally, address and data buffers provide connections to the external world. Any group of signals possessing some related function collectively forms what is known as a bus, and the data and address buses are the lines of communication with devices such as ROM (which store the basic operating software), RAM (which stores data, including software loaded from an external source such as a disk), and a variety of input/output (I/O) devices. Buffers merely boost signal power from relatively feeble intrachip levels to the values necessary to drive external loads.

8. FUNDAMENTAL PERFORMANCE LIMITATIONS

We have seen that a variety of technological improvements in recent years have yielded large increases in computing speed per unit energy. It is natural to consider what the fundamental limits on such improvements may be.

Central to this end is an acknowledgment that computation is a *physical* process since all systems that manipulate data ultimately must represent information as physical, sensible quantities such as charge or magnetic flux. With this idea in mind, we can establish some rough bounds on computation speed and power consumption in a systematic way. Furthermore, these bounds allow us to evaluate and compare various technologies, both real and proposed.

Let us first examine how much energy is required to perform computation, where we shall define "computation" as a cyclical change in state (i.e., from 0 to 1 to 0). One factor that sets a lower bound on this energy derives from a consideration of thermally induced errors; the energy separating the 0 and 1 states must be chosen sufficiently large to guarantee unambiguous identification of those states, even in the presence of thermal fluctuations.

The probability of a thermal fluctuation of an amount of energy E_0 occurring in a system within a response time τ is given by the Boltzmann relation:

$$P=\exp(E_0/kT), \tag{18}$$

so that the mean time between errors (MTBE) is

$$\mathrm{MTBE} = \tau \exp(E_0/kT), \tag{19}$$

or, solving for the energy fluctuation, we obtain

$$E_0 = kT \ln(\mathrm{MTBE}/\tau). \tag{20}$$

Since we need to separate our 0 and 1 states by an amount that exceeds E_0, we conclude that the "switching energy" (the energy required to switch from high to low and back to high) must be chosen as a large multiple of kT (say, $100kT$) in order to provide a reasonable MTBE from thermal fluctuations. At a temperature of 300 K, $100kT$ is approximately 0.4 aJ, which is four or five orders of magnitude smaller than the energy consumed by a typical GaAs gate.

One reason for the great difference between the minimum switching energy computed on the basis of thermal considerations and the energy typically consumed by physical circuits is the need to choose power supply voltages that are large enough to accommodate manufacturing variations of various types. In the case of MOSFETs, for example, a parameter known as the threshold voltage is dependent on a host of factors such as temperature and doping levels. Because threshold voltage is related to the value of gate-to-source voltage that determines a device's transition from off to on, any variation in this parameter is effectively a noise term that corrupts the interpretation of logic signals. Since the variation of threshold voltage can be controlled in practice only to a certain extent, the logic levels must be chosen with a sufficient separation to guarantee that threshold-variation-induced errors are satisfactorily improbable. Use of higher voltages in turn results in higher power consumption.

A more significant reason for seemingly excessive power consumption is that operational speeds generally increase with power. In FET logic, for example, there are various parasitic (undesirable but irreducible) capacitances that must be charged and discharged to effect changes in state. Hence faster switching can be obtained, but at the expense of increased power consumption. In general, then, we see that various factors of a practical nature can force the use of switching energies that greatly exceed the thermally limited value.

Because the foregoing statement initially appears to apply strictly only to the MOSFET case studied, it is interesting to evaluate superconducting logic circuits with these ideas in mind. Consider a technology in which information is represented as flux stored in a superconducting ring and controlled with some superconducting switching element (e.g., a Josephson junction). Assume that one flux quantum Φ_0 ($= 2\times10^{-15}$ Wb) is stored in the ring. In this case, the switching energy is simply

$$E_{\mathrm{sw}} = LI^2 = \Phi_0^2/L, \tag{21}$$

where L is the inductance of the ring and I is the current circulating in the ring.

Assuming that the inductance L can be any chosen value, we see that the switching energy can be made as small as desired so that the thermally limited value can be approached. However, since the inductance L scales with the size of the loop, large inductances are obtained at the expense of reduced circuit density.

If higher densities are pursued, higher switching energies must be employed. In general, it may be shown that *any* logic device working at its quantum limit requires a higher switching energy as dimensions are made smaller. Furthermore, the quantum-limited response time τ_Q grows at the same time switching energy decreases according to the following relation:

$$\tau_Q \gtrsim h/\pi E_{\mathrm{sw}}, \tag{22}$$

where h is Planck's constant, 6.6×10^{-34} J s/rad. If one substitutes the thermally limited value of $100kT$ for E_{sw}, we obtain the following relationship:

$$T\tau_Q \gtrsim h/100\pi k \approx 1.5\times10^{-13}\ \mathrm{K\,s}. \tag{23}$$

That is, the product of absolute temperature and response time in any system possessing an acceptably low rate of thermally induced errors must always exceed about 10^{-13} K s.

Using this relationship, we find that the quantum-limited response time at liquid-nitrogen temperatures exceeds about 2 fs, while this value is tens of femtoseconds at liquid-helium temperatures. Even though one may employ smaller loops to reduce the inductance and consequently increase speed, one may not reduce delay times below these quantum limits.

Mead and Conway (1980) have compared switching energies of room-temperature MOSFET and superconducting logic as a function of feature size and have found that MOSFET logic actually does better than superconducting logic systems (on a switching energy basis) for feature sizes smaller than about 0.5–1.0 μm. Thus as higher densities are pursued, superconducting logic looks progressively less attractive as far as switching energy is concerned. Alternatively, as lower switching energies are pursued in superconducting logic, both allowable densities and attainable speeds suffer. At 1-μm feature sizes, the switching time of a minimum switching-energy superconducting device at 4 K is approximately 20 ps. Heterojunction high-electron mobility FETs (HEMTs) operated at a temperature of 77 K have achieved speeds of the same order.

When the maximum switching speeds of individual elements are considered, however, superconducting logic is superior, with switching times as fast as a few hundred femtoseconds at liquid-helium temperatures (with the choice of a suitably large switching energy), compared with the tens of picoseconds typically attainable in FET technologies. Although one can trade speed for power in virtually any technology, this tradeoff extends to higher speeds for superconducting logic than for FET logic because the former allows operation nearer the quantum limits of switching energy and speed if density considerations are ignored.

Even though the switching speeds of individual superconducting elements are superior, much of this advantage can erode when larger systems of these elements are constructed because of unavoidable speed-of-light delays (and dispersion) along the interconnecting wires. Although this delay is approximately 3 fs/μm in free space, it may be as large as 5–10 fs/μm in the materials commonly used in integrated circuits. This delay can easily dominate in superconducting systems, not only because a given delay represents a higher fraction of the intrinsic response time, but also because the lower allowed densities force the use of longer interconnecting paths and thus greater delays than for FET technologies.

In general, use of superconducting logic at present may be justifiable only in special circumstances, where its superior raw speed can accomplish what other technologies cannot (even with architectural enhancements such as a high degree of parallelism), and where one is thus willing to tolerate lower circuit density, higher power consumption (including that associated with the cryogenic apparatus), and increased difficulty of fabrication.

GLOSSARY

Bus: A collection of related signals (e.g., as in an address or data bus).

Clock: Usually a periodic signal used to control the timing of events in digital circuits.

Combinational Logic: Logic circuits in which the outputs are functions of only the present values of the inputs.

Flip-Flop: A sequential logic element with two stable states.

Karnaugh Map: A particular arrangement of a truth table that aids in the synthesis of logic circuits.

Random-Access Memory (RAM): Memory in which read and write operations may both be performed, and in which all memory cells are equally accessible. Most RAMs lose their contents when power is removed.

Read-Only Memory (ROM): A memory circuit that is generally programmed (written to) only once or rarely. The stored data are not lost when power is removed.

Sequential Logic: Logic circuits in which the outputs may be functions of present and past values of the inputs, as well as past values of outputs.

State Machine: A synonym for sequential logic.

Synchronous Systems: Logic circuits in which states may change only at intervals controlled by a clock.

Truth Table: The input–output behavior of a combinational circuit expressed in simple tabular form.

INTRODUCTION

Coal is, by a very large margin, the largest known fossil-fuel resource occurring in the world, and, as technologies exist at this writing, the largest reserve of controllable energy in the world. In the early part of the twentieth century, coal became the dominant energy resource used in the industrialized world. However, as petroleum and natural gas resources were developed, and systems for their distribution installed, coal yielded its position of dominance to these two resources, primarily on the basis of cleanliness and convenience (fluids as opposed to solid). As reserves of petroleum and natural gas decline, most observers in the field of energy supply predict a return of coal to its position of dominance, particularly in applications where electric energy may not be suitable. This article will introduce the reader to this important energy resource, identifying many of the aspects of coal that must be addressed if it is to move to the position of prominence being predicted for it.

1. COAL RESOURCES

Quantities of coal in the United States are stated to be as small as 225 billion metric tons, and as large as 3180 billion metric tons. It is important to understand the bases for these various estimates. The parameters used in these estimates have not been completely standardized among nations, and sometimes not even among states or provinces within a nation. The system of parameters utilized in this treatise is one quite commonly employed in the literature.

1.1 Coal Resources versus Coal Reserves

In this system four parameters are utilized in the determination or estimation procedure, namely degree of exploration, depth of the coal seam (thickness of overburden), seam thickness, and fraction of coal recoverable. The degree of exploration, in turn, is utilized under four definitions:

- Measured—core holes are drilled not more than 0.8 km apart, thereby establishing the thickness of the seam, the lateral extent of the seam, and the quality of the coal.
- Indicated—core holes are drilled not more than 2.4 km apart.
- Inferred—an occasional reference or control point established, as by core holes more than 2.4 km apart, or outcropping, then extrapolation beyond the control point to distances greater than 2.4 km, based upon geological factors.

- Potential—an outcropping or other visual observation, followed by extrapolation based only upon geologic and geographic patterns.

1.1.1 Parameter Values for Estimating Resources. The term *resources* is a general term comprising many combinations of applications of the factors presented above. *Gross resources,* a very large number often quoted, is the sum of coal quantities estimated by all of the above degrees of exploration, with no restrictions placed upon seam depth or seam thickness, and assuming 100% recoverability. This is the basis for the estimate of 3180 billion metric tons of coal in the United States. Other smaller numbers are often quoted by placing some restriction upon certain of the above factors, most often excluding the "Potential" category under exploration and placing some limitation upon thickness of overburden. These estimates, in general, do not consider whether the coal thus estimated can actually be mined, and are without economic connotation.

1.1.2 Parameter Values for Determining Reserves. The term *reserves* generally means *demonstrated reserve base,* meaning known and recoverable by current mining technology. Although not all countries have adopted the same restrictions for what is deemed to be recoverable, the limitations applied quite generally in the United States, and certain other countries are given here.

1.1.2.1 Degree of Exploration. Estimates derived from both measured and indicated resource categories are considered to be quite reliable for this purpose, and are usually combined in determining coal reserves. Estimates in the inferred and potential resource categories are usually considered to be too speculative and are not generally included in determining reserves. It must be recognized that there are exceptions to these uses in some countries.

1.1.2.2 Depth of Coal Seam. Deep mining of coal at depths greater than about 300 m is not practiced in many countries; hence, for those countries only coal with less than 300 m of overburden is counted in reserve determinations. This is not uniform, however. In countries or regions where coal is deep-mined to depths up to 900 m, the 900-m restriction may be used in determinations of reserves. (See Sec. 3.3.5.)

1.1.2.3 Seam Thickness. The restriction applied relative to this factor strongly depends upon the degree of depletion of the coal reserves of the area. For example, in the United States where reserves are still very large, deep mining of seams less than 70 cm in thickness is considered to be uneconomic; hence, such seams are not included in reserves. By contrast, in certain European countries where good quality coal is largely deleted, seam thicknesses down to 35 cm are included in reserves.

1.1.2.4 Recoverability. The degree of recoverability is dependent upon the mining technique to be used as well as other factors, and may range from less than 50% of the coal in place to near 100%.

1.2 World Coal Reserves and Resources

In Table 1 are presented world coal reserves, as discussed above, and two categories of world coal resources frequently reported

Table 1. World coal reserves and resources (billions of short tons).

Continent or Region	Demonstrated reserve base (1)	Identified resources (2)	Gross resources (3)
Asia, including USSR	752	3000	11 000
North America	476	1900	4 400
Europe	75	300	800
Africa	23	90	250
Australia, New Zealand, New Caledonia	18	70	130
South and Central America	8	30	40
Total	1352	5390	16 620

in the literature. Column (1) presents quantities determined by the following criteria: measured and indicated resource categories, 0–300 m depth, and seam thicknesses as utilized in various countries or regions (usually either 70 or 35 cm). Column (2) includes inferred resource quantities along with measured and indicated resources, and depths 0–900 m. Column (3) represents gross resources as defined in Sec. 1.1.1 above. Because of the different criteria used by the various estimators, the values in column (1) involve reasonable adjustments to some data to arrive at a consistent determination. The values presented are conservative. In further years, as coal reserves are more widely used, coal resources not now included in the demonstrated reserve base will be further explored, moving many of those resources into the demonstrated reserve base and greatly increasing the known and recoverable coal reserves.

2. ORIGIN AND CLASSIFICATION OF COAL

Coal is considered by geologists to be a rock. Hence the scientific study of coal is called *coal petrology*. The description or classification of coal is called *coal petrography*. Coal is a heterogeneous material, so much so that the use of the word *polymeric* in relation to coal is quite inaccurate. Rather, coal is composed principally of microscopically distinguishable entities of organic origin, distinctive both physically and chemically, called *macerals*. Varying amounts of inorganic material are also found distributed through the coal seams.

2.1 Origin of Coal

Organic coal macerals are derived from plants, ranging from large trees to tiny plants, even spores and exudates. Over long periods of time the plant materials accumulated and were preserved in the moist environment of a swamp. As the trees and other plants fell, they were covered by water, thus isolating the decaying plant material from the atmosphere. Organic material preserved in this fashion is called *peat*. It was necessary that the level of the water in the swamp adequately cover the peat, yet not preclude plant growth. Considering the rather delicate balance required, one readily can understand that a coal seam of thickness of 30 m or more would be, and is, an unusual occurrence. In the course of time sediments washed in upon the peat, burying it and sealing it from air oxidation and erosion processes.

During the time of accumulation of the plant material in the peat swamp, inorganic substances entered the swamp, mostly carried in by water, either as particulate mineral grains or as ionic compounds dissolved in the water. These materials were deposited throughout the period of organic accumulation, resulting in mineral grains or combined with organic fractions. In general, the mineral deposits occurred from rather quiescent water movements, resulting in small mineral grains in the coal, although rapid water flows occasionally deposited rocks or large concentrations of inorganic material within the peat accumulation.

Following burial of the organic and inorganic materials under thick layers of sediment, geological activity in the earth subjected the peat to varying degrees of pressure and temperature. The alteration of these accumulated plant substances resulting from the effects of elevated pressure and temperature is termed *metamorphism*. The severity of the metamorphism determined many of the physical and chemical properties of the coal.

The coalification process represents a phenomenon whereby hydrogen and oxygen were removed from the carbon skeletal units of the woody material and any other organic materials present, being released chiefly as water, carbon dioxide, and methane. This release from a solid skeletal structure created tiny micropores throughout the coal, even down to the molecular scale. Hence coal is a highly porous material with large internal surface areas. The transformation of plant substances into coal is generally believed to involve two stages: a biochemical stage in which the woody material is transformed into peat, and a geochemical (metamorphic) stage in which peat is transformed into coal. The nature of the original plant material (e.g., tree trunk, leaves, etc.) passes its imprint through both stages. This imprint can be observed by viewing the coal maceral under a microscope; this viewing is called petrography and defines the coal type. The product from the geochemical stage additionally depends upon the severity of the metamorphism, which establishes coal rank.

2.2 Coal Type (Petrography)

One is interested in understanding, or even predicting, the response of a particular coal in a utilization process. The nature of the plant material as it existed before coalification began may greatly influence how the coal maceral formed from that plant material behaves in the utilization process. The maceral formed from one portion of a plant may have a different visual appearance or other different optical properties than one formed from another portion of the plant material. If a carefully prepared sample from the coal, such as a thin section or a polished surface, is examined under a microscope, it is possible to determine the relative proportions of the various maceral components and other optical features that correlate with chemical behavior. When carefully performed, this procedure can provide reasonably accurate analyses of the coal in terms of organic origin of its component macerals. This procedure is known as a petrographic analysis.

Three principal classes of substances are generally recognized as the major petrographic constituents of coal, namely, vitrinite, liptinite (sometimes called exinite), and fusinite (also called inertinite).

Vitrinite originates from the larger portions of plant material such as tree trunks, large branches, etc. In most coals vitrinite constitutes from about 50% to as much as 90% of the volume of the coal (commonly 75%–80%).

Liptinite originates from leaves, spores, resins, and other chemically similar materials in the plant. It typically possesses a higher hydrogen content than vitrinite and is usually more reactive than vitrinite. Liptinite is typically about 3%–5% of the coal.

Fusinite is relatively inert in many utilization processes, hence the alternate name "inertinite" preferred by some petrologists. Its origin relates more to the history of the woody material than to the chemical nature of the original plant material. The carbon content is considerably higher than observed in vitrinite or liptinite. Fusinite particles appear to have resulted from a forest fire or other extreme phenomenon such as could alter the chemical structure in the direction of carbon enrichment. Fusinite is normally present at lower than 10% concentration in the coal. In liquefaction of coal, it does not participate as a reactant. In the manufacture of metallurgical coke it does not participate in the transition to coke, but remains as an "inclusion" in the coke walls or in larger boundary definitions.

2.3 Coal Rank

As the peat accumulation was covered by sediments of increasing thickness, geothermal processes inside the earth provided heat, which caused the chemical release of oxygen and hydrogen. The heat and pressure generated by geothermal activity were often supplemented by other geologic activity, sometimes generating extremely high pressures, with accompanying increases in temperature. By this means the organic material was converted progressively toward more carbon-rich material. The physical and chemical properties of the resulting organic mass (coal), as well as the chemical composition, were largely determined by the severity of this metamorphic process. Consequently, coals are ranked in relation to the severity of the metamorphism by which they were formed.

Peat is a precursor of coal, not yet having been subjected to the geochemical processes, and hence is not generally included among coal ranks. Four principal categories, with a few subcategories, are used to classify coals according to rank. The principal categories are anthracite, bituminous, sub-bituminous, and lignite. (In some countries the term *brown coal* is used, which encompasses lignite and part of the sub-bituminous rank.)

Two or more properties are usually combined to define coal rank. The property that most consistently correlates with coal rank is elemental carbon content. Two additional properties frequently used (usually one but not both) are volatile-matter content (Sec. 5.1) and heating value.

Table 2 presents typical values of the most often used properties associated with each principal rank. For the higher-rank coals (anthracite, low-volatile bituminous, and medium-volatile bituminous) the percentage of volatile-matter content is usually used in combination with elemental carbon content to define rank. For the lower-rank coals (high-volatile bituminous, sub-bituminous and lignite), heating

Table 2. Typical parameter values for rank definition.

Coal rank	Fixed carbon (dry basis) (wt %)	Volatile matter (dry basis) (wt %)	Heating value (moist basis) (kJ/kg)
Anthracite	86–98	2–14	
Low-volatile bituminous	78–86	14–22	
Medium-volatile bituminous	69–78	22–31	
High-volatile bituminous[a]	52–69		25 500–32 500
Sub-bituminous[a]	50–58		19 000–30 000
Brown coal, including lignite	46–56		< 19 000

[a] An additional parameter distinguishes between high-volatile bituminous and sub-bituminous, i.e., high-volatile bituminous is agglomerating, while sub-bituminous is nonagglomerating.

value is used in combination with elemental carbon content. Anthracite is usually found in steeply pitched seams, indicating strong geologic activity accompanied by great pressures and high temperatures during coalification. By contrast, lignites, and generally sub-bituminous coals, are found in essentially horizontal seams.

3. MINING OF COAL

Coal, after its formation, must remain protected from the atmosphere to prevent slow degradation by a process known as *weathering*, a process of chemical attack by oxygen and moisture. Consequently any coal deposit of value will be covered by soil and/or rock ranging up to several thousand meters thick; this covering is called *overburden.*

3.1 Deep Mining

Coal rank bears a direct relationship to the severity of the metamorphic process. The higher-rank coals (anthracite and bituminous) were formed under conditions of high pressures and elevated temperatures, with overburden layer thick enough and of sufficient nature and strength to contain the organic mass while subjected to great geologic forces. Geological activity subsequent to formation of the coal may have altered the overburden thickness, and the erosive forces of water and wind have often reduced the thickness of the overburden, sometimes exposing the coal seam in an *outcropping.* Following all of these activities, anthracite and bituminous coals are usually found under a layer of rock and soil ranging in thickness from a few tens of meters to several thousand meters. The most practical means of removing these coals from seams situated under thick overburden is to follow the coal-seam contour without removing or disturbing the overburden.

3.1.1 Room-and-Pillar Mining. High-rank coals are usually located under rock overburden. However, when the coal is removed, which in the seam is supporting the overburden, the roof of the mine will collapse unless adequate support is provided. The oldest and still most widely used technique is to leave coal pillars in place to support the roof. Quite typically several parallel entry or development channels are mined into the coal seam and connected by cross channels. This mining pattern leaves behind supporting coal pillars about 18×24 m in cross section. The height of the cut into the coal seam depends upon the mining equipment used, and is typically about 3 m. Thus, of the 3 m thickness of coal potentially minable in this pattern, only about 40% is actually removed during the advance into the coal seam. If the seam is more than 3 m thick, additional coal will be left behind, generally in the roof, but sometimes in the floor, depending upon the composition and condition of the floor. In some instances additional coal is mined when retreating from the mine, by removing part of the pillars or some of the coal left in the mine roof or floor. On average only about 50% of the coal in place is removed in room and pillar mining. The entry channels provide for ventilation of the mine, to remove dust and flammable gases, particularly methane, which is present in all coal seams.

3.1.2 Longwall Mining. Following completion of the above-described retreating operation and withdrawal of the equipment, it is not considered to be practical, consistent with safety requirements, to reenter that section of the coal seam to attempt to recover a portion of the remaining coal. With the objective of increasing the percentage removal of the coal in place, by refraining from leaving coal behind in pillars, a technique known as *longwall mining* is used in some countries. Several parallel entry channels are mined into the coal seam. A pair of these channels are typically 180 m apart and extend as far as 1800 m, or even further, into the coal formation, following the coal-seam contour. A cross channel is then mined in the seam at this depth into the seam, connecting the two parallel channels. A specially designed mining machine then removes coal from the face along the cross channel by moving back and forth, advancing toward the mine mouth on each new cut. As the operation progresses toward the mine mouth, leaving a cavern behind, the roof caves in behind the mining machine. The special design and construction of the longwall mining machine provides protection to the operator, as well as to the complete operation. No coal pillars are thus left unmined, but the thickness of the coal mined is restricted to the height minable in the single pass, typically 3 to 4 m. On average, about 80% of the coal originally in place is removed in this technique.

3.2 Surface Mining

Low-rank coals, particularly brown coal (which includes lignite) and some sub-bituminous coals, are situated in environments that do not allow underground mining. The environments are often swampy, or the overburden is of such nature that it will not support itself above any entry channel of practical width. If such coals are to be mined, the operation involves removal of the overburden to expose the coal for recovery. The operation is variously known as surface mining, strip mining, or sometimes open-pit mining. The economics of surface mining dictate whether such a technique should be applied, governed by the thickness and nature of the overburden to be removed in relation to the coal-seam thickness and the quality and value of the coal. In general, at least 95% of the coal in place can be recovered in surface mining. However, even for very thick seams, overburden thickness greater than about 45 m usually discourages surface mining as a means of recovery.

There are several advantages in surface mining of coal. These include lower mining cost per ton of coal recovered, higher recovery, and greater safety. A major disadvantage is destruction of the surface. However, this disadvantage may be overcome by restoring the surface, which is considered to be practical if the surface is relatively flat.

3.3 Thickness of Overburden in Underground Mining

In general, in consideration of weight of the overburden, deep mining is not conducted at depths greater than 300 m. In a few areas of the world where the nature of the rock constituting the overburden may indicate sufficient strength, such as the Rocky Mountain region of Utah and Colorado, some mining is conducted to 900 m, but is not commonly done. It is for this reason that recoverable coal reserves generally do not include coal seams at depths greater than 300 m.

4. TRANSPORTATION, STORAGE, AND HANDLING OF COAL

4.1 Transportation

The demonstrated reserve base for coal is several hundred times larger than identified and recoverable petroleum reserves. Although coal exhibits serious disadvantages when considered as a substitute for petroleum and natural gas, the developed nations of the world will almost certainly be compelled to make such substitutions. Coal reserves usually are not located near large coal markets, mostly requiring transport of the coal over distances ranging from a few kilometers to 1600 km or more on land, or up to several thousand kilometers on the oceans.

4.1.1 Transportation Methods

4.1.1.1 Rail—Unit Trains Railroads are the principal means of long-distance transport for coal, the result of consideration of both cost and availability for most coal markets. The individual freight car, as part of a typical freight-hauling system, spends about half of its time in railroad yards, 40% in customers' yards or sidings, and only 10% of its time moving. This realization gave rise to the concept of the *unit train.* Since coal movements often involve very large quantities of coal, it is practical for a complete freight train—all of the cars in the train—to carry only coal, all loaded at one origin, all unloaded at one destination each trip, and moving in both directions on a predetermined schedule. This is the general concept of the unit train. Unit-train cars spend virtually no time in railroad yards, time available for the other functions of the cars is doubled at the outset, and productivity is greatly increased. Energy consumption per ton-km is about one-third of the consumption for mixed-train freight. The unit train in the United States typically contains 100 to 125 cars, carrying an average of 90 metric tons per car, and is moved by five or six diesel-powered locomotives of 3000 horsepower each.

An important aspect of coal transport by open-top rail cars is the loss of coal along the route due to wind, and called in the industry *windage*—about a 1% loss of the coal transported. This loss is often reduced by spraying the coal with water or oil, or sometimes by covering with a lid.

4.1.1.2 Trucking. Although a large amount of coal is moved by truck, the larger portion of this movement is with off-highway vehicles, defined as those which are too long, too wide, or too heavy for use on public highways. They are used in short-haul movements, such as from the mine mouth to an electric power plant built nearby. Trucks built for use on public highways may carry coal payloads up to 60 metric tons, while off-highway coal trucks may haul up to 180 metric tons of coal. The smaller trucks are often rear-dump, although the larger highway vehicles may be bottom-dump. The larger off-highway trucks are bottom-dump, hence of the tractor-trailer type (sometimes also called semi-trucks). Trucks for coal transport are essentially all diesel powered.

4.1.1.3 Slurry Pipeline. While it is known to most people that transport of liquids and gases in pipelines is an efficient and proven method of conveyance, it is not so generally known that transport of solids by pipeline enjoys the same advantages of economy, simplicity of operation and protection of the environment. For transport of coal by this means, coal is ground to a fine size, mixed with water to form a slurry, then pumped through a pipeline. The pipeline hydraulics require the coal to pass through 20 Tyler mesh (all particles smaller than 833 μm). Such transport is particularly suited to coals to be used in pulverized coal-combustion systems, which require grinding until about 80% will pass through 200 mesh (74 μm). Quite typically the coal–water slurry is about 50% solids by weight and moves through the pipeline at a velocity of about 1.5 m/s. If the coal is too coarse (greater then 20 mesh) a higher pumping velocity is required. If the coal is too fine, the slurry pumps more easily, but dewatering before combustion becomes more difficult. One seeks for the optimum balance between pumpability and dewatering characteristics. The slurry is usually transported through steel pipelines, and corrosion is controlled by adding corrosion inhibitors. Top-size particle control helps to limit erosion and prevents pipeline plugging. Booster pump stations are typically located from 100 to 160 km apart, depending upon the terrain. Continuous centrifuges are most commonly used for dewatering the slurry.

Although no serious technical problems exist relative to the coal-slurry pipeline, difficult political problems do exist. The coal-slurry pipeline is in direct competition with the railroad for coal transport. In the United States, transportation of coal represents a major source of revenue for the railroads. The railroads almost unanimously refuse to grant a right-of-way for coal-slurry pipelines to cross the railroad. Some form of eminent-domain legislation will be required to resolve this right-of-way problem. At the time of this writing, the railroads and other special-interest groups have successfully blocked such legislation in the United States. Without rights-of-way across railroads, coal transport by slurry pipeline will remain extremely limited.

4.1.1.4 Water Transport. Transportation by water is the least expensive method for shipping coal, therefore, the preferred route where a waterway exists. The vast majority of coal moved on rivers is carried on barges. "Jumbo" barges are as large as 10 m wide and 60 m long, and carry up to 1350 metric tons of coal. The barges are moved in "tows" of as many as 48 in number for waterways where locks are not required. For river transport where locks are involved, lock sizes are the major limitation in determining the number of barges in a tow. Other limiting factors may be the capacity of the towboat, current velocity, and the width and depth of the river channel. The towboat actually pushes the barges and usually its power ranges from 3000 to 10 000 horsepower. The tow speed usually ranges from 5 to 20 km/h. Energy consumption for transportation of coal on barges ranges from 260 to 450 kJ/ton km.

Because of the lower cost of coal transport by waterway, it may be cost-effective to transfer the coal from railroad to barge during a long-distance shipment. For example, western U.S. coal is shipped by unit trains from mine mouth to the western end of the Great Lakes, transferred to vessels, and hauled by waterway to the final destination along the shores of the lakes. Very large self-propelled vessels, hauling up to 40 000 metric tons of coal per trip, are used for large coal shipments on lakes. These vessels are equipped with a self-unloader able to discharge the cargo in about four hours.

Since the large increase in world prices of petroleum in the 1970s, transport of coal across oceans for such uses as electric power generation has increased. Ocean transport is coupled with either rail–land transport or pipeline. Where the land transport system is the pipeline, adequate water removal from the slurry must be achieved before loading into the ship, to ensure that the ship's stability will not be endangered. Furthermore, shipping of excess water is uneconomical. In terms of tonnage, coal is now the third largest commodity of international trade, exceeded only be petroleum and iron ore.

4.2 Storage

The use of coal as a major source of energy, such as at modern electric power generating plants, requires storage of large quantities of coal, both for day-to-day use (called live storage) and to ensure long-term availability (called dead storage). The live-storage area may contain as much as 100 000 metric tons of coal, with an additional 1 million metric tons in dead storage. Storage of large quantities of coal is usually achieved in open stockpiles on the ground. The site is prepared for stockpiling by removing the topsoil and installing a layer of crushed rock or other material as a stabilizing layer. Adequate drainage is also provided. While live storage piles may remain exposed to the atmosphere and weather, dead storage piles are usually covered, either by a roof or by spraying the surface of the pile with a chemical that dries to form a "skin" over the pile. As an alternative, coal is sometimes stored in bins and silos, constructed of concrete or steel. Such storage facilities are more environmentally acceptable, as they control dust as well as runoff from rain water.

4.2.1 Spontaneous Ignition and Weathering. A major danger in coal storage is spontaneous combustion. Coal is a porous material with a large internal surface area, typically greater than 50 m^2/g. Oxygen in the air reacts with the surface of the coal slowly at ambient temperatures. If the rate of liberation of heat by these oxidation reactions exceeds the rate of dissipation of heat from the pile, the temperature increases, resulting in an increase in oxidation rate, until a combustion flame appears. Moisture tends to promote these reactions. The heat of wetting of dry coal by rain increases the temperature of the pile, increasing the rate of oxidation. In order to prevent spontaneous ignition, run-of-mine coal should not be stockpiled. Because air enters the bottom of the pile and diffuses upward, the pile must either allow air circulation freely enough to dissipate the heat of oxidation, or be compact enough to prevent air circulation. In piling the coal, it should be laid down in layers about 0.5 m thick and each layer compacted by suitable equipment. Even when great care in stockpiling is exercised, the heating value of the coal will be reduced by 1% to 2% during the first year of storage. Coking quality is also reduced during storage.

4.3 Handling

From removal of coal from the seam to final utilization in an electric power plant or other use, coal handling is a major part of the total coal utilization system. Most of the equipment is highly specialized and has been developed specifically for the coal industry, e.g., underground mining machines; conveyors; loading, unloading and trans-shipment terminals; equipment for stacking and reclaiming in coal yards; and coal feeders. The trend has been to continuous systems, as well as to larger units. A total handling system approach is now normally used to permit complete integration of the various equipment items and automation to reduce the number of operating personnel to a minimum.

5. ANALYSES AND COMPOSITION OF COAL

Every chemical element occurring in nature can be found in some coal, somewhere, and all coals contain a very large number of the elements. Most of these elements are present only in trace amounts and may not influence the behavior of the coal in its final use. A few trace elements, however, may be harmful in a particular process, such as the ability of very small amounts of certain metals, occurring in the organic portion of the coal as organic metallic structures, to deactivate a catalyst during a conversion process.

Five elements usually account for more than 99% of the atoms in the organic portion of any coal, namely carbon, hydrogen, oxygen, sulfur, and nitrogen. These five elements are responsible for essentially all of the properties, both good and bad, of a coal. Hence any chemical analysis of a coal will usually specify the quantities of these five elements. For special uses of a coal, other elements may exhibit effects, usually adverse effects, but these will not be discussed.

Two types of analysis of coals are widely used in the selection of a coal for a particular use, namely proximate analysis and ultimate analysis. For a detailed discussion of these analyses, as well as other specialized tests, the reader is referred to the supplemental reading lists at the end of this chapter (Elliott, 1981).

5.1 Sampling

When one considers the manner in which the raw materials accumulated prior to the formation of coal (Sec. 2.1), one readily understands that a coal seam is not uniform in composition. If one proceeds a few feet through a coal seam, significant differences in composition are often observed. The analysis should be representative of the total amount of coal in the *lot*. The lot may consist of a few kilograms for laboratory use, a truck load of 20 tons, a unit-train load of 10 000 tons, or a ship load of 100 000 tons. In general, the value of the analysis data may not be greater than the care exercised in obtaining the samples for analysis.

A number of sampling techniques has been developed for various applications. Factors that influence selection of a procedure include the size of the lot to be sampled, the number of increments required to be taken for the lot size, and the top size of the coal particles in the increments, as well as others. It is important that some form of grid system be applied to the taking of increments from the lot to ensure their systematic spacing. If adequate care in sampling is exercised, a 50-g sample may be representative of a 10 000-ton unit train of coal. Coal exposed to the atmosphere will slowly oxidize, and hence change its chemical composition over time. In order to obtain an analysis of coal as it exists in the coal seam, the sample must be stored under an inert atmosphere.

5.2 Proximate Analysis

The proximate analysis reports the content of four quantities, namely moisture, volatile matter, fixed carbon, and ash. The analysis is conducted in three distinct steps, each step precisely defined in terms of temperature and time, as prescribed by the American Society for Testing and Materials (ASTM) under the designation ASTM-D3172. In order for results to be compared for various coals, in relation to the intended use, the various steps and parameters must be precisely followed.

- Moisture—A 1-g sample of coal of minus 250-μm particle size (all particles smaller than 200 μm diameter) is dried at a temperature of 110 °C for 1 hour. The weight loss of the sample is reported as moisture content, expressed as a percentage of the original sample weight.
- Volatile matter—A 1-g sample of coal of minus 250-μm particle size is heated to 950 °C in an inert atmosphere, and held at this temperature for 7 min. The weight loss of the sample during this operation, less the moisture, is reported as volatile-matter content, expressed as a percentage of the original coal sample.
- Fixed carbon—The remaining portion of the sample, with moisture and volatile matter removed as described above, is burned in air until a constant weight is attained. This weight loss is reported as fixed carbon,

expressed as a percentage of the original sample.

- Ash—The weight of the remaining material after combustion to constant weight is reported as ash content, expressed as a percentage of the original sample.

These quantities, however, are not absolute quantities present in the original coal. There does not exist an absolute method for determining the true moisture content of coal by heating, because of the wide variance in temperature at which different forms of moisture are liberated (surface, chemically combined, and water of hydration in clay minerals). Ash is a product of the oxidation process, during which iron pyrite, FeS_2, is converted to oxides of iron with liberation of oxides of sulfur, and other chemical changes. Hence ash is really not a component in the original coal. The fixed-carbon portion should not be confused with elemental carbon content, since a large amount of the carbon atoms in the original coal is released in the volatile matter, and some hydrogen and other elements may remain in the solid residue after completion of the volatile-matter evolution. The quantity of volatile matter evolved is a function of the maximum temperature achieved, the heating rate applied in achieving that temperature, and the time at that temperature.

Volatile-matter content, as determined in the proximate analysis, is very useful in relation to predicting combustion characteristics of a coal, and hence in burner design. In relation to assignment of rank designation, volatile-matter content is combined with percent carbon (elemental carbon) for the higher-rank coals. It also is useful in evaluating coals for coking. Thus, although not an absolute analysis, the proximate analysis is a very useful analysis.

5.3 Ultimate Analysis

The ultimate analysis of a coal reports the percentage by weight of the five major elements: carbon, hydrogen, oxygen nitrogen, and sulfur. The analysis is usually made on the coal after removal of moisture by the technique of the proximate analysis and is reported as being on a *dry basis*. The analysis is made on the coal with the mineral matter in the coal, sometimes reported on this basis, and sometimes reported after calculation to an *ash-free* basis. The usual procedure involves chemically determining the quantities of carbon, hydrogen, nitrogen, and sulfur, then calculating the oxygen content by difference. Hence the oxygen content as reported contains the accumulation of the errors that may exist in the other determinations and may be in error by as much as a few percent. An instrumental determination of oxygen, such as neutron activation, where available, is preferred. A prescribed procedure for the ultimate analysis for coal is given in ASTM-D3176. Inasmuch as the reported results are intended to be absolute quantities of these five elements, any accurate method of measurement is valid.

5.4 Physical Structure of Coals

During the metamorphic phase of the coalification process, some of the carbon, hydrogen, and oxygen present in the woody material was released. The peat mass was solid during this transformation; hence, pores were formed where these materials were released from the solid structure. The resulting coal thus contains pore spaces ranging in size from large macropores greater than 3000 Å diameter down to micropores a few angstroms in diameter. This pore structure gives rise to large internal surface areas, typically ranging from about 30 to 200 m^2/g or higher. The internal volume is also large, the greater portion usually being located in the large macropores, cracks, and fissures for lower-rank coals (less than 75% carbon), while for bituminous coals (75% to 84% carbon) pores smaller than 200 Å in diameter account for the major portion of the pore volume. Consequently, the bulk density of coal is typically of the order of 1.27–1.35 g/cm^3. The pore volume and pore size distribution in coal are important in governing the rate of diffusion of methane through and from a coal seam when the seam is opened. They are also of importance in processes for conversion of coal to liquids or gases.

Surface areas of coals are most often measured by adsorption of a vapor (most commonly N_2 at $-196\,^\circ C$ or CO_2 at $-78\,^\circ C$) into the pores and applying the Brunauer–Emmet–Teller theory to the adsorption isotherms. True densities of coals are usually measured by displacement of helium, methanol, or water. Pore volumes are calculated from true density measurements. Electron microscopy and x-ray diffraction have revealed additional features within the solid matrix in coals (Brunauer, 1945).

5.5 Chemical Structure of Coals

Because of the great heterogeneity of coal, it is not possible to draw a picture that represents all of the structural units in coal. It is not accurate to represent coal as a system of repeating units of the nature of a polymer. It is practical to try to represent types of structural units in coal which seem to be dominant, and the manner in which these units are joined in the solid matrix. Such a representation is helpful in visualizing how coal is attacked chemically in combustion or conversion processes.

Various chemical and instrumental techniques have been utilized in an effort to assemble such a representation. Generally each technique reveals but one small element of the picture. The sum of all of these experiments leads to the following description of the chemical structure of bituminous coal. In the organic portion of the solid matrix, which constitutes the major portion of the coal, from 60% to 75% of the carbon atoms are aromatic carbons, from 15% to 25% are saturated carbons located in rings with aromatic carbons, called hydroaromatic carbons (e.g., the saturated carbons in tetralin), and the remaining 5% to 10% of carbons are aliphatic hydrocarbon or other carbon functional groups. The dominant structures in the solid matrix are clustered-ring-type structures, on average about 2 to 3 rings per unit cluster for bituminous coals, somewhat less for sub-bituminous, even less for lignite, but much higher in anthracite. These ring-type clusters are joined principally by short aliphatic bridges and ether linkages. For a particular ring cluster, the number of covalent chemical bonds joining it to a neighbor in the plane of the cluster is fewer in a second dimension than in the first (perhaps one-fourth) and far fewer in the third dimension (perpendicular to the plane of the cluster), where hydrogen bonding and other van der Waals–type forces seem to predominate. Coal thus has a layered appearance at the unit structure level, but not layered in the same plane over long distances. In bituminous coals the oxygen is mostly phenolic and etheric, while in lignite a rather large number of carboxylic acid groups occur. In addition to the solid matrix, varying amounts of a *mobile phase* (organic material not chemically bound to the solid matrix) seem to be present, but always in amounts much smaller than the solid matrix. For purposes of attempting to visualize how coal must be attacked, particularly in conversion to liquids, the representation of structural groups and connecting bridges in bituminous coal (Fig. 1) has been prepared by the author.

5.6 Mineral Matter in Coals

Mineral matter was deposited along with the accumulation of plant material. It is usually quite uniformly distributed throughout the coal seam, as grains or thin bands. Coal typically contains between 4% and 20% mineral matter on a weight basis, although some coals, from certain portions of a seam, may be as high as 30% mineral matter. The dominant compounds in the mineral matter are usually SiO_2 and Al_2O_3, with some sulfates and pyrite (in most coals), and smaller amounts of carbonates and oxides of alkali and alkaline-earth metals. Trace amounts of radioactive elements may be present. Several of these compounds undergo chemical change during combustion; hence, ash produced in the analysis (by combustion) is quite different from mineral matter in the coal, as to both weight and chemical composition.

6. PROPERTIES OF COALS

6.1 Physical Properties

The physical properties of coal are a consequence of the cumulative effects of the nature of the original plant material, the manner in which the plant material accumulated, the severity of the metamorphism that determined the rank of the coal, and the specific form of plant debris that determined the petrography of the coal. Only a few of the most important physical properties of coals can be identified here, and these only superficially. For a detailed discussion of instruments and techniques, the reader is referred to Elliott (1981).

6.1.1 Reflectance. The determination of reflectance of a coal provides valuable infor-

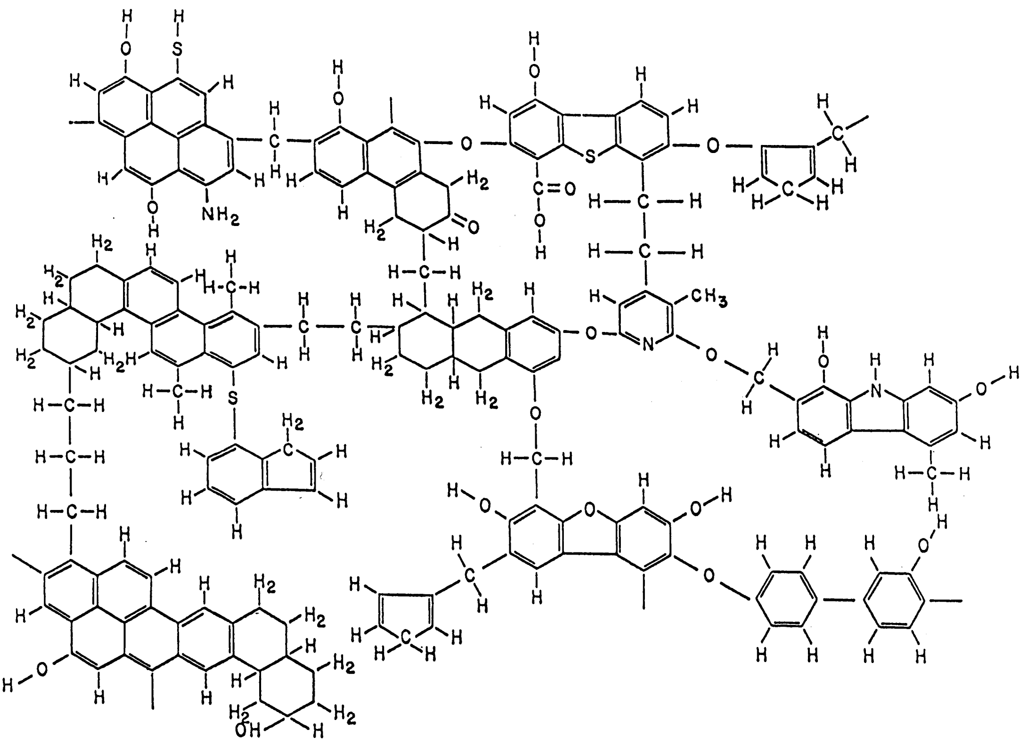

FIG. 1. Schematic representation of structural groups and connecting bridges in bituminous coal. [From Wiser (1978).]

mation concerning the origin of coal and coal structure, as well as predictions of behavior of a coal in a particular process. Various optical constants of a vitrinite, the principal component of most coals, can be derived from reflectance measurements. The optical constants of vitrinites in high-rank coals depend upon the orientation of the bedding planes with respect to the impinging radiation. A continuous increase of reflectance with rank of the coal is ascribed to the growth and ordering of aromatic layer clusters.

6.1.2 Porosity and Surface Area. These features of coals represent physical properties because of their importance in various uses of coal. The diffusion of reactant gases into coal pores during combustion, followed by reaction on the surfaces within these pores, is important to the combustion process. Diffusion of reactant gases and/or liquids, and sometimes catalysts, into the pores of the coal in coal liquefaction and gasification processes is vital to the success of such conversion processes. The formation of adsorbants from coal, such as activated carbon, relies upon the porosity and surface area of the parent coal in order to yield a product satisfying the requirements of high surface area.

6.1.3 Electrical Conductivity. Coals are generally classed as semiconductors, with specific resistance in the range $1\text{–}10^{14}$ Ω cm. The specific resistance decreases with increase in rank, the increase in rank being accompanied by an increase in mean aromatic layer diameter, then falls abruptly for coals of carbon content greater than 90% (the anthracite range). Specific resistance also decreases with increase in temperature, a behavior characteristic of semiconductors. The anisotropy observed for reflectance is also observed with electrical conductivity, the resistivity being much higher when measured perpendicular to the layer planes than when measured parallel to them.

6.1.4 Magnetic Susceptibility. The organic portions of coal are essentially diamagnetic, but traces of paramagnetism are also observed, possibly due to measurable unpaired electrons or free radicals in coal. By comparing diamagnetic susceptibilities of coals with studies on pure aromatic hydrocarbons, deductions have been possible concerning the number of rings in a condensed aromatic cluster in coal, yielding the value of 2–3 rings per cluster for bituminous coals, cited earlier.

6.1.5 Specific Heat and Enthalpy. Although a large number of experimental investigations have been conducted in measuring specific heats on coals, the data obtained are of limited value except for the coal for which the measurements were made. This is due to the heterogeneous nature of coals and the widely different compositions. The problem is aggravated by the occurrence of a plastic state for coals in the bituminous ranks and extending into the sub-bituminous rank. The degree of plasticity also varies widely.

6.2 Mechanical Properties

The mechanical properties of coals are important for coal mining in two ways: ensuring stable and safe mine operation and ensuring that coal is removed from the seam effectively. As greater reliance upon coal as a source of fuel and chemicals becomes necessary, the traditional trial-and-error methods of mine development must be superseded by added emphasis upon better knowledge of the mechanical properties of coals and their associated strata. This will make possible development of innovative methods to achieve higher productivity, greater recovery, lower costs, greater confidence relative to safety, and easier access to deposits in difficult locations.

Most classification of coals is based upon the "nonmechanical" characteristics, namely coal rank, carbon content, volatile matter, reflectance, gross specific energy, and petrographic composition. Attempts to correlate these characteristics with mechanical properties, or to use them to predict mechanical properties, are mostly unfruitful. Hence the application of nonmechanical characteristics of coals to mining needs are of little value. At the same time few data have been obtained by measuring and describing the overall mechanical properties of virgin coal seams. Measurements on coal seams would have to rely largely upon dynamic methods, e.g., sound waves and radar. Interpretation of such data for application to mine operation is difficult and somewhat imprecise at best.

6.2.1 Elasticity. When a hard coal (i.e., bituminous or anthracite) is subjected to a stress in compression, initially it exhibits a nonlinear stress–strain curve associated with closure of cracks, which is followed by an essentially linear elastic range. These observations are made upon coal samples that have been removed from the seam, and the initial nonlinear portion of the stress–strain curve may be the result of the mining operation rather than a property of the coal *in situ*. Coals exhibit anisotropy with respect to compression. The elastic modulus perpendicular to the bedding plane is significantly lower than that parallel to the bedding plane. However, within the bedding plane the moduli parallel to it appear to be independent of direction of applied stress around an axis perpendicular to the plane. Hard coal thus tends toward transverse isotropy.

6.2.2 Strength. Failure of a hard coal under stress is signified by an abrupt fracture and major structural change. The value of the stress that produces such a change is usually quite distinct, and defines the strength of the coal. Little attention has been given to the measurement of tensile strength, or shear strength, in coals. It is difficult to clamp a coal sample in a way to perform tensile and shear tests without altering these properties in the coal sample. On the basis of limited tests, the compression strength of coal is observed to be greater than its tensile strength by an order of magnitude. As a minimum, energy consumed in breakage of a solid must provide for creation of new surface and crack propagation. One such minimum value has been reported to be approximately 10 J/m^2.

6.2.3 Hardness and Abrasiveness. Hardness is a convenient measure of the tendency of the coal to cause abrasive wear, as well as of the deformability of the coal. Two techniques are most widely used for evaluating hardness in coals. In the rebound technique a hammer is dropped a certain distance to impact the surface of the coal, and the rebound of the indenter is a measure of the dynamic hardness of the coal. The height of drop must be controlled to ensure that the coal is not stressed beyond its elastic limit, at which point plastic failure occurs and the share of energy returned in rebound energy is reduced. In the static indentation technique a load is applied to the coal surface and the area of the permanent indentation is measured, the static hardness being expressed as the ratio of the load applied to the contact area of the indentation. No anisotropy has been observed in the hardness of coal samples.

The type, quantity, and distribution of minerals in coal determine its abrasiveness. Typically the hardest of these minerals are quartz (Vickers hardness numbers of 1100–1260) and pyrites (Vickers hardness numbers of 840–1130), compared with a hard steel at 600–700.

6.3 Plastic Properties of Coal

When bituminous coal is heated to temperatures above about 350–375 °C, the coal softens and becomes plastic. Both the rate at which plasticity develops and the degree of plasticity increase as the temperature increases. The appearance of the plastic state is accompanied by extensive evolution of organic molecules. If the coal sample is held at a temperature above 375 °C, the degree of fluidity increases to a maximum value, then decreases until the coal mass again becomes solid. The anthracites do not exhibit plastic behavior. Similarly the brown coals or lignites do not. Some degree of plasticity may be observed in some sub-bituminous coals, although to a much lesser degree than in bituminous coals.

In Sec. 5.5, bituminous coal is represented as consisting of clusters, both aromatic and hydroaromatic, joined by short bridges such as a methylene bridge. At temperatures above 350–375 °C, rupture of these connecting bridges becomes increasingly extensive, the rate increasing as the temperature increases. Utilizing electron spin resonance, an increase in free-radical concentration has been observed during the time when fluidity is increasing in the coal mass. Thermal bond rupture of the connecting bridges in this temperature range proceeds via a free-radical mechanism. During this time of increased concentration of free radicals and increasing fluidity, particle agglomeration occurs, forming a coke mass. The plastic coal mass adheres strongly to the walls of the container, leading to plugging. Both the agglomerating and plugging tendencies are the direct result of the formation and reactions of free radicals.

Various theories have been set forth to explain the existence and behavior of the plastic state. One can visualize the coexistence in the plastic mass of solids, liquids and gases, accompanied by a comparatively high concentration of free radicals. This is a time period of extensive thermally initiated chemical reactions. Particle agglomeration and growth are the consequence of stabilization of the free radicals via condensation reactions. Sticking to vessel walls is also a consequence of the behavior of free radicals. The fluidity is the manifestation, even down to a molecular level, of the coexistence of solids, liquids, and gases. When the chemical reactions are completed, and the volatiles evolved, the physical state becomes solid. Most of the organic material remaining has become a part of the solid mass or coke, the result of the agglomeration processes.

The formation of the plastic state in coal has been erroneously referred to as a melting phenomenon. The phenomenon is a chemical process that bears essentially no relationship to melting. Very serious problems have developed in reactor systems when there was an attempt to accommodate the behavior of the coal on the basis of melting, and real chemical processes were not recognized.

7. COAL PREPARATION

The principal objective of coal preparation is the separation of impurities from coal, most notably mineral matter (often, although incorrectly, called ash) and sulfur. A second objective, of growing importance, is to provide a coal feed of uniform particle size. The vast majority of coal utilization is in combustion. In recent years the urgent need to protect the environment during fuel combustion has dramatically increased the role of chemistry in coal preparation. Special emphasis is directed to the problem of sulfur oxide emissions from combustion of coal. Adverse effects resulting from sulfur emissions, as well as other negative impacts of coal combustion, are discussed in Sec. 11.

7.1 Size Reduction

Quite typically in a coal containing more than 2% sulfur, more than half of the sulfur is in the inorganic portion of the coal. For high-sulfur coals, most of the sulfur may occur as pyrites and sulfates in the inorganic portions. Pyrite and sulfate sulfur may be liberated by crushing. A physical separation technique, such as, for example, a sink–float operation, may then effect separation of the liberated sulfur-bearing particles from the organic portion of the coal. In many coals the total mineral matter content can be greatly reduced by physical separation following size reduction.

An increasing number of coal combustion operations utilize entrained flow or fluidized beds, or some other system where uniform particle size is important. For such processes the coal is crushed and mechanically cleaned, in order to liberate and separate impurities and provide a feed of uniform size. Whereas in the mid-1900s only a few percent of the total bituminous coal production was crushed, today more than 90% is crushed before use.

The dominant machine used for years for coal size reduction is the roll crusher. This machine feeds run-of-mine coal, usually delivering a fairly coarse product (e.g., 20-cm top size). The hammermill is the most commonly used coal pulverizer. Wet rod mills and ball mills are used or proposed for preparing a fine coal slurry for pipeline transport. For preparation of ultrafine coal, attrition mills and jet mills are of special interest. Several good reviews describing these and other techniques may be found in the literature. (For references, see Elliott, 1981, p. 578).

Of greatest theoretical and practical concern in size reduction are energy consumed in relation to change in size distribution, wear on machines, and size separation during transport. A mathematical model is used that attempts to correlate the characteristics of the mill and the operating variables to predict the nature and quality of the product. At this writing, modeling activity is demonstrating the ability to optimize size reduction in mineral processing at greatly reduced cost; potential for application to coal size reduction is obvious.

7.2 Beneficiation

Following size reduction to liberate impurities from the solid coal matrix, actual separation of the impurities from the coal is called *beneficiation.* A large number of processes have been devised and are used for this purpose, each with special features for specific applications. Some of these separation processes operate upon dry feed, while others are wet processes. A few examples, by name only, are jigs, cyclones (both wet and dry), concentrating tables, froth flotation, and high-gradient magnetic separation. A description of these and other beneficiation techniques may be found in the literature. (For references, see Elliott, 1981, pp. 580–585.)

7.3 Dewatering and Drying

The drive toward full mechanization of the coal-mining operation has resulted in an increase in production of coal fines and dust within the mine. Underground dust suppression operations add water to the coal leaving the mine. Furthermore, the widespread use of size-reduction and beneficiation operations, many of them wet processes, leads to a need to remove water from the coal. The increased moisture, if not removed, represents an economic burden in transporting the coal, as well as a reduction in heating value per pound of feed coal due to vaporization of the water during combustion. In addition, excess moisture may result in freezing during transport and increased difficulty in handling.

Examples of water-removal and moisture-reduction equipment, by name only, include screens, cyclones, centrifuges, filters, and thermal dryers. Interested readers may find a description of these and other techniques in the literature. (For references, see Elliott, 1981, pp. 587–594.)

7.4 Automation

In order to improve the competitive position of coal in the world energy mix, the need becomes urgent to increase operational efficiency throughout the full train of preparation processes, from preliminary storage to delivery to the marketplace. Automation represents a key element in the drive to improved efficiency, spurred by recent developments in instrumentation in relation to the various steps in the sequence of events. Mathematical models are used to simulate the various steps, which may be combined into one large model defining a complete beneficiation process. Optimization procedures utilizing computers make possible the preparation of flow sheets for new plants, identifying optimum parameters as dictated by required yields at specified ash and/or sulfur contents. (For references, see Elliott, 1981, pp. 596–597.)

8. COAL CARBONIZATION

The term *carbonization*, when applied to coal, generally means heating coal to a temperature above about 400 °C, in an inert atmosphere, yielding as the principal product a solid richer in carbon than the initial coal. This carbon enrichment is the result of expelling from the solid mass gaseous and liquid compounds that are richer in hydrogen, or oxygen, or perhaps other elements, than was the starting coal. The term *pyrolysis* is often used in connection with the same type of heating operation with coal. Although the distinction between the two terms is not clear-cut, and the uses not universal, in general the term carbonation is applied when the solid, carbon-rich product is of the greatest interest, and pyrolysis is applied when the volatile products to be liberated by heating are of primary interest. Thus the primary product of the operation when viewed as carbonization becomes the by-product when viewed as pyrolysis.

8.1 Principles

The chemical structure of coal is described in Sec. 5.5. When coal is heated, at temperatures above 375 °C the connecting bridges between clusters begin to rupture. The degree of rupture increases with temperature, becoming essentially complete at 500–550 °C. The free radicals thus formed seek stabilization by such means as may be available to them. Principal among the options is the abstraction of hydrogen from a hydroaromatic structural unit in the vicinity. If the unit thus formed exhibits a sufficiently high vapor pressure, it will evolve as a volatile product. A direct correlation between hydroaromatic hydrogen in the coal and the quantity of evolved product has been experimentally observed. When all such options for producing stable molecules of sufficient vapor pressure have been exhausted, the balance of the skeletal structural units of the coal undergo condensation reactions that result in a solid product, even at the elevated temperature, called char or coke. In practice, at all temperatures considerably more than half of the coal by weight remains as char or coke.

8.2 Low-Temperature Carbonization

Low-temperature carbonization is defined as occurring at temperatures between the onset of thermal bond rupture, as described in Sec. 8.1, and about 750 °C. In this temperature range, in general, hydrogen is not released from aromatic carbon atoms to a significant extent. The formation of carbon–carbon bonds occurring in the production of char or coke in this temperature range is limited chiefly to the carbon atoms involved in the rupture of bridges between condensed configurations, in removal of side chains or of functional groups from these condensed configurations, and in other weak bonds involving ring carbons that can be thermally ruptured in this temperature range. The resulting char formed is not very strong because of limited cross-linking, thereby restricting its uses.

8.2.1 Products and their Uses. The quantity and properties of char produced are a function of the coal being carbonized and the temperature of carbonization. In general, low-temperature carbonization processes operate at temperatures between 450 and 700 °C. Char yields range from about 60% to 75% by weight of the coal. In most cases the volatile by-products are about equally divided between liquids and gases.

Low-temperature carbonization has usually been practiced primarily to produce a char or coke. In general these cokes are irregular in structure and in shape, and dull black in appearance. They are less dense and weaker than high-temperature coke, and hence tend to be rather dusty. Because of the moderate temperature of low-temperature carbonization, the volatiles are only partially expelled, as related to the standard volatile-matter test performed at 950 °C. The volatile-matter content of low-temperature coke ranges from 7% to 20% by weight of the coke.

Probably the most valuable characteristic of low-temperature coke is its high reactivity. This property, coupled with the moderate content of volatiles, results in a fuel that ignites easily and burns reliably. These cokes are very good fuels for use in furnaces, space heaters, and fireplaces. While they are good solid fuels for some foundry uses, their lack of strength precludes their use in the blast furnace, or other uses where a substantial overburden must be supported. Because of their high porosity and reactivity, they are also advantageous for use in production of water gas.

A typical low-temperature carbonization operation may yield as liberated volatile products about 80 to 120 standard cubic meters of gases with heating values of the order of 30 000–37 000 kJ/m,^{3} 9.5 to 11 L of light oil, and 50 to 120 L of tar, all per ton of coal carbonized. A large number of retort processes have been developed, most of them prior to 1960. The interested reader will find a good review of these processes in Lowry (1963).

In recent years carbonization of coal has been under development under the name of pyrolysis, with production of liquid fuels and/or chemicals as the principal objective. This potential application, with this objective, is discussed in Sec. 10.2.1.

8.3 High-Temperature Carbonization

The primary objective of high-temperature carbonization is the production of a strong and uniform coke for use in metallurgical operations, such as the blast furnace. To achieve this objective, temperatures in the range 900–1300 ° C are required in the carbonization process. Consideration of the fundamental chemistry involved reveals that a strong coke cannot be produced at lower temperature. In practice coke ovens operate at temperatures up to 1300 °C, the upper limit controlled by safe operating limit of the wall brick (now usually silica brick).

8.3.1 Metallurgical Coke Manufacture. The required physical properties of a metallurgical coke can be illustrated by reference to the blast furnace in reduction of iron ore. Three essential ingredients are fed to the top of the furnace, in sequence, namely coke, iron ore, and limestone. The iron component of the ore, chiefly Fe_2O_3, is to be reduced to metallic iron, by interaction with a reducing agent, principally gaseous carbon monoxide:

$$Fe_2O_3+3CO \rightarrow 2Fe++3CO_2.$$

The CO is produced by oxidation of the coke with a limited supply of air according to the reactions:

$$C+O_2 \rightarrow CO_2,$$

$$C+CO_2 \rightarrow 2CO.$$

The limestone acts as a flux to remove silicates and certain other minerals present in the ore, forming a slag that is molten at furnace temperatures. The air for reaction with the coke is introduced at the bottom of the furnace. The coke must maintain its structural integrity as it moves downward through the furnace. If it breaks and crumbles, the bed porosity will be lost and the efficiency of reduction of the iron ore greatly reduced. For satisfactory operation the coke must be strong to support the overburden above, uniform to provide for the chemistry of ore reduction throughout the cross section of the bed, and porous for rapid reaction with the air.

The strength of the coke relates directly to the degree of cross-linking between the condensed ring structures of the coal, which occurs during the carbonization process. At temperatures above 800 °C, the hydrogen atoms present on aromatic carbons increasingly are thermally released, providing opportunities for increased cross-linking. In the temperature regime of 1200–1300 °C this hydrogen release nears completion and a maximum degree of cross-linking is achieved. A high degree of plasticity, with attendant expansion of the coal mass during formation of plasticity, is always observable during production of a metallurgical coke of the required strength. Anthracite, brown coal or lignite, and in most cases sub-bituminous coal do not exhibit plasticity, and will not produce a strong metallurgical coke. Medium-volatile bituminous coal will yield strong metallurgical coke when carbonized alone. High-volatile bituminous coal can yield a strong coke when blended with an appropriate amount of low-volatile bituminous coal. The horizontal slot-type oven, also known as a by-product coke oven, is the most important and most used means of producing high-quality blast furnace or foundry coke. For a technical description of the horizontal slot-type oven, see Chap. 14 of Elliott (1981).

8.3.2 By-Products and their Uses. A typical yield of volatile products from a horizontal slot-type coke oven is 250 to 350 standard cubic meters of gases, 40 to 60 L of tar and light oil, and 2 to 4 kg of ammonia, all expressed per ton of coal carbonized. Principal components in high-temperature coke-oven gas, expressed on a volume basis, are hydrogen, about 60%, and methane, about 30%. Most of the balance consists of combustible hydrocarbons. This gas can be used as a fuel with heating value of about 20 000 kJ/m^3. Coke-oven gas is frequently separated into products with greater market value than the value in combustion.

Benzene, toluene, and the xylenes are the principal components of the light oil. Separation techniques most often employed are distillation, absorption in liquids, absorption by solids, and compression and cooling of the gas.

The tars contain a very great number of compounds, including phenols, cresols, naphthalenes, and benzene and its homologs. The tar fractions are marketed in such products as tar acids, tar bases, anthracene oil, creosote, and pitches. Separation of the tars into these fractions is usually accomplished by distillation. The pitches constitute the largest fraction, and are used for fuel, for road and roofing tars, and for manufacture of other pitch products. Creosote is highly toxic to wood-destroying fungi and insects. Wood preservation is its most important application.

Ammonia is recovered from coke-oven gas. It is the principal nitrogen-containing ingredient in agricultural fertilizers, which products represent a major market for ammonia.

9. COAL COMBUSTION

For several centuries coal has been an important energy resource. Early in the 19th century it began to replace wood as a fuel, and later in that century became the dominant fuel in industrialized countries where coal resources existed. As petroleum and natural gas were developed, they in turn replaced coal as the dominant fuels in many uses. However, in countries where coal resources occur, coal retains a dominant position in a few uses, most important among them being raising steam for electric power generation. As an example, at this writing 80% of all coal consumption in the United States is in electric power generation, and 56% of electric power in the United States is generated from the combustion of coal. Coal combustion, at this writing, supplies 23% of the total energy consumed in the United States, and is increasing its percentage of the total energy supply.

In recent years, particularly since the close of World War II, a substantial effort in research and development has been directed toward improving the efficiency of coal combustion. Initially these efforts were motivated by economic considerations, but more recently environmental and health considerations would seem to represent the principal motivators. The most recent and sophisticated coal combustion technologies of today include provisions for major reductions in unburned carbon and sulfur emissions, when compared with pre–World War II technologies.

9.1 General Principles

Coal contains widely varying amounts of volatile materials ranging from as low as 4% by weight for anthracite to more than 40% by weight for some bituminous and sub-bituminous coals. Most of these volatiles are combustible. The volatile matter content of a coal greatly influences its combustion characteristics, particularly the ease of ignition and of sustaining combustion, thereby dictating to some degree the burner design for combustion of a coal. As a quantity of coal is heated en route to its ignition temperature, volatiles are liberated from the coal by action of the heat applied. The combustion process thus becomes concerned with three basic phenomena, namely pyrolytic liberation of volatiles, combustion of carbon, and parallel or sequentially prior combustion of volatiles. When one desires to study the fundamentals of the overall combustion of coal, one usually examines these three aspects separately. While the solid matrix that remains as volatiles are liberated is predominantly carbon, usually called char, it is not graphite. The most important reactions involved in coal combustion are those occurring with the char. The char reacts at both external and internal surfaces, at rates determined by both chemical and physical processes. An excellent, detailed treatment of the studies in coal combustion may be found as Chap. 19 in Elliott (1981).

9.2 Coal-Combustion Systems

The principal objectives in the design of coal-combustion equipment are to achieve continuous economical operation, while minimizing the discharge of sulfur oxides, nitrogen oxides, and particulates to the environment, at the same time avoiding slagging and/or fouling problems resulting from the ash. In practice the coal is either suspended on a grate or in the air. Air-suspension combustion systems involve either fluidization of the coal bed with the air or entrainment of the coal in the air stream.

9.2.1 Combustion on a Grate. In the more common grate system, raw coal is fed to the fuel bed from above the fire. As combustion proceeds, the solid material yet unreacted moves downward, progressing through several stages, with the mineral matter (ash) passing through the grate. Primary air is admitted from beneath the grate, moving upward and countercurrent to the stream of solids. A series of zones may be visualized in the bed. Immediately on top of the grate is an ash zone, essentially all combustible material having been removed. Next above the ash zone is an oxidizing zone. It has been experimentally observed that the reaction between the fixed carbon of the solid and oxygen, occurring in the vicinity of the solid, proceeds to CO_2 via the overall reaction

$$C+O_2 \rightarrow CO_2.$$

Next above the oxidation zone occurs a reduction zone in which the following reaction occurs:

$$CO_2+C \rightarrow 2CO.$$

The top layer, containing the raw coal, responds to the high heat evolution from below, and the volatiles in the raw coal are liberated. Secondary air is admitted above the bed providing for the combustion of the volatile material (VM) and the carbon monoxide from the reduction zone:

$$(VM+CO)+O_2 \rightarrow CO_2+H_2O.$$

The volatile matter and carbon monoxide reaching this region above the raw coal layer may represent as much as 60% of the total heating value of the original coal. A high degree of turbulence in this region, involving the secondary air, is required to achieve good combustion efficiency as well as to avoid excessive smoke.

Mineral matter from the coal is a potential source of mechanical difficulty. In a top-feed grate system the ash layer on top of the grate, assisted by the cool primary air stream, insulates the grate from the very high temperatures of the combustion zone above, thus avoiding melting of the cast-iron grate. If temperatures are too high, fusion of the ash occurs (slagging), forming clinkers which may not pass through the grate. Furthermore, the slag may cause fouling of surfaces, or corrosion of key elements of the combustion system.

9.2.2 Atmospheric Fluidized-Bed Combustion. If coal is crushed, and a feed stream to a combustion reactor selected to contain only particles smaller than about 6 mm diameter (the usual size limitation) the upward velocity of the air, admitted at the bottom of the coal bed, can be increased until the coal particles begin to be lifted by the air stream. As the gas velocity increases, the pressure drop ΔP through the bed increases, reaching essentially a constant value. This condition defines the minimum fluidizing velocity. Operation will be conducted at some velocity above this value. The bed into which the crushed coal is fed may consist of an inert material, such as sand or ash, or a chemically reactive material, such as limestone or dolomite. The heat-transfer surface, such as tubes in which water is to be converted to steam, is submerged in the bed. The operating temperature in the bed is generally between 750 and 1000 °C.

The fluidized bed provides several advantages relative to problems historically associated with coal combustion for steam raising.

1. Fluidization of small coal particles with air establishes good contact between coal particle and oxygen, resulting in improved combustion efficiency. Good combustion efficiency has been achieved with excess air quantities as low as 2%.
2. Fluidization of coal in a bed containing limestone achieves removal of sulfur from the combustion product gases according to the reaction

$CaO+SO_2+\frac{1}{2}O_2 \rightarrow CaSO_4.$

3. The fluidized bed provides for maintaining a uniform temperature, characteristically about 870 °C, low enough to limit formation of NO_x. At this temperature, NO_x formation appears to result almost wholly from fuel-bound nitrogen, rather than fixation of air nitrogen.
4. The uniform temperature in the fluidized bed remains below the melting temperature of the mineral matter of the coal, thus avoiding slagging with its attendant problems of corrosion and fouling of surfaces.

9.2.3 Pressurized Fluidized-Bed Combustion. When a fluidized bed is operated for coal combustion at elevated pressures up to 10 atm, the principles and advantages presented in the preceding subsection apply. A slight improvement in reduction of NO_x formation is also observed at the elevated pressure. However, interest in operating with increased pressure in the combustion zone is born of the realization that as combustion pressure increases, the size of the combustor decreases, as also does the area of heat-transfer surface required for maintaining a specified bed temperature. These factors reduce investment cost. Furthermore, if electric power generation is an objective of the combustion operation, the combustion gases at elevated pressures (e.g., 10 atm.) may be expanded in a gas turbine, thus providing a form of *combined cycle* generation system and resulting in an improved power generating efficiency (see Sec. 10.1.7).

9.2.4 Entrained-Flow Combustion. Large industrial boilers often operate at a steam output demand of a few million kilograms of steam per hour. Certain other processes require temperatures in the combustion zone of 1500 °C or higher. Pulverized-coal (entrained flow) firing is readily adaptable to these demands, and has gained prominence in such uses. The coal is crushed to a very fine size, the feed typically being about 80% through 200 mesh, Tyler screen series (-74 μm), and is transported into the combustion chamber entrained in the primary air supplied for combustion. A high degree of turbulence is provided resulting in excellent combustion efficiency. Temperature in the combustion chamber is typically 1600 °C or higher.

Combustion of the char or fixed-carbon portion of the coal particle (the solid remaining after evolution of the volatiles) occurs at the surface of the particle. For particles larger than 65 μm the surface flux of volatiles is large enough to prevent oxygen from reaching the particle surface, and combustion of the volatiles precedes solid burning. The surface flux of volatiles decreases as particle size decreases. For particles between 65 and 15 μm diameter, gas phase and solid burning proceed together. For particles smaller than 15 μm in diameter, the initial burning appears to be completely heterogeneous. In practice, in pulverized-coal-fired furnaces most of the coal fired is smaller than 65 μm, and 20%–30% is smaller than 15 μm. Not more than 2% is larger than 300 μm. These burning patterns for very small coal particles provide for extremely high heat flux, with resulting high temperatures.

10. SYNTHETIC FUELS AND OTHER PRODUCTS FROM COAL

As discussed in Sec. 1.2, known and recoverable reserves of coal in the world are very great. Coal has been used as an energy resource much longer than petroleum and natural gas. But coal has suffered a decline as an energy resource, both with respect to total consumption and as a percentage of consumption. It is generally recognized that coal must play a larger role in supplying the energy needs of the industrialized nations as reserves of petroleum and natural gas decline. However, there are several reasons why substituting coal for either petroleum or natural gas is difficult. Principal among these reasons are these:

1. Coal is dirty to use—when burned it emits both solid and gaseous pollutants to the environment (see Sec. 11) in large quantities.
2. Coal is much less convenient to distribute and to use than are petroleum and natural gas, because it is a solid.
3. Many areas of energy demand in modern society, such as transportation by auto, truck, or airplane, as well as certain uses in the industrial sector, simply cannot use a fuel in solid form.

For these, as well as several other reasons, if coal is to be extensively substituted for petroleum and/or natural gas, it must first be converted to a liquid or a gaseous form.

10.1 Gaseous Fuels from Coal

Coal reacts with steam to produce combustible gases. At temperatures of 950 °C or higher, the reaction proceeds noncatalytically at a satisfactory rate, according to the reaction

$$\text{coal (mostly carbon)} + H_2O \rightarrow CO + H_2. \quad (1)$$

The reaction between carbon and steam is strongly endothermic in the amount of 136 kJ/g mol of carbon determined at 925 °C. Energy in the form of heat must be supplied to raise the temperature of the coal bed to 950 °C and to hold the temperature at that value, as well as to sustain the endothermic reaction. The usual practice is to introduce either air or oxygen to the gasifier in a controlled amount, to provide for the following overall reaction:

$$C + \tfrac{1}{2}O_2 \rightarrow CO. \quad (2)$$

This reaction is exothermic in the amount −110.5 kJ/g mol of carbon reacted, at 25 °C. CO as a fuel gas exhibits a heat of combustion of −283 kJ/g mol, and hydrogen exhibits a heat of combustion of −285.9 kJ/g mol, both determined at 25 °C.

Three additional reactions may occur in a coal gasifier, depending upon reaction conditions. Steam added as a reactant may react with CO produced in one or more reactions occurring in the reactor, according to the reaction

$$CO + H_2O \rightleftarrows CO_2 + H_2. \quad (3)$$

This reaction, known as the water–gas shift reaction, is exothermic in an amount of −33.5 kJ/g mol, determined at 700 °C. The reaction exhibits an equilibrium constant K_p equal to 1 at 827 °C, with K_p increasing as the temperature decreases.

When hydrogen is present in the gasifier, it is possible that some methane may be formed by the following reaction:

$$CO + 3H_2 \rightleftarrows CH_4 + H_2O. \quad (4)$$

This reaction is exothermic in an amount −225.9 kJ/g mol, determined at 700 °C. The equilibrium constant K_p increases as the temperature decreases. In addition, hydrogen may react directly with carbon according to the following reaction:

$$C + 2H_2 \rightleftarrows CH_4. \quad (5)$$

This reaction is exothermic in an amount −91.4 kJ/g mol, determined at 700 °C. The reaction exhibits an equilibrium constant K_p equal to 1 at 546 °C, with K_p increasing as the temperature decreases.

10.1.1 Producer Gas. Perhaps the simplest concept for producing a gaseous fuel from coal, when only a gaseous fuel is desired, is to react coal with a limited quantity of air, according to Eq. (2) above, yielding a gas consisting essentially of CO and the nitrogen that entered with the air. Typically the heating value of such a gas, called producer gas, is about 4460 kJ/m^3 [120 Btu/standard cubic foot (SCF)]. With such a low heating value, this fuel gas is only practical for use at or very near the site where produced.

10.1.2 Water Gas. The objective is to burn a portion of the coal, the carbon proceeding completely to CO_2, to provide heat to sustain the steam–carbon reaction of Eq. (1). The process is cyclic. In the first, or "blow" portion, excess air is blown through the fixed coal bed, the combustion increasing the bed temperature to a value above 950 °C, typically about 1300 °C. The exit gas from the blow is principally CO_2, H_2O, and N_2, with no heating value. The air is discontinued and steam is blown under pressure through the hot coal bed. The reaction proceeds according to the endothermic reaction of Eq. (1) until the bed has cooled to a temperature where the reaction rate is too low. The gas from this portion of the cycle contains principally CO and H_2, with a heating value of about 11 297 kJ/m^3 (300 Btu/SCF) and is collected as the product fuel gas. The cycle is then repeated.

10.1.3. Low-Heating-Value Gas. Air and steam are introduced simultaneously into the coal feed, with the intent that a portion of the carbon in the coal will react with the limited air to yield CO according to Eq. (2), while the balance of the carbon in the coal will react with steam according to Eq. (1) to yield CO and H_2. Some gasifiers (e.g., Lurgi) operate with an exit gas temperature low enough to permit formation of a significant amount of methane according to Eqs. (4) and (5). Other gasifiers (e.g., Koppers-Totzek) operate at high temperatures in order to obtain maximum efficiency in decomposition of the steam, but producing no methane because of the high temperature. The product gas consists of CO, H_2, and perhaps some CH_4, but is diluted by the N_2 that entered in the air. The heating value of the product gas ranges from about 4854 kJ/m^3 (130 Btu/SCF) to about 6695 kJ/m^3 (180 Btu/SCF), depending upon the amount of CH_4 in the product gas.

10.1.4 Intermediate-Heating-Value Gas. In order to produce a fuel gas of higher heating value, by eliminating nitrogen and its diluting effect from the product gas, oxygen is first separated from the nitrogen and other components of the air, usually by distillation of liquid air. The procedure is then similar to that of Sec. 10.1.3. In this case the product gas contains principally CO, H_2, and perhaps some CH_4, depending upon temperatures in the gasifier. Heating values of product gases range from about 10 460 kJ/m^3 (280 Btu/SCF) to about 12 970 kJ/m^3 (350 Btu/SCF), depending upon the amount of CH_4 in the product gas.

10.1.5 High-Calorie Gas or Substitute Natural Gas. The ratio of H_2 to CO in the product gas of Sec. 10.1.4 is usually considerably less than 1. In order to produce CH_4 by the hydrogenation of CO according to Eq. (4) one must first increase the ratio of H_2:CO to at least 3:1. This can be done by the water–gas shift reaction of Eq. (3). If the equilibrium constant K_p of Eq. (3) is to be great enough to achieve a ratio of H_2:CO of 3:1, the temperature must be no greater than about 430 °C in the shift converter. At this low temperature a catalyst (e.g., Fe_3O_4) is required to achieve a satisfactory reaction rate. In practice, this reaction is continued to a H_2:CO ratio of about 3.1:1. This gas, enriched in H_2, is then reacted over a nickel catalyst at a temperature of about 450 °C to yield a product gas of high CH_4 content (usually greater than 95% CH_4, with CO content less than 0.1%) and a heating value greater than 35 150 kJ/m^3 (950 Btu/SCF). This product gas is completely interchangeable with natural gas as far as its behavior in a burner is concerned, hence its name substitute natural gas (SNG).

Many technologies have been developed to achieve a high-calorie gas product from coal. The steps in the process do not always appear in the same order, but the chemistry is essentially that described by Eqs. (1)–(5).

The chemistry described above is initiated by the noncatalyzed reaction of steam with carbon at temperatures of 950 °C or higher. One may conduct the steam–carbon reaction at a considerably lower temperature (e.g., 700 °C) by employing an appropriate catalyst (e.g., potassium). Under such conditions the yield of CH_4 in the gasifier may be great enough to represent the only net product from the process. The basic chemistry occurring is as represented in Eqs. (1)–(5) above. At temperatures above about 800 °C, the reaction between steam and carbon tends to be as shown in Eq. (1). As the temperature is decreased, a different reaction pathway begins to appear, namely

$$2C + 2H_2O \rightarrow CH_4 + CO_2. \qquad (6)$$

At a temperature of 260 °C, the reaction tends to be mostly as indicated by Eq. (6), and is almost thermally neutral.

If the reader is interested in technologies that have been developed to carry out the chemistry indicated in Eqs. (1)–(5), a description of those processes may be found in Elliott (1981), Chap. 24.

10.1.6. Underground Gasification. As discussed in Sec. 1, large quantities of coal have been identified that are not considered to be economically recoverable by mining techniques. In particular, very thin seams less than 35 cm thick, and seams with overburden greater than 900 m, are not considered to be minable. For such coal seams, as well as certain other special types of resources, the chemistry identified in Eqs. (1)–(5) and more especially Eqs. (1) and (2) may be carried out *in situ*.

The technique involves drilling a well into the coal seam through which is injected air, and water or steam if the moisture content in and adjacent to the coal seam is insufficient for the gasification process. A second well is drilled at an appropriate distance from the injection well, from which product gases will be removed. Ignition may occur at the bottom of the injection well (forward burn) or at the bottom of the product recovery well (reverse burn). With air injection, the product gas is similar in composition to a low-heating-value gas, described above, but with a heating value slightly lower, generally ranging from 3350 to 4850 kJ/m^3 (90 to 130 Btu/SCF). If the overburden is tight enough to prevent loss of the injected gases, oxygen rather than air may be injected, thereby producing a gas similar in composition to an intermediate-calorie gas, but again of slightly lower heating value. (For processes, see Elliott, 1981.)

10.1.7 Integrated Gasification Combined Cycle. An attractive application for intermediate-calorie gas is electric power generation. If this fuel gas is burned to produce steam, and the steam expanded in a turbine to drive a generator, the overall efficiency is limited by the temperature and pressure of the turbine operation, about 38% in most fossil-fuel plants. An alternative is to expand the hot gasification-product gases in a turbine, generating some electric power by that operation. This is followed by the ordinary fuel-gas-combustion–steam cycle normally operative in fossil-fuel power plants. This combination of gas turbine and steam turbine power generation results in overall efficiency improvement of several percent, e.g., from 38% to 42–44%, a significant improvement. The concept is known as combined cycle and the system is integrated gasification combined cycle (IGCC).

10.2 Liquid Fuels from Coal

Coals of interest for conversion to liquid fuels generally exhibit an atomic hydrogen: carbon ratio of 0.8 to 0.9, with a few coals approaching a value of 1.0. Liquid fuels derived from coal must have atomic H:C ratios greater than 1.0, in order to be liquids. The atomic H:C ratios of a few fuels with which liquid fuels from coal would be compared are listed in Table 3 with characteristic values of atomic H:C ratios. Referring to Fig. 1, the bridges that join the condensed units in coal begin to rupture thermally at about 350 °C, and the rupture of the bridges is essentially complete at 450 °C. Nearly all direct coal liquefaction processes are carried out near 450 °C, or slightly higher, in order to realize full benefit of this thermal action. If the free radicals thus formed are stabilized immediately, as by addition of a hydrogen atom, a stable molecule is formed, which may be of such size (vapor pressure) as to become part of a liquid fraction, or at least be soluble in the liquids present. Inasmuch as the objective is to form liquid-size molecules, rather than something larger, stabilization of the free radicals with hydrogen is usually the preferred practice.

Hydrogen is an expensive commodity and represents a large expense in the conversion of coal to liquids. The heavy, raw liquid formed in direct coal conversion processes does not represent a large consumption of hydrogen. Starting from a bituminous coal with an atomic H:C ratio of 0.90, the primary, raw liquid product typically has an atomic H:C ratio of about 1.1. However, a considerable amount of hydrocarbon gases may be produced during the conversion process (accompanied by large consumption of hydrogen), the principal component of which is CH_4. The ratio of liquids to hydrocarbon gases usually ranges from about 1 to about 4, depending upon the process approach. The various approaches presented below for conversion of coal primarily to liquids are classified to a degree on the basis of the manner in which hydrogen is provided for stabilization of the thermally produced free radicals.

10.2.1 Coal Pyrolysis. By definition, coal pyrolysis is the process of heating coal in the absence of a reacting atmosphere, and without an externally applied catalyst. A variation of pyrolysis is hydropyrolysis, wherein coal is heated in the presence of molecular hydrogen, but still in the absence of an externally applied catalyst. In a typical pyrolysis process for production of liquids, the coal is heated to a temperature between 450 and 525 °C. As the

Table 3. Characteristic atomic H:C ratios of some liquid fuels.

	Atomic H:C ratio
Bituminous coal (as reference)	0.8–0.9
Naphthenic crude (petroleum)	1.6
Unleaded gasoline	1.6
Diesel fuel	2.1
Fuel oil	1.8

connecting bridges rupture, the free radicals thus formed abstract hydrogen from the hydroaromatic structures in close proximity to the bond rupture, thereby forming molecules that may be evolved as volatiles. For a bituminous coal the volatile product yield, liquids plus gases, is 35%–40% by weight of the dry, mineral-matter-free (dmmf) coal, about equally distributed between liquids and gases, resulting in about 1 barrel (42 U.S. gallons) to 1.25 barrels of liquid per ton of bituminous coal. If heating rates and product removal are very rapid, thus reducing the time for the liquids in the hot zone, the liquid yield may be increased by decreasing thermal cracking of the liquid molecules to form gases.

In hydropyrolysis, heating of the coal is conducted in a hydrogen atmosphere. In the temperature range for liquids production as the desired product (e.g., below 525 °C), hydrogen does not react very readily to stabilize the thermally produced free radicals without the aid of a catalyst, hence volatile yields are not greatly increased in this temperature range compared with ordinary pyrolysis. At higher temperatures, e.g., 600 °C and higher, hydrogen reacts more readily, increasing conversions substantially, with most of the increased yield being gases.

10.2.2 Solvent Extraction. In solvent extraction processes the coal is first slurried in a hydrogen-donor solvent, usually coal-derived. The slurry is pumped into a reactor at a temperature usually between 430 and 450 °C, and hydrogen pressure of 14 MPa (2000 psi) or higher. An external catalyst is not applied with the raw coal. As the free radicals are thermally produced, hydrogen from two sources is available for radical stabilization, namely from the hydroaromatic structures of the coal, and from hydroaromatic structures in the donor solvent. The former usually enters into the reactions before the latter, probably because it is nearer to the bond-rupture sites. Most of the organic portion of the coal is dissolved, and the remaining solids, consisting of the mineral matter and a few percent of unreacted organic matter, are removed while the product is still at the elevated temperature (e.g., 430–450 °C). Solid-removal techniques include flash distillation, critical solvent de-ashing, filtration, hydrocyclone, and centrifuging.

When addition of hydrogen from external sources is limited to about 2% by weight of coal, and the solvent removed, the remaining liquid at the elevated temperature becomes solid at ambient temperature, with a solidification temperature (or fusion point) of about 175 °C. This product is called solvent-refined coal (SRC). Usually the mineral matter content has been reduced to about 0.1% to 0.5% by weight, and the sulfur content to about 0.7% (from a coal of 3% sulfur or higher). The net SRC product represents about 56% of the dmmf coal fed, the balance being recycle solvent and gases.

If addition of hydrogen is increased to 3.5%–4.0% by weight of coal, a product that is liquid at ambient temperature is obtained. The ratio of liquids to HC gases is about 3:1 to 4:1. Again, most of the hydrogen consumed appears in the gases. For a self-sustained process, after providing for energy input and hydrogen production, the net liquid-product yield is about 2.5 barrels per ton of coal. The practice of slurrying the coal in a hydrogen-donor solvent achieves three important objectives:

1. permits pumping the coal into the pressurized region,
2. controls agglomeration of a caking coal, and
3. provides a source of hydrogen without adding a catalyst.

10.2.3 Catalytic Liquefaction. Catalytic liquefaction involves the addition of a catalyst to the system to assist in the conversion of coal to liquids. Usually the coal is slurried in a hydrogen-donor solvent, process-derived, as described for solvent extraction processes. Temperatures and hydrogen pressures are similar to those identified for solvent extraction. The conversion process is initiated by thermal bond rupture in the connecting bridges between clusters in the coal structure. In this system three sources of hydrogen are available for stabilization of radicals and other reactions that may occur, namely hydrogen from the hydroaromatic structures in the coal, hydrogen from the donor solvent, and hydrogen from the gas phase as may be effected by the catalyst. If the catalyst is a solid phase, such as cobalt-molybdenum supported on alumina, contact between the coal units and catalyst is limited until the process of dissolving the coal in the donor solvent is well advanced. Thus the catalytic hydrogenolysis occurs in the later stages of the liquefaction process. Certain catalysts may be dissolved in a solvent, then impregnated into the coal pores prior to coal heat-up. A vapor-phase catalyst may achieve penetration into the coal pores prior to heat-up. In these cases catalytic hydrogenolysis may begin as soon as the appropriate temperature and pressure are achieved.

In catalytic liquefaction the catalyst encounters a severe environment. Not only must it withstand deactivation by sulfur and nitrogen in the coal, but there are also many elements, especially metals in the mineral matter of the coal and organometallic structures, which may "poison" active sites on the catalyst, perhaps making regeneration of the catalyst impractical, or even impossible. Essentially all of the organic portion of the coal is converted to liquids and gases, with ratios of liquids to gases similar to solvent extraction (about 3:1 to 4:1). Solid-removal techniques are the same as identified above for solvent extraction. Gross liquid yields up to four barrels per ton of coal may be obtained, but net yields per ton of coal, for a self-sustained process, are similar to those for solvent extraction, although they may be of somewhat higher quality due to the activity of the catalyst. In this case hydrogen consumption is also higher.

10.2.4 Synthesis Gas from Coal. In Secs. 10.1.3 and 10.1.4, conversion of coal to a gas consisting principally of carbon monoxide and hydrogen is described. When that gaseous product is intended for use as a fuel, it is referred to as intermediate-calorie gas. If the intended use of the gas is to produce other products, such as the high-calorie gas of Sec. 10.1.5, or alcohol, or a host of other chemicals, or other liquid fuels, that same gas, produced by the same technology, is called synthesis gas. The pathway followed in further reaction of the CO and H_2 and the resulting products depends upon the function and selectivity of the catalyst used, and the reaction conditions.

10.2.5 Indirect Liquefaction. Coal is reacted with oxygen and steam by the reactions of Eqs. (1) and (2) of Sec. 10.1. The ratio of H_2 to CO present in the gas thus produced may range from 1:2 to 2:1, depending upon the technology and temperature used to produce the synthesis gas. This gas is then reacted over a catalyst [Eq. (3)] to increase the H_2:CO ratio. The ratio of H_2:CO required depends upon the intended product, which in turn dictates the required temperature: the higher the required H_2:CO ratio, the lower the temperature. The CO may then be hydrogenated to a wide range of products, with the choice of catalyst providing some measure of selectivity toward certain products. Two examples follow as illustrations.

10.2.5.1. Liquid Hydrocarbon Fuels. Two general reactions are observed to occur over an iron catalyst:

$$y\mathrm{CO}+2y\mathrm{H}_2\rightarrow(\text{—CH}_2\text{—})_y+y\mathrm{H}_2\mathrm{O}, \qquad (7)$$

$$2y\mathrm{CO}+y\mathrm{H}_2\rightarrow(\text{—CH}_2\text{—})_y+y\mathrm{CO}_2, \qquad (8)$$

with an exothermic heat of reaction of -165 kJ/mol calculated at 25 °C. The product contains the full range of linear hydrocarbons, from CH_4 all the way to waxes. Oxygenated compounds, e.g., alcohols, ketones, etc., are also produced. An example of typical operating parameters is as follows: catalyst, Fe_3O_4, promoted with potassium; temperature, 315 °C; pressure, 2.1 MPa. About 30% of the product is hydrocarbons in the gasoline range (e.g., C_6 to C_{12}), with a research octane number of about 60. The process is called the Fischer–Tropsch synthesis, after the two German researchers who first produced gasoline from coal by this technique in the 1930s. The general technology produced a significant portion of the liquid hydrocarbon fuels used in Germany during World War II, and produces more than half of the liquid hydrocarbon fuels used in South Africa today.

10.2.5.2 Alcohol (Methanol). When synthesis gas is passed over a catalyst consisting of zinc, chromia, and copper, the principal reaction is

$$\mathrm{CO}+2\mathrm{H}_2\rightarrow\mathrm{CH}_3\mathrm{OH}, \qquad (9)$$

with an exothermic heat of reaction of -158 kJ/mole calculated at 25 °C. Typical operating parameters are catalyst, $ZnO:CuO:Cr_2O_3=6:3:1$; temperature, 300 °C; pressure, 4.9 MPa.

At this writing, methanol is being promoted as a transportation fuel, principally from environmental considerations. While it does exhibit certain advantages, it also presents several disadvantages. Chief among its advantages are that it

1. is clean burning, with low CO emissions, and lower NO_x emissions than gasoline due to lower combustion temperature;
2. exhibits high octane number, permitting high compression ratio up to 16 (compared with 8 to 9 for automobiles burning unleaded gasoline), and hence higher efficiency.

Chief among the disadvantages are that

1. it has low heating value per gallon, about 0.54 that of gasoline;
2. it is toxic to humans;
3. it does not start well at temperatures below about 15 °C.

Alcohol also attacks certain components in the standard automobile fuel system, such as the carburetor and fuel pump. For extended use of alcohol fuels the automobile engine should be built for that purpose.

Methyl tertiary-butyl ether (MTBE) can be produced from methanol, to be used as an octane-improving additive to gasoline. Its use will permit higher compression ratios, hence higher efficiency, than is achievable with unleaded gasoline.

Mobil Oil Company developed a special catalyst with high selectivity for conversion of CH_3OH to gasoline, a molecular sieve known as ZSM-5. The overall reaction is

$$x\mathrm{CH_3OH} \rightarrow (\text{—}\mathrm{CH_2}\text{—})_x + x\mathrm{H_2O}. \qquad (10)$$

Reaction parameters are as follows: temperature, inlet 360 °C and outlet 415 °C; pressure, 2.1 MPa. The hydrocarbons released from the catalyst are chiefly (80%) in the gasoline range. Because of this phenomenon the catalyst is sometimes referred to as a shape-selective catalyst. From a material balance on Eq. (10) one can observe that the conversion of CH_3OH to gasoline-range hydrocarbons is about 40% on a weight basis. The research octane number of that gasoline is about 85. For process descriptions for conversion of coal to liquids, see Elliot (1981), Chap. 28.

10.3 Briquetting of Coal

The fine sizes of coal, and sometimes of coke, may be transformed into larger structures, called briquettes, by application of heat, pressure, and usually also a binder, thereby becoming suitable for use as domestic fuels, particularly in fireplaces and space heaters. Briquettes also find use in certain commercial and industrial operations. The coals most frequently used in manufacture of briquettes are anthracite (noncaking) and low-volatile bituminous (caking). The material most often used as a binder is coal tar pitch. A few other materials, such as petroleum bitumen, are being used increasingly as binders, helping to reduce smoke emissions from briquette combustion. Briquettes made for industrial plants are usually cubes or bricks weighing between 0.5 and 2.0 kg. Briquettes for domestic use usually are shaped as eggs or pillows, with a weight from 16 to 80 g.

In briquetting of noncaking coals, the coke-forming components of the pitch used as binder are of great importance. The strength of the briquette must be derived from the coke-forming components of the binder. Since coal-tar pitches contain larger quantities of coke-forming components than do bitumens, they are often preferred in briquetting anthracite. Briquetting of caking coal without binder has been extensively investigated, but the quality of the briquettes has been found to be inferior to those produced using a binder.

10.4 Methane Production from Coal Seams

As a consequence of the coalification process, and the high porosity of most coals, varying amounts of methane are trapped in the coal pores and confined by the pressure maintained in the coal seam. In coals in the United States, the estimated quantities of methane range from about 2 standard cubic meters (SCM)/metric ton in a western coal to about 20 SCM/metric ton for an eastern coal. The total estimated quantity of methane in U.S. coals (about 11 trillion SCM) is more than twice as great as known and recoverable reserves of natural gas in the United States. Various techniques of recovery of the methane from coal seams are being investigated. However, the methane exists in an adsorbed state on the internal surfaces in the coal, and rates of diffusion through the porous coal structure are slow. Consequently a very large external surface must be created by fracturing in order to realize a practical rate of recovery of methane from coal.

11. ENVIRONMENTAL, HEALTH, AND SAFETY IMPACTS FROM COAL UTILIZATION

As noted in Sec. 3.1, the occurrence of large coal reserves under thick overburden necessitates sending people and machines underground to recover the coal, thus exposing them to health and safety hazards. As described in Sec. 5, the skeletal structure of coal is composed principally of polynuclear aromatic units, many of which form carcinogenic compounds when released from the coal structure. Coals contain varying amounts of sulfur and nitrogen; these elements form compounds during combustion that are detrimental to human health and destructive to the environment if released into the atmosphere. Thus, along the full train of events, from recovery to utilization, coal may produce negative impacts unless properly handled.

11.1 Impacts from Coal Mining

Underground mining operations have always involved grave dangers to the mining personnel, and while the dangers have been greatly reduced during this century, mine disasters still occur and dangers persist. The mining of coal produces the largest number of accidental deaths and injury to workers of any sector of the coal energy system. Underground mining causes about four times as many deaths or injuries as surface mining per million tons of coal mined.

11.1.1 Explosions. The principal cause of fatalities in underground coal mining is gas explosions. Mining operations release methane, somewhat in relation to the fineness of the coal produced during the mining process. If the concentration of methane in the air is allowed to rise above the lower flammability limit of 5.0% by volume, a spark of sufficient energy, such as an electrical spark, may lead to an explosion or a fire. Air is circulated through the mine in sufficient quantities to attempt to ensure that the methane concentration will remain well below the lower explosion limit, and usually less than 1% by volume. Explosion-proof lights and motors are also required.

Reaction between coal and air occurs at surfaces. If in the mining operation large external surface areas are generated by formation of extremely fine coal dust, such as may be produced in high concentrations in longwall mining, the resulting increased reaction rates may also lead to an explosion. The dust concentration is controlled by air circulation through the mine.

11.1.2 Mine Cave-In and Subsidence. In room-and-pillar mining, pillars of coal are left in place to support the roof of the mine. Mining safety regulations restrict the width of any development or entry channel within the mine, unless additional ceiling reinforcement is provided, including floor-to-ceiling support, between the walls of the channel. In spite of these precautions, occasionally an unanticipated instability in the overburden may create pressure upon the supports beyond their capacity thereby causing the supports to fail and the roof to cave in. Such occurrences are rather rare today.

In longwall mining the roof is allowed to cave in behind the mining machine as it progresses into the coal seam, resulting in cavitation in the overburden above the cavern. Depending upon the strength and stability of the overlying rock, the cavitation may extend to the surface, resulting in a depression in the surface above the mine. This phenomenon is known as *subsidence*. After many years the mine roof may fail and settle. It is a fairly common occurrence for the cavitation thus created to extend to the surface, causing subsidence. This phenomenon has occurred in locations where towns had been built above the region that was subsequently mined, causing serious environmental damage, even property destruction. Where resources of good coals are scarce, towns have been relocated to permit underground mining of coal in regions under the prior location of the town.

11.1.3 Surface-Mining Environmental Impact. When coal is recovered by surface mining, plant life on the affected surface is destroyed. Environmental considerations, often even legislation, dictate the restoration of the overburden and revegetation. If these steps are not properly carried out, the result may be erosion of the exposed surface, destruction of wildlife habitats, and disruption of previous land use. Erosion by water may also increase sediment loading in streams. In areas of sloping terrain, terracing may be required. In the United States, surface mining legislation mandates restoration of the overburden to a slope approximating the original slope, as well as providing stipulations concerning revegetation and certain other factors. As the slope of the terrain increases, it becomes more difficult to comply with the terms of the legislation, and in some cases this precludes application of surface mining for recovery of coal.

11.1.4 Impact upon Health. Coal dust is hazardous to the health of the miners, particularly those who work in underground mining at the face of the coal seam being mined. Severe respiratory diseases often result from prolonged exposure to high dust concentration in underground mines. Examples of consequences of such exposure are tuberculosis, chronic bronchitis, and coal workers' pneumoconiosis, as well as others. As legislation has been enacted to provide benefits to victims of these ailments, the various obstructive airway diseases thus inflicted have been brought together under the name "black lung disease."

11.2 Impacts from Carbonization

Carbonization processes include those operations wherein the coal is heated in the absence of air or other reacting atmosphere. These processes are usually conducted at or near atmospheric pressure and are usually not sealed against evolution of volatiles to the environment. Bituminous coals are most commonly used in such processes, which coals evolve up to 40% or more of the weight of the coal at process conditions. Both epidemiologic studies involving human workers and laboratory studies involving animals have confirmed the carcinogenicity of many of these coal-derived compounds. The principal cancer-causing compounds thus identified are polynuclear aromatic hydrocarbons and polycyclic amines. High-temperature coal tars, such as from metallurgical coke ovens, contain more of these compounds than the volatiles usually produced in gas plants (Lloyd, 1971).

11.3 Impacts from Combustion

Coal is utilized predominantly in combustion, with the largest segment being in electric power generation, which represents 80% of all coal consumed in the United States. Inasmuch as coal combustion in power generation and other industrial applications is conducted in a fuel-lean mode, essentially no carbon monoxide or unburned hydrocarbons are emitted to the environment from this source. However, combustion in a fireplace, residential space heater, or home furnace is not subject to regulation to the fuel-lean mode, and may release polynuclear aromatic hydrocarbons or nitrogen-bearing heterocyclic compounds, as well as other pollutants. The principal products from coal combustion viewed as pollutants are unburned carbon, ash particulates, sulfur oxides, and oxides of nitrogen. Very recently some groups have begun to relate CO_2 emissions to potential global warming, and in that context view CO_2 as a pollutant.

11.3.1 Particulates. The very fine dispersion of inorganic particles within the coal matrix, as a consequence of the manner in which the coal bed was formed, coupled with disintegration of fine particles during combustion (e.g., oxidation of pyrites in the mineral matter), gives rise to liberation of extremely fine particles of inorganic matter, called *fly ash*. In addition, some combustion processes do not accomplish complete conversion of the carbon, resulting in tiny carbon particles being emitted. These particles from both sources are small enough to be emitted with the combustion gases. The particles themselves may be harmful to the lungs when inhaled, especially to people suffering from respiratory ailments. In addition, the mineral matter often contains metallic elements in trace amounts, such as arsenic, cobalt, lead, mercury, and several others, which are toxic to the body, and possibly carcinogenic. The particulates also cause defacing of buildings and other structures.

These particulates, both varieties, may be effectively removed in an electrostatic precipitator, the manufacturers stating an effectiveness of at least 99.9% solid removal. This technique is most widely used for solid removal from combustion effluent gases in electric power generation. Other devices finding use include the bag house and cyclone separator.

11.3.2 Oxides of Sulfur. When coal is burned in air, the sulfur in the coal, both organic and pyritic, is converted to sulfur oxides, in a ratio of about 5 parts SO_2 to 1 part SO_3, mole basis. The sulfur content in coals presently used industrially varies from as low as 0.3% by weight to 5.0% by weight, or even higher. While combustion of the very-low-sulfur coal may meet acceptable emission standards without sulfur removal, serious environmental and health effects result from the combustion effluent from high-sulfur coals, unless the sulfur oxides are removed. Coal combustion is the principal source of fuel-generated sulfur oxide emissions to the atmosphere.

Sulfur oxides are very soluble in water, SO_2 forming H_2SO_3, a weak acid, and SO_3, forming H_2SO_4, a strong acid. Many of the harmful effects of sulfur oxides are due to the action of these acids. When air containing sulfur oxides is inhaled, moisture in the respiratory system may lead to acid formation and oxidation reactions in the system. As a consequence, breathing air that contains sulfur oxides may aggravate existing respiratory illness, and prolonged exposure to sulfur oxides may cause respiratory illness.

As rain droplets pass through an atmosphere than contains sulfur oxides, these oxides dissolve in the liquid droplets, forming the acids identified above and producing "acid rain." Sulfur oxides are the largest contributors to the formation of acid rain. Plants in general are sensitive to pollutants in the air, and many plants are adversely affected by acid rain. While a certain amount of damage to crops and forests has been traced to acid rain, the effects upon aquatic life in lakes and rivers is still, at this writing, the subject of strong controversy.

Sulfur oxides lead to large amounts of damage to buildings and other structures, both as pollutants added to rain and by direct attack. The cost of this damage, resulting from defacing of the structure as well as structural damage, is great.

Sulfur oxides may be removed from combustion product gases by chemical reaction with a number of compounds, a popular example being limestone. The "scrubbing" compound may be added to the coal bed in the case of fluidized-bed combustion, one of the advantages of that type of combustion system. Alternatively, the combustion-product gases may be passed through an appropriate scrubbing system, called a *stack gas scrubber*, before being emitted to the atmosphere. At this writing, all new electric-power-generating plants constructed in the United States to burn coal are required to be equipped with stack gas scrubbers for removal of sulfur oxides, regardless of the sulfur content of the coal being fed.

11.3.3 Oxides of Nitrogen. Nitrogen can react with oxygen to form several oxides of nitrogen, designated NO_x. From the point of view of air pollutants resulting from coal combustion, the principal oxides of interest are NO and NO_2. The extent of reaction between nitrogen and oxygen to form NO is a function of temperature, the degree of reaction increasing as temperature increases. Some coal-combustion systems attempt to operate at temperatures low enough to limit NO_x formation. At higher temperatures, molecular nitrogen from the air reacts with atmospheric oxygen to form NO.

Coals in general contain bound nitrogen ranging from about 1.0% to 1.5% by weight of the coal. Research in recent years has demonstrated that the bound nitrogen in the coal reacts more readily with atmospheric oxygen during the combustion process to form NO_x than does atmospheric nitrogen, and it does so at a lower temperature. The stack gas srubbers currently used to remove sulfur oxides from coal combustion product gases do not remove NO_x.

NO_2 is one of the essential ingredients in the formation of photochemical smog, which is the smog of greatest concern and most frequent occurrence. The other two essential ingredients are hydrocarbons and sunlight. The chemistry of smog formation is discussed in the article AIR POLLUTION: COMPONENTS CAUSES, AND CURES.

Photochemical smog causes serious loss of productivity of crop plants. It also attacks rubber, paints, fabrics, and other materials. Coal combustion is a principal contributor of NO_x to the formation of photochemical smog. In cities with smog problems, the automobile is the principal contributor of hydrocarbons to photochemical smog formation.

11.3.4 Carbon Dioxide. Coal combustion is a principal source of addition of CO_2 to the atmosphere. In a direct sense CO_2 would not be considered to be a pollutant, but some groups are expressing concern about a possible global warming effect and a perceived contribution by CO_2 to such a warming trend. Some groups have advocated a dramatic reduction in the use of coal combustion, as well as other fossil fuels, to address this perceived atmospheric temperature phenomenon. At this writing the question of prediction of a global warming is controversial. Different scientific and engineering groups disagree as to whether a global warming trend is occurring, or whether what is now being observed is a part of the cyclic pattern established over the past 100 years. There is further disagreement among these groups as to what contributions, as a percentage of all contributing factors, may be attributable to CO_2 production. Finally, there is strong disagreement among scientists as to the adequacy of the models used in predictions of global warming. Further information concerning the basis for the global warming concern is presented in the article AIR POLLUTION: COMPONENTS, CAUSES, AND CURES.

11.3.5 Clean Coal Technologies. Direct combustion of coal presents several hazards to the environment. It is possible by means of precombustion processing of the coal to reduce some of those environmental hazards substantially, such that pollutant removal from the combustion effluent may not be required. Of particular interest is reduction of sulfur and reduction of the mineral matter, which contains many potential pollutants in addition to a portion of the sulfur. Included under the umbrella of clean coal technologies are several concepts for delivering a cleaner-burning fuel. At this writing, these concepts are either among topics already discussed, or are only research concepts which may or may not prove to be successful.

11.4 Impacts from Coal Conversion

Coal-conversion technologies of greatest interest and importance are conducted in a closed system under pressure. Consequently gaseous or liquid products of environmental concern are, or should be, contained during the conversion train, and can be collected or processed before release to the environment. In the reducing atmosphere within the reactor system, sulfur is converted to H_2S and nitrogen is converted to NH_3. Both of these products are readily removed from the exit gases by well-developed and reliable technologies.

Workers need to avoid contact with coal-derived liquids and vapors in coal-conversion plants. However, because of the nature of the coal-conversion systems, adverse health effects from the closed systems are expected to be less extensive than those from coke ovens.

12. ECONOMIC CONSIDERATIONS

The economic position occupied by coal in relation to other energy resources is subject to many factors. These factors in turn vary widely among the different countries, affected by political considerations, resource availability, existing and projected energy consumption patterns, and others. Only a few general observations can be made.

1. Combustion of oil or natural gas exhibits two major advantages that establish its preference over coal, namely cleanliness in combustion and convenience in delivery to the combustion site (even to the burner), since they are fluids, while coal is a solid. In a free-market environment, coal must demand a lower price per unit heating value than oil or natural gas to offset these factors, or it cannot compete in the marketplace. These factors may be overruled by government subsidy or other non-free-market factors.
2. In the development of synthetic fuels from coal, the projected, required selling price has always been higher than the world market price of petroleum or natural gas delivered to the market location. Synthetic fuels plants are all very expensive to construct, and they are constructed with existing energy costs factored into the cost of materials for constructing the plant. When the high cost of plant construction is amortized, and factored into the selling price of the product, that price at the time of entry of the product into the market will always be higher than the market price of the product with which it must compete. At this writing that market price differential is about 50%–100%.

GLOSSARY

BET (Brunauer–Emmet–Teller): A technique for calculating surface areas from gas adsorption isotherms.

dmmf: Dry, mineral-matter-free.

Metamorphism: Alteration of plant substances resulting from the effects of elevated pressure and temperature.

Mobile Phase: Organic material in coal not chemically bound to the solid matrix.

Overburden: The layer of rock and soil on top of a coal seam.

Petrographic Analysis: Identification of the types and quantities of organic material in coal, as determined by observation under a microscope.

Petrography: A description or classification of coal (from the word roots petros = rock, graphy = description of).

Petrology: The scientific study of coal (from the word roots petros = rock, logos = the science of).

SCM: Standard cubic meter, measured at 0 °C and 1 atm pressure.

SCF: Standard cubic foot, measured at 0 °C and 1 atm pressure.

INTRODUCTION: COHESION IN SOLIDS

Cohesion in solids arises when the free energy of the atoms in the solid is lower than that of the vapor or liquid. The cohesive energy of a solid can be defined as the difference in energy per atom in the solid at 0 K at 1 atm versus the solid separated into isolated, neutral atoms in their lowest-energy state. Since the solid is taken to be at absolute zero, entropic considerations do not enter and the free energy corresponds to the enthalpy of the solid. A related term is the energy to separate an ionic crystal into the constituent ions. This energy difference is known as the "lattice energy."

From an experimental point of view, the cohesive energy of a solid can be determined by precise calorimetry measurements. For example, if the heat of sublimation is measured and the heat capacities of the gas and solid are known as functions of temperature, it is possible to determine the enthalpy difference between the gas and the solid at a given temperature. This difference at absolute zero would correspond to the cohesive energy. In some cases, it is possible to estimate the cohesive energy from known experimental data and some simple approximations. For example, the Born–Haber cycle can be used to determine the heat of formation of an ionic solid. If we are interested in reacting metallic sodium and chlorine gas to form solid sodium chloride, then we could *conceptualize* this process taking place in several steps. First, we form a neutral monatomic gas of Na and Cl. We could vaporize the sodium metal and measure the heat of sublimation. For the chlorine gas, we could measure the energy to dissociate the Cl_2 molecule to monatomic chlorine. Second, we consider creating a gas of ionic species Na^+ and Cl^- by ionizing the Na and adding an electron to Cl to form a negative ion. To determine the energy of this step we would measure the ionization energy of Na and the electron affinity of Cl. Third, we consider bringing together the Na^+ and Cl^- species to form a crystal composed of the ionic species. This energy may be determined by summing up all the classical electrostatic

interactions in the crystal as discussed in the section on ionic bonding (Sec. 1.3). By considering the difference in energy from forming the crystal of ions and the "preparation energy" from sublimating the Na metal, dissociating the Cl_2 molecule, and forming the (Na^+,Cl^-) ions, we can obtain an accurate measure of the heat of formation (Swalin, 1972).

In general, calorimetry measurements are difficult, as the difference between competing solid states can be quite small. For example, the energy difference between carbon in the diamond and graphite structures can be a few kcal/mol. Nonetheless, for most elemental solids and many binary alloys, the cohesive energy has been measured. In Table 1, the cohesive energy is given for most of the elemental solids.

From a theoretical point of view, binding in solids is fairly well understood. The forces in solids are purely electronic. The interactions can be categorized as electron-nuclear, electron-electron, and nuclear-nuclear. Unlike the situation in nuclear physics where the forces are not well defined between nucleons, the forces in solids are. Specifically, the Hamiltonian for a solid can be written down exactly. Quantum chemists have demonstrated for molecules that the calculated values for binding energies agree well with experiment. One has no reason to believe the situation for solids would be different.

Although the interactions in solids are well understood, it is not an easy task to evaluate the total energy of the solid, even at absolute zero. In principle, two factors complicate the problem. The energy of an isolated atom can be very large. For example, the energy of an isolated, heavy atom such as uranium can be estimated to be on the order of $\sim 10^6$ eV or more, but the cohesive energy of uranium is only about 6 eV/atom. (This is an extreme example to be sure, but it illustrates just how difficult the problem can be.) To obtain a reasonable estimate of the cohesive energy in this case, one must have a method that is accurate to one part in 10^6, or better. The other fact that greatly complicates the evaluation of cohesive energies by theoretical methods is the number of particles involved. Given that a macroscopic solid may contain 10^{23} nuclei and electrons, it is impossible to determine the total energy of the crystal without some approximations.

Several advances have made it possible to predict the cohesive energy of solids by numerical solutions of the quantum-mechanical equations of motion, i.e., the Schrödinger equation. One advance has been of a technological nature: the invention of high-speed computers. Another major advance was to devise one-electron potentials that greatly simplify many-body interactions. Also, several electronic structure methods have been developed that separate the problem of describing strongly bound core electrons from that of weakly bound valence electrons. For further discussion of these developments, see ELECTRONIC STRUCTURE OF SOLIDS. The accuracy of these computations is usually not at the same level as experiment. Nonetheless, it is now possible, for elemental solids and simple compounds, to predict whether a given crystal structure is the most stable one at 0 K and 1 atm.

1. BINDING IN SOLIDS: CLASSIFICATION BY TYPE OF CHEMICAL BOND

It is useful to classify solids by the type of chemical bond that stabilizes the solid (Kittel, 1986). For example, electrostatic forces between ions dominate the properties of solids such as sodium chloride. By attributing the binding in NaCl to electrostatic interaction between Na^+ and Cl^- ions, it is possible to account for many properties such as the cohesive energy, compressibility, elastic properties, vibrational spectrum, and crystal structure. Broadly speaking, there are five types of bonding in solids: van der Waals, hydrogen, ionic, covalent, and metallic.

1.1 Closed-Shell Binding: van der Waals Solids

Inert gases have filled *s* and *p* shells (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES). These elements have no orbitals available for forming bonds. Thus, it is not surprising that these elements form weakly bound solids. Crystals made of inert gases have low melting points, sublimation energies, and bulk moduli. They are also electrically inert and transparent. The closed-shell atomic structure of these elements results in crystal structure in which directional forces are not significant.

Table 1. Cohesive energies, melting points, and bulk moduli for elemental solids as tabulated by Kittel (1986), Brewer (1977), and Gschneidner (1964).

Element	Cohesive energy (eV/atom)	Melting point (K)	Bulk modulus (10^{11} N/m^2)	Element	Cohesive energy (eV/atom)	Melting point (K)	Bulk modulus (10^{11} N/m^2)
Actinium	4.25	1324	0.25	Neon	0.002	24.56	0.010
Aluminum	3.39	933.5	0.722	Neptunium	4.37	910	0.68

Since pairwise forces dominate the bonding in inert-gas crystals, the structures are close-packed.

1.1.1 Dipole–Dipole Interactions. If we consider interactions present between static, electrically neutral, spherical charge distributions, then no cohesion is possible. However, if we allow dynamical fluctuations of dipoles that arise from the motion of the electrons in the inert-gas atom, then an attractive interaction is possible. Specifically, a dipole present in one atom can induce a dipole moment in a neighboring atom. Suppose at some time an atom A has an instantaneous dipole moment $\mathbf{p}_A$. An atom B will experience an electric field that is proportional to p_A/R^3 at a distance R from A. This field will induce a dipole on B given by $p_B=\alpha E_A \sim \alpha p_A/R^3$, where α is the polarizability of the atom. The energy of this interaction is given by $U_{AB} \sim -p_B p_A \sim -\alpha p_A^2/R^6$. The time average of $\mathbf{p}_A$ vanishes. However, since the dipole enters as the square, the interaction energy does not vanish. More precise treatments of this interaction require the consideration of three or more interacting atoms (Horton, 1968).

1.1.2 Lennard–Jones Potentials. The attractive dipole-dipole interaction is opposed by the Pauli repulsive forces. A fundamental principle of quantum mechanics is that two electrons cannot occupy the same state, i.e., they may not have the same quantum numbers. If atoms with closed shells overlap some electrons must be promoted to unoccupied, higher-energy states. This promotion results in a higher-energy state and an effective repulsion between the atoms. Empirically, this repulsive interaction is found to be very short ranged. One of the more common approximations is to assume a pairwise interaction that scales as $\sim 1/R^{12}$. Another form often used is exponential scaling, i.e., $\sim \exp(-R/\rho)$, where ρ is a parameter that indicates the range of the interaction.

Combining the repulsive and attractive terms results in the Lennard–Jones potential. The potential between two atoms can be written as

$$U(R)=4\epsilon\left[\left(\frac{\sigma}{R}\right)^{12}-\left(\frac{\sigma}{R}\right)^{6}\right], \tag{1}$$

where U is the interaction energy between two atoms, R is the interatomic distance and (ϵ,σ) are parameters. Values for ϵ and σ can be extracted from gas-phase measurements and transferred for solid-state calculations.

At very low temperatures, and for heavy atoms, we may neglect the kinetic energy and use Eq. (1) to determine the cohesive energy of an inert-gas solid. The total energy per atom, E_{total}, is given by

$$E_{\text{total}}=2\epsilon\left[\sum_{m,n\neq m}\left(\frac{\sigma}{R_{nm}}\right)^{12}-\sum_{m,n\neq m}\left(\frac{\sigma}{R_{nm}}\right)^{6}\right], \tag{2}$$

where we have taken the nth atom as the reference atom, R_{nm} is the distance of atom m from the reference atom, and the m sum is over all the atoms in the system, except the reference atom. If we define a dimensionless parameter ρ_{nm} such that $R_{nm}=\rho_{nm}R$ where R is the nearest-neighbor distance, then we may define E_{total} as

$$E_{\text{total}}=2\epsilon\left[\alpha\left(\frac{\sigma}{R}\right)^{12}-\beta\left(\frac{\sigma}{R}\right)^{6}\right], \tag{3}$$

where (α,β) correspond to structurally dependent parameters, e.g., $\alpha=\Sigma_{n,m}(1/\rho_{nm})^{12}$. For the face-centered-cubic (fcc) structure, $\alpha=12.131\,88$ and $\beta=14.453\,92$; the corresponding values for the hexagonal-close-packed (hcp) structure are 12.132 29 and 14.454 89. One can see how small the differences are between hcp and fcc structures. Both structures have 12 nearest neighbors and differ only in the placement of the second neighbors. The short-range nature of the van der Waals forces accounts for $(\alpha,\beta)\approx$ number of nearest neighbors. Thus a body-centered structure with eight nearest neighbors would have values of $(\alpha,\beta)\approx 8$.

By taking the derivative of E_{total} with respect to R, one can find the equilibrium value of the bond length. For the fcc structure, $R_0 \approx 1.09\sigma$. Using this value, the cohesive energy can be found. For fcc crystals, we find the cohesive energy $\approx 8.6\epsilon$. For example, for a dilute argon gas, $\epsilon=0.0104$ eV/atom. Using Eq. (3), we would predict a cohesive energy of $\cong 0.09$ eV/atom; the experimental value is about 0.08 eV/atom. In Table 2, we summarize the Lennard–Jones parameters for the inert gases. Note how the binding energy increases with electron number; this is a consequence of the higher polarizability of the heavier atoms. Heavier inert-gas atoms have outer electrons that are more loosely bound than those in lighter inert gases. Hence, it is easier to induce larger dipoles in the heavier atoms. As a consequence, the binding energy for Xe is nearly an order of magnitude larger than Ne. This feature is unusual. For example, group-IV solids show the reverse

Table 2. Inert-gas parameters for the Lennard–Jones potential. From Kittel (1986) and Horton (1968).

	ϵ (10^{-16} erg)	σ (Å)	Nearest-neighbor distance (Å)	Cohesive energy (eV/atom)	Melting point (K)
Helium	14	2.56	···	···	···
Neon	50	2.74	3.13	0.02	24
Argon	167	3.40	3.76	0.08	84
Krypton	225	3.65	4.01	0.12	117
Xenon	320	3.98	4.35	0.17	161

trend: Diamond exhibits a much stronger binding energy than does lead. This reversal is a consequence of weaker covalent bonds being formed by heavier atoms, as discussed in the section on covalent bonding.

The differences between the experimental and theoretical values *increase* as the mass of the inert gas atom *decreases*. This effect is "quantum mechanical" in origin. The zero-point motion of the atoms constitutes a significant correction for light atoms as the term scales inversely with the atomic mass. In the case of helium, a solid cannot be formed at 1 atm even at absolute zero as the zero-point motion exceeds the attractive Lennard–Jones potential.

Although our discussion has concentrated on inert gases, solids such as benzene, nitrogen, methane, and chlorine are bound via van der Waals interactions. The bonding orbitals of the constituent species in these solids, e.g., N_2, CH_4, etc., are completely filled. Thus, just as in the inert-gas atoms, only weak dipole interactions are present.

Dipole-dipole interactions also occur in polar molecules that have permanent dipole moments. Such molecules can form weakly bound solids similar to molecular solids.

1.2 Hydrogen Bonding

Another example of weak bonding in solids arises from *hydrogen bonding* (Pauling, 1960). Hydrogen bonding was first recognized in 1912. It is present in organic solids and in solids such as ice, boric acid, and hydrogen fluoride, i.e., the solid contains hydrogen and an electronegative element such as oxygen, fluorine, or nitrogen. In such solids, the hydrogen atom serves to bond two negative ions. This is a surprising result as one might expect hydrogen to form a single covalent bond to only one atom. However, given that hydrogen bonds form only with highly electronegative atoms, it is believed that the hydrogen is ionized and that the forces involved are electrostatic in nature. In the most extreme case, such as $[HF_2]^-$, the bare proton is thought to form a "bond" between two F^- ions.

The binding energy of a hydrogen bond is typically on the order of 0.1–0.5 eV/atom. Given this weak bond, the hydrogen bond plays an important role in organic reactions at room temperature. It is also responsible, along with the permanent dipole moments, for the striking physical properties of water and ice. It is for these reasons that Pauling has stated that the hydrogen bond may be the most important bond for understanding the biochemistry of living organisms.

1.3 Ionic Bonding

Solids made of elements from the extremes of the periodic table, e.g., from groups I and VII, form ionic solids. In these solids, electrons are transferred from the cation to the anion. In the language of Pauling, the electropositive atom such as Na yields a valence electron to form a closed-shell positive ion. The electronegative atom such as chlorine gains an electron to form a closed-shell negative ion. The binding energy in these crystals is large, and the structures formed tend to be close-packed.

1.3.1 Electrostatic Interactions in Ionic Solids. Although the bonding in ionic solids is very different from the bonding found in molecular solids, it can be described accurately by *pairwise* forces. The attractive origin of bonding in ionic solids is electrostatic in nature between the positively charged cations and the negatively charged anions. In sodium chloride, Na^+ ions attract Cl^- ions. One can envision forming a sodium chloride crystal as follows. Energy is required to ionize a Na atom to form Na^+ and a free electron. The electron is added to Cl to form Cl^-. Energy is liberated in this latter process; however, the net process is endothermic. The ionization energy of Na is 5.14 eV; the electron affinity of Cl is 3.61 eV. The energy to create an ion pair is 1.53 eV. When these ions are brought together we gain a "lattice energy" contribution from the electrostatic interactions. This term is about 7.9 eV/molecular unit; the cohesive energy is $(7.9-1.5)=6.4$ eV/molecular unit.

1.3.2 Madelung Constant. The lattice energy in an ionic solid can be evaluated by summing over the electrostatic interactions. If we consider a rocksalt structure (a simple-cubic lattice with alternating cation and anion sites), then the summation would proceed as

$$E_S=-(e^2/R)[6-12/\sqrt{2}+8/\sqrt{3}-\cdots], \qquad (4)$$

where E_S is the electrostatic interaction, R is the interatomic distance between the cation and anion, and we have taken the charge on the ions to be unity. The summation in Eq. (4) arises from 6 nearest neighbors at a distance R, 12 second-nearest neighbors at $\sqrt{2}R$, 8 third-nearest neighbors at $\sqrt{3}R$, and so on. The sign on each shell of neighbors differs. The summation in Eq. (4) is conditionally convergent. This poor convergence is a consequence of the long-range nature of the Coulomb forces. The sum in brackets in Eq. (4) is structure dependent and is called the *Madelung constant*, A_M. Consider a simple ionic solid with a basis of two ions with opposite charges. An example of such a solid would include the rocksalt, cesium chloride, and zinc-blende structures. The Madelung constant can be written as

$$A_M=R\sum_n\left(\frac{1}{R_n}-\frac{1}{|\mathbf{R}_n-\boldsymbol{\tau}|}\right), \qquad (5)$$

where R is the nearest-neighbor distance, $\mathbf{R}_n$ is a lattice vector, and $\boldsymbol{\tau}$ is the basis vector that gives the atomic position within the crystalline unit cell. The first term in the sum excludes the divergent term, i.e., the $R_n=0$ term. Equation (5) can be evaluated by a technique developed by Ewald. In Table 3, values for the Madelung constant are given for some common ionic crystals. For simple binary solids, the value of A_M resides between 1.5 and 2.0. For fluorite structures the value is near 5 and for alumina the value is 25.

Table 3. Madelung constant for some binary structures.

Structure	Madelung constant
Rocksalt	1.7476
Cesium chloride	1.7627
Zinc blende	1.6381

Just as for the inert-gas case, at very short distances there is a repulsive term that prevents the crystal from collapsing. A simple form of this interaction is $E_R=B\exp(-R/\rho)$. With this term the total lattice energy (Born and Huang, 1954) is given by

$$E_{\text{lattice}}=B\exp(-R/\rho)-A_Mq^2/R, \qquad (6)$$

where B is a constant that depends on the structure and we assume that the charge on the ions is q. By taking the derivative of Eq. (6) with respect to R and setting it equal to zero to find the nearest distance, one can eliminate B from the equation. The equilibrium lattice energy per molecular unit is given by

$$E^0_{\text{lattice}}=\frac{-A_Mq^2}{R_0}\left(1-\frac{\rho}{R_0}\right), \qquad (7)$$

where R_0 is the equilibrium nearest-neighbor distance. The bulk modulus of the solid can be used to estimate ρ; typically $\rho/R\approx0.1$. Thus, the repulsive term in Eq. (7) is a 10% correction to the lattice energy. Another common form used for the repulsive term is $E_R\approx B/R^n$ where $n\approx6$–9. In Table 4, values for the ionic parameters in Eq. (6) are given along with the experimental lattice energy for the alkali halides.

From Table 3, one might expect the most ionic binary structure to be of the cesium chloride structure as this structure has the highest Madelung constant. However, the structure of a highly ionic crystal such as CsF is not cesium chloride, but rocksalt. Subtle differences in the bonding orbitals may play a more important role in determining which structure is favored (Tosi, 1964).

While this picture of ionic bonding is simple and able to describe the physical properties of alkali halides, it is limited in its applicability. It may be difficult to determine the charge state on the cation and anion. For the alkali halides, it does not seem unreasonable to assume that the charge transfer is complete.

Table 4. Properties of alkali halide crystals [see Eq. (6)]. From Tosi (1964).

Alkali halide	B (10^{-8} erg)	ρ (Å)	R_0 (Å)	Lattice energy (kcal/mol) Theory	Lattice energy (kcal/mol) Experiment
LiF	0.30	0.291	2.01	242.2	242.3

KBr	2.30	0.366	3.30	154.5	158.5
KI	2.85	0.348	3.53	144.5	149.9
RbF	1.78	0.301	2.82	180.4	181.4
RbCl	3.19	0.323	3.29	155.4	159.3
RbBr	3.03	0.338	3.45	148.3	152.6
RbI	3.99	0.348	3.67	139.6	144.9

However, for other seemingly ionic materials, the issue is problematic. For example, in oxides the charge state of oxygen appears to be O^{2-}; however, an isolated oxygen atom cannot bind a second electron. It is unclear what to use for the preparation energy of the oxygen anion in the solid. Quantum-mechanical calculations have shown that the charge transfer is rarely complete for solids other than the alkali halides.

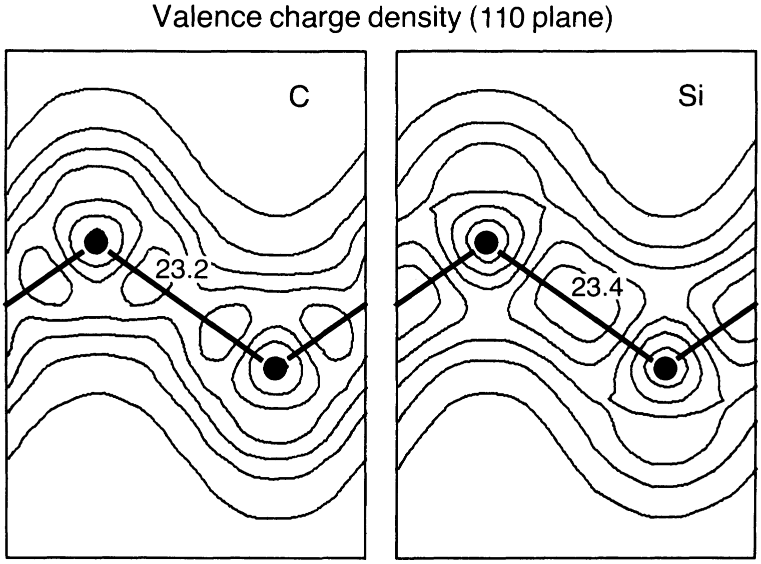
1.4. Covalent Solids

Crystals such as carbon, silicon, and germanium (group IV of the periodic table) form in the diamond structure. They exhibit strong binding. For example, carbon in the diamond structure has a cohesive energy of about 7.3 eV/atom (graphite has a slightly higher cohesive energy). The origin of the bond in these crystals cannot be as simple as that found in the inert gases or ionic solids. The binding in these latter solids results in close-packed structures, which is consistent with *pairwise* interactions. Unlike the close-packed structures, the diamond structure is open and each atom is bonded to four nearest neighbors. The forces here are not pairwise and are angularly dependent. The existence of a stable open structure such as diamond is a strong signature for the existence of quantum-mechanical forces. Classical forces that arise from purely Coulombic interactions would be pairwise in nature and would lead to close-packed structures.

1.4.1. Classical Chemical Bond in Solids. The origin of the traditional covalent bond is from the sharing of electrons between two atoms. Organic chemistry is usually considered the domain for the study of the covalent bond. This is true in some sense; inorganic covalent solids are rare. Consider that of the 100-plus elements that form solids, fewer than a dozen form covalent solids. Nonetheless, the covalent bond is crucial to understanding the behavior of semiconductors and superconductors.

In Fig. 1, the valence charge density is presented for both carbon and silicon in the diamond structure. Carbon is unusual in that the covalent bond between the atoms consists of a "double hump" as opposed to the single maximum in the silicon structure. This difference arises from differences in the core electronic structure of carbon as opposed to silicon, i.e., carbon has no *p* states in the core; silicon does.

If the number of nearest neighbors in a crystal equals the number of valence electrons, then localized covalent bonds may be formed (Pauling, 1960). In the diamond structure the number of nearest neighbors is four. If we were to consider a hypothetical structure for silicon such as simple cubic which has six nearest neighbors, we would expect silicon to be a metal in this structure. The number of valence electrons present would not saturate the bond. Partially filled bonding orbitals allow electrons to be easily propagated through



Valence charge density (110 plane)

FIG. 1. Contour plot of the valence charge density of carbon and silicon from Yin and Cohen (1982). The core states have been omitted from the plot. The density is normalized to the number of electrons in the unit cell.

the solid, creating a metallic crystal. Quantum calculations have verified this picture.

1.4.2 Example of the H_2 Molecule. The energetics of the covalent bond can be addressed best from a quantum-mechanical perspective. One of the first cases to be examined was the hydrogen molecule. This is the simplest system that illustrates the covalent bond and includes electron-electron interactions.

The molecule contains four interacting particles: two protons and two electrons. To determine the binding energy of this system, we solve the Schrödinger equation for the electronic wave functions and energy levels. The Hamiltonian for the electronic interactions is easy to write down:

$$\mathscr{H}(\mathbf{r}_1,\mathbf{r}_2)=-\frac{\hbar^2\nabla_1^2}{2m}-\frac{\hbar^2\nabla_2^2}{2m}-\frac{e^2}{r_1}-\frac{e^2}{r_2}-\frac{e^2}{|\mathbf{R}-\mathbf{r}_1|}-\frac{e^2}{|\mathbf{R}-\mathbf{r}_2|}+\frac{e^2}{|\mathbf{r}_1-\mathbf{r}_2|}. \qquad (8)$$

The first two terms correspond to the kinetic energy of the electrons, and the last five terms correspond to the electron-proton and electron-electron interactions. The protons are assumed to be at rest and a distance R apart.

The separation of the nuclear coordinates from the electronic coordinates is a consequence of the Born–Oppenheimer approximation. In this approximation, one assumes the electronic motions are so rapid, as compared to the nuclear motions, that the electrons respond instantaneously to a fixed set of nuclear coordinates. This approximation works better for heavier nuclei, as one would expect.

A quantum mechanical treatment of the hydrogen molecule was performed by Heitler and London (1927). The first step in their treatment is to write an approximate wave function for the molecule. Their wave function is based on assuming the molecular wave function could be written as follows:

$$\Psi(\mathbf{r}_1,\mathbf{r}_2)=a_1\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2)+a_2\phi_b(\mathbf{r}_1)\phi_a(\mathbf{r}_2), \qquad (9)$$

where ϕ_a (ϕ_b) is a hydrogenic wave function centered on the a (b) proton. The first term in Eq. (9) can be interpreted as electron 1 localized on proton a and electron 2 localized on proton b. The reverse situation is also possible so we include this term in our wave function.

The binding energy of the molecule can be found by solving a simple 2×2 determinant for the parameters a_1 and a_2 in Eq. (9). The results for the electronic energies and wave functions are given by

$$E_{\pm}=\frac{H_{11}\pm H_{12}}{1\pm S_{12}}$$

and

$$\Psi_{\pm}=\frac{\phi_a(1)\phi_b(2)\pm\phi_a(2)\phi_b(1)}{\sqrt{2(1\pm S_{12})}}, \tag{10}$$

where $\phi_a(1)=\phi_a(\mathbf{r}_1)$, $\phi_a(2)=\phi_a(\mathbf{r}_2)$, etc., and H_{11}, H_{12}, and S_{12} are defined as

$$H_{11}=\int\int \phi_a(1)\phi_b(2)\mathscr{H}(1,2) \times\phi_a(1)\phi_b(2)d^3r_1d^3r_2,$$

$$H_{12}=\int\int \phi_a(1)\phi_b(2)\mathscr{H}(1,2) \times\phi_a(2)\phi_b(1)d^3r_1d^3r_2,$$

$$S_{12}=\int\int \phi_a(1)\phi_b(2)\phi_a(2)\phi_b(1)d^3r_1d^3r_2.$$

The matrix elements H and S were evaluated using the hydrogen-atom wave function: $\phi(r)=\exp(-r/a_0)/\sqrt{\pi}a_0^{3/2}$, where a_0 is the Bohr radius (i.e., 0.529 Å). H and S are only functions of the interatomic distance and the electron charge and mass. The two signs in Eq. (10) correspond to "bonding" for the + sign and "antibonding" for the − sign. If the molecule is in the antibonding state, the electronic interactions are purely repulsive. The state with attractive electronic interactions corresponds to the bonding state. The corresponding wave function is Ψ_+, i.e., the symmetric combination. By the Pauli principle the wave functions must be antisymmetric upon exchange of the two electrons. Thus, the spin part of the wave function must be antisymmetric, i.e., the electrons must have opposite spin. For Ψ_- the electrons have parallel spin. The difference of the interaction energy between parallel and antiparallel electron spins is called the "exchange interaction."

To evaluate the binding energy of the molecule, we must add to the electronic energy the proton-proton interaction energy:

$$E_{\text{binding}}=\frac{e^2}{R}+\frac{H_{11}+H_{12}}{1+S_{12}}. \tag{11}$$

The binding energy as a function of the interatomic distance is plotted in Fig. 2. The minimum energy occurs at $R_0=0.8$ Å and the difference in energy from the isolated hydrogen atom is about 3.2 eV. The corresponding values from experiment are 0.74 Å and 4.75 eV. We also show in Fig. 2 the energy of the molecule if the electrons were in the antibonding state. The interaction between electrons of parallel spins (paired electrons) is always repulsive compared to the isolated hydrogen atoms.

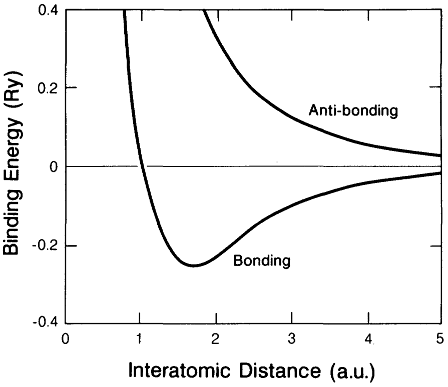


FIG. 2. Energy of the hydrogen molecule as a function of interatomic distance. The most stable curve is the bonding state where the electrons are of opposite spin. The antibonding state occurs if the interacting hydrogen atoms have the same spin. After Heitler and London (1927).

In Fig. 3, the electron distribution functions for the bonding and antibonding states are sketched. The square of the wave function is related to the probability of finding the electron in a given region of space. From Fig. 3, the probability of finding the paired electrons (bonding electrons) between the two atoms is much higher for the bonding than for the antibonding state.

1.4.3 Solid-State Treatments of the Covalent Bond. Although the agreement between experiment and the Heitler–London theory is only fair by contemporary standards (McLean *et al.* 1960), the basic principles of the covalent bond were demonstrated. Electrons of opposite spin can pair up to form a covalent bond between like species of open-shell atoms. For the solid state, the problem is compounded by the number of interacting atoms. However, the essential features are the same.

To handle the large number of electrons and nuclei in solids, an additional approximation is usually incorporated beyond the Born–

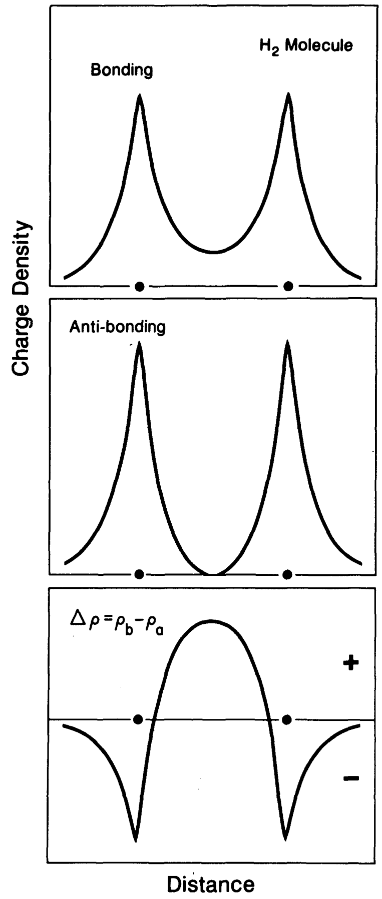

FIG. 3. Schematic charge density for the bonding and antibonding states of the hydrogen molecule. Also shown is the charge density difference between the bonding and antibonding states. The bonding state puts more charge between the atoms.

Oppenheimer approximation. The "one-electron" (or Hartree) approximation treats the interaction of an electron in the solid by averaging over the motion of all the other electrons in the solid. With this approximation, the Schrödinger equation is written as

$$\mathscr{H}\Psi=\left(-\frac{\hbar^2\nabla^2}{2m}+V(\mathbf{r})\right)\Psi(\mathbf{r})=E\Psi(\mathbf{r}). \qquad (12)$$

One of the chief efforts in theoretical investigations of solids concerns the construction of accurate one-electron potentials. Various approximations have been used to address this issue, which is called the "many-body" potential problem. A useful approximation is to assume an effective potential for the exchange energy. Often, this effective potential is based on the electron distribution function, or the electron charge density. Such theories are called "density-functional" theories (Hohenberg and Kohn, 1964) (see ELECTRONIC STRUCTURE OF SOLIDS).

Given Eq. (12), it is often convenient in the solid state to form wave functions from combinations of atomic orbitals matching the symmetry of the neighboring atoms (Madelung, 1981). Crystalline silicon forms in the diamond structure, which has four nearest neighbors arranged in a tetrahedral pattern. The ground-state configuration of silicon is $3s^2 3p^2$. From the two s and two p orbitals, one can form so-called sp^3 hydrids. Such a combination is often very accurate for the covalent bond. For silicon, one might write

$$\begin{aligned}
\Psi_1&=(s+p_x+p_y+p_z)/2,\\
\Psi_2&=(s-p_x-p_y+p_z)/2,\\
\Psi_3&=(s+p_x-p_y-p_z)/2,\\
\Psi_4&=(s-p_x+p_y-p_z)/2,
\end{aligned} \qquad (13)$$

where (s,p_x,p_y,p_z) are atomic wave functions for the valence states in silicon. Other common combinations of wave functions are sp^2 (trigonal planar), d^2sp^3 (octahedral), and d^4sp^3 (dodecahedral). Carbon can exhibit both sp^2 and sp^3 bonding in graphite and diamond structures, respectively. Linus Pauling (1960) was one of the first to recognize the correspondence between orbital symmetry of the bonding orbitals and the resulting structure.

1.5 Metallic Bonds

Metals are fundamentally different from the solids we have discussed. Unlike van der Waals solids, ionic crystals, or covalent crystals, metals have electrons not localized on atoms (or ions), or in a bond. Simple wave-function descriptions based on Eq. (13) are inappropriate for delocalized, or metallic, bonds. The electrons are free to traverse the solid at large. The resistivity of a metal ranges from zero for a superconductor to about 10^{-2} Ω cm. From 10^{-2} to about 10^9 Ω cm, the solid is a semiconductor, and above 10^9 Ω cm the solid is considered an insulator. Another important distinction between a metal and a semiconductor (or insulator) is that as the temperature of the solid is increased, the conductivity of a metal is reduced, whereas for a semiconductor the conductivity increases. The conductivity of the semiconductor increases because as the temperature of a solid increases, the electronic energy increases. This increase in energy can be exhibited by exciting an electron out of a bond and into a delocalized state that can conduct electricity. In the language of band theory, the electron is excited from a completely filled valence band to an empty conduction band. For a metal, the temperature increases the possibility of a lattice vibration (phonon) scattering an electron, thereby inhibiting its flow through the solid, but does not change the accessibility of the empty states.

From a bonding point of view, if the solid has more nearest neighbors than valence electrons, then an elemental crystal is usually a metal. The covalent bonds cannot be saturated by the available number of electrons. (Inert gases are the notable exception, as the constituent atoms possess closed shells).

1.5.1 Delocalized Electrons. The cohesive energy of metals is attributed to a delocalization of the valence electrons of the atoms into wave functions that extend throughout the solid. By "delocalizing" an electron over several atoms the kinetic energy of the electron is reduced and the electronic energy of the solid is lowered. As a very simple example, consider an electron localized in a cube. The lowest-energy state of this electron is given by $E_0 = 3(h^2/8mL^2)$, where L is the length of the cube. If the length of the cube is doubled, E_0 is reduced to $E_0/4$.

1.5.2 Wigner–Seitz Method. Eugene Wigner and his first graduate student, Frederick Seitz, were among the first to account for the cohesive energy of a simple metal. Their paper "On the Constitution of Metallic Sodium" was published in 1933 in *The Physical Review*. This paper presented a simple model for calculating the electronic structure of sodium. A key feature was to view the crystal as being composed of identical cells that surrounded single metallic ions (see ELECTRONIC STRUCTURE OF SOLIDS). The conduction electron in each cell would interact only with the ion within the given cell.

Wigner and Seitz (1933,1934) considered the cell to be spherical and equal in volume to the primitive crystallographic cell. At the cell boundary they assumed the derivative of the wave function must vanish:

$$\left.\frac{\partial \Psi(r)}{\partial r}\right|_{r=R_0} = 0, \tag{14}$$

where R_0 is the size of the Wigner sphere. This approximation is appropriate for close-packed metals such as fcc, hcp, or bcc structures. For bcc sodium, $R_0 = 3.95$ Å.

Wigner and Seitz suggested the reason metals cohered was that their wave functions were probably "smoother" than the wave functions of isolated atoms. In a free atom the wave function of the electron must go to zero at large distances, whereas in the solid it does not. The boundary condition in Eq. (14) reduces the curvature of the wave function at the cell boundary relative to the atomic limit. The reduction in curvature reduces the kinetic energy of the electron relative to the free atom. (Recall that the quantum-mechanical operator for the kinetic energy is the curvature of the wave function. Little curvature or "smooth" wave functions have less kinetic energy than rapidly oscillating wave functions.) The reduced kinetic energy leads to the binding in Na and other metals. The cohesive energy determined by the Wigner–Seitz method is about 1 eV/atom. This number agrees with experiment.

The Wigner–Seitz paper was important as one of the first papers to calculate the cohesive energy of a *real* material, as opposed to an idealized model. Moreover, it spelled out in some detail how to proceed in a logical progression to determine the properties of a metal. In this sense, their paper marked the beginning of the application of electronic structure theory to the quantitative prediction of materials properties.

Cohesion in transition metals and rare-earth metals is more complex than in simple metals such as sodium. In transition metals, the *d* orbitals are sufficiently localized to form "covalent"-like bonds between the atoms.

1.6 Mixed Bonding in Solids

We have concentrated on archetypical examples of bonding as a guide to explaining the cohesive energy of a solid. However, real solids are not perfectly ionic or covalent or metallic. The constituents of all solids are nuclei and electrons which interact via the Coulomb law subject to the Pauli principle. The imposition of terms such as "ionicity" or "covalency" on the chemical bond is useful only so far as it aids us in predicting the properties of solids.

Even in elemental solids, one can have "mixed" bonding. Carbon in the graphite structure shows strong covalent bonding within the graphitic planes, whereas between the planes van der Waals forces are thought to be important. The intraplanar bonds are thought to be among the strongest covalent bonds formed for any solid; the interplanar bonds are among the weakest solid-state bonds.

An important theory for examining semiconducting or insulating solids has been developed by Phillips (1973). He applied a dielectric theory to describe the fractional ionicity of the chemical bond in binary crystals of the form $A^N B^{8-N}$, where A and B are not transition metals, and N is the number of valence electrons on the cation. Ionicity is a measure of the charge transferred from one atom to another upon the formation of a chemical bond. This method has been very useful in predicting chemical trends in solids, including heats of formation. This theory is based on dividing the "average optical gap" in the AB crystal into a covalent and ionic contribution. The average optical gap corresponds to the energy at the maximum photon absorption in the optical spectrum of a solid. In the dielectric theory the ionicity of a crystal is of the form

$$f_i = C^2/(E_h^2 + C^2), \qquad (15)$$

where C is the ionic contribution to the gap and E_h is the covalent contribution. The average gap, E_{gap}, is given by $E_{\text{gap}}^2 = C^2 + E_h^2$. If the optical spectra are measured, this determines E_{gap}. E_h can be found by scaling the covalent contribution with the lattice constant of a perfectly covalent solid such C, Si, Ge, or Sn.

For elemental crystals such as silicon, $C = 0$, and the ionicity of the crystal $f_i = 0$. For a highly ionic crystal such as RbF, $C \gg E_h$ and $f_i \approx 1$. It can be shown that this ionicity scales roughly as $f_i \approx 1 - N_a/4$, where N_a is the number of valence electrons on the free-atom cation. In Table 5 ionicity values for some common semiconducting crystals are given.

Another successful theory for covalent solids treats a solid as a "large molecule." The wave functions for the solid are handled as in Eq. (13). The various matrix elements that enter the theory are parametrized or extracted from simple scaling arguments (Harrison, 1980).

Table 5. Phillips's ionicity parameters for selected tetrahedral semiconductors. From Phillips (1973).

Crystal	E_h (eV)	C (eV)	E_{gap} (eV)	f_i
C	13.5	0	13.5	0
Si	4.77	0	4.77	0
Ge	4.31	0	4.31	0
Sn	3.06	0	3.06	0
BP	7.44	0.68	7.47	0.006
AlSb	3.53	2.07	4.41	0.250

HgS	3.76	7.3	8.3	0.79

In intermetallic alloys, the interplay between ionic, metallic, and covalent contributions can be complex. For example, CsAu is an intermetallic compound that is strongly ionic and is a semiconductor. NaTl can be thought to contain elements of covalent, ionic, and metallic binding simultaneously (Anderson, 1963).

In Table 6, we summarize the types of bonding that lead to cohesion in solids.

1.7 Noncrystalline Solids

Another issue that increases the complexity of understanding cohesion comes from noncrystalline solids such as glasses. Normally when solids are formed from the melt, a discontinuous change in the structure occurs. However, when a material forms from a normal liquid state and shows no discontinuous change, it is called a glass. A glass becomes more rigid through a progressive increase in its viscosity. In principle, a liquid cannot support a shear whereas a solid does. In practice, a liquid whose shear viscosity is greater than about 10^{13} P is called a glass. This value defines the boundary between the liquid and glassy state (Kittel, 1976; Jones, 1971; Goldstein and Simha, 1976). Glasses are char-

Table 6. Properties of the chemical bond in the solid state, after Anderson (1963).

Type of chemical bond	Examples	Origin of cohesion	Properties	Occurrence
Molecular	Xe,Ne,N_2	Fluctuating dipoles	Good insulator, weak binding, close-packed structures	Rare gases, halogen dimers
Hydrogen bond	H_2O,$[HF_2]^-$	Bare proton bond	Fairly weak bonds, loose structures. Peculiar dielectric properties	H with electronegative elements such as O or F
Ionic	NaCl,CsCl	Electrostatic attraction between closed-shell ions	Strong bonds, close-packed structures, ionic conduction	Electropositive with electronegative elements
Metallic	Na,Mg,Al	Lowered kinetic energy; delocalized bonds	Moderate to strong bonds, high conductivity, close-packed structures	Most common bond of elemental solids
Covalent	C,Si,Ge	Shared electrons, exchange forces important	Hard, open structures, strong bonds	Uncommon, tetravalent elements

acterized by a lack of crystalline order as evidenced by the absence of sharp x-ray diffraction patterns. Glasses may have one or two diffuse rings in the x-ray diffraction pattern, which is in contrast to the sharp rings of polycrystalline aggregates. Glasses also have the elastic properties of an isotropic solid.

Glasses, or amorphous solids, are often formed by rapid cooling. In Fig. 4, a schematic volume-versus-temperature curve is illustrated for a glassy material. With rapid cooling, the individual atoms have not had time to assume the lowest-energy structure; the resultant structure is often noncrystalline. Although a glass may not be in absolute thermodynamic equilibrium, it may be stable for extended periods of time with respect to the crystalline state.

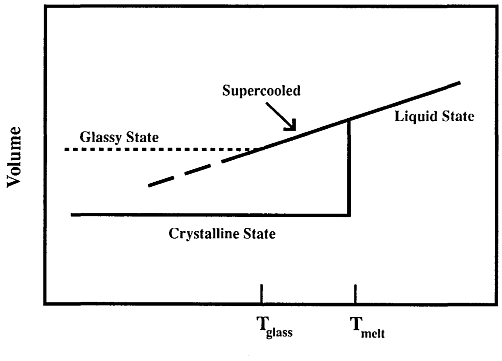

FIG. 4. Schematic volume-vs-temperature relation for a glassy material. The liquid may be supercooled below the melting point T_{melt}. At the glass transition temperature T_{glass}, the supercooled liquid becomes a glass. The details of the glass transition are somewhat dependent on the cooling rate. [Kittel (1976).]

Thus, it may be possible to discuss quasiequilibrium thermodynamic variables, e.g., a glass transition temperature. The microscopic structure of glassy solids is poorly understood and is a contemporary research topic. One suggestion for the structure of a glassy solid is that such a solid is really a disordered assemblage of microcrystallites. Another suggestion is that such a structure is a continuous network with short-range order. The lack of detailed structural information greatly inhibits our understanding of these materials.

One promising approach to remedy this situation is to model interatomic forces, or use quantum mechanics to find the true interatomic forces. These forces are then used within molecular dynamics simulations (Ciccotti *et al.*, 1987) to model the crystallization process. In this approach, the atoms are given initial velocities corresponding to a high temperature. The classical trajectories are computed as a function of time. The kinetic energy of the assemblage is lowered systematically, corresponding to a reduced temperature. Initially, if the temperature is above the melting point, the system will correspond to a liquid. As the temperature is reduced below the melting point, the system will solidify. If this process could be performed slowly, the solid-state form could be crystalline. However, the time scale for computer simulations are often orders of magnitude shorter than the experimental times for crystallization. Hence, the final solid state is invariably amorphous. In addition to the problem of time scales, several issues have limited this technique. One is the construction of accurate interatomic potentials, or quantum-mechanical forces. This is particularly true of covalent solids where the interaction between atoms is not pairwise.

2. TOTAL-ENERGY CALCULATIONS OF THE COHESIVE ENERGY

In 1929, the famous physicist P.A.M. Dirac wrote: "The underlying physical laws necessary for the mathematical theory of ... the whole of chemistry are thus completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble." This has been the case until recently. While some approximations are necessary, to handle many-body forces such as exchange and correlation, it is now possible, for many solid-state systems, to determine without experimental input the cohesive energy of a crystalline solid.

Two major advances have contributed to the present capabilities. First, fast computing machines now allow complex equations to be solved. A second advance was the construction of simple potentials for handling exchange and correlation. (*Correlation* interactions are any many-body terms other than *exchange*.) These advances allow the total electronic energy of an atom in the solid and the energy of an isolated atom to be computed. These two values known, the cohesive energy is determined from the difference.

The spatial and the energy distribution of electrons in solids must be known to compute the total energy of a solid. These distributions can be determined by a solution of the one-electron Schrödinger equation:

$$\left(\frac{-\hbar^2\nabla^2}{2m}+V_{\text{ion}}(\mathbf{r})+V_{\text{H}}(\mathbf{r})+V_{\text{xc}}(\mathbf{r})\right)\Psi(\mathbf{r})$$
$$=E\Psi(\mathbf{r}). \qquad (16)$$

The first term corresponds to the kinetic energy. $V_{\text{ion}}(\mathbf{r})$ is the bare potential of nuclei. $V_{\text{ion}}(\mathbf{r})$ can also be taken to be an effective potential that includes the potential of the bare nuclei plus the tightly bound core electrons, i.e., a pseudopotential (Cohen and Chelikowsky, 1989). $V_{\text{H}}(\mathbf{r})$ is the electrostatic potential that can be solved from the Poisson equation. $V_{\text{xc}}(\mathbf{r})$ is the exchange-correlation energy, which is taken to be a functional of the charge density. The total energy of the crystal can be determined by the following expression:

$$E_{\text{total}}=\sum_i E_i-\frac{1}{2}\int \rho(\mathbf{r})V_{\text{H}}(\mathbf{r})d^3r+\int \rho(\mathbf{r})$$
$$\times[\epsilon_{\text{xc}}(\mathbf{r})-V_{\text{xc}}(\mathbf{r})]d^3r+E_{\text{ion-ion}}, \qquad (17)$$

where the charge density is given by

$$\rho(\mathbf{r})=\sum_{\text{occupied}} |\Psi(\mathbf{r})|^2,$$

summing over the occupied states. The lead term in Eq. (17) is a sum over occupied energy levels. The second term is to subtract off double-counting terms. The exchange and correlation terms require some care: The potential energy term has been subtracted from the total-energy expressions, and the energy density ϵ_{xc} has been added.

The total-energy expression in Eq. (17) is nontrivial to evaluate as the electrostatic terms diverge individually. If we have an infinite solid, then we have an infinite number of nucleus–nucleus and electron–electron interactions. These terms can be handled by an Ewald summation method.

Table 7 illustrates the accuracy of this method for some elemental solids. The determination of the cohesive energy is the most difficult part of these calculations. The total energy of the solid and atom is determined by independent calculations and the energy difference taken. The local-density approximation is expected to be accurate to about ≈10%. If the error in the atom and the error in the solid are in the same direction, then the cohesive energy can be quite accurate. Typically, the cohesive energy determined in this manner is in error by about 5%–10%. Generally, the cohesive energy determined by this method is greater than the experimental value.

3. HIGH-PRESSURE TRENDS IN COHESION

If we can predict the cohesive energy of a solid as a function of pressure, then we can compare to pressure measurements. Specifically, if we determine the cohesive energy for different crystal structures as a function of volume, we can predict which structure will be most stable as a function of pressure.

Table 7. Calculated cohesive energies and structural properties for selected elemental solids (Yin and Cohen, 1982; Chelikowsky *et al.*, 1986; Chelikowsky and Chou, 1988). In the case of ruthenium, two lattice parameters are required to specify the hexagonal-close-packed (hcp) structure (Kittel, 1986).

Crystal	Lattice parameters (Å)	Cohesive energy (eV/atom)	Bulk modulus (10^{11} N/m^2)
Carbon (diamond)			
Theory	3.60	8.10	4.33
Experiment	3.57	7.35	4.43
Silicon (diamond)			
Theory	5.45	4.84	0.98
Experiment	5.43	4.63	0.99
Germanium (diamond)			
Theory	5.66	4.26	0.73
Experiment	5.65	3.85	0.77
Ruthenium (hcp)			
Theory	2.68(a) 4.16(c)	7.70	3.5
Experiment	2.71(a) 4.28(c)	6.62	3.2
Copper (fcc)			
Theory	3.62	3.83	1.88
Experiment	3.60	3.50	1.42

This area has been a successful use of cohesive energy computations. Many calculations now exist for elemental solids and simple compounds; they are quite accurate when compared to experiment (Yin and Cohen, 1982; Moruzzi *et al.*, 1978). In Fig. 5, the total energy of silicon in various crystal structures is shown as a function of volume. This calculation was one of the first total-energy calculations to reproduce accurately the phases of silicon. A typical pressure-versus-volume relationship is given by the Murnaghan (1944) equation of state:

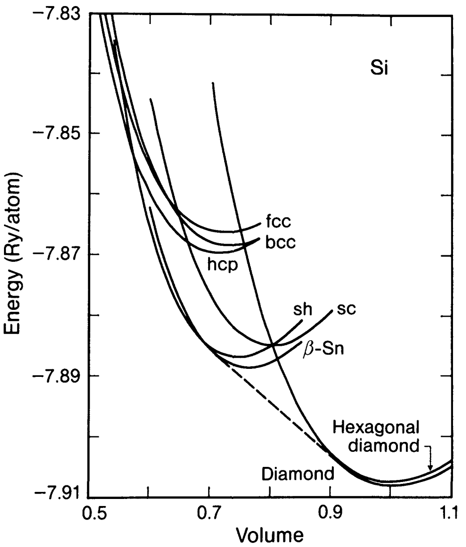

FIG. 5. Calculated equations of states for silicon in various crystal structures. The volume has been normalized to the experimental atomic volume (20.0 Å^3). [Yin and Cohen (1982).]

$$P(V)=\frac{B_0}{B_0'}\left[\left(\frac{V_0}{V}\right)^{B_0'}-1\right], \tag{18}$$

where P is the pressure, B_0 is the equilibrium bulk modulus, B_0' is the pressure derivative of the bulk modulus, and V_0 is the equilibrium volume. Values for V_0, B_0, and B_0' can be determined from fitting the calculated energy versus volume to an equation-of-state function.

In Fig. 5, several polytypes of silicon are considered. The lowest-energy structure is the diamond structure. As the pressure increases, we might expect that closer-packed structures would become stable versus the open diamond structure. This is the case. As the pressure increases, the white-tin or β-Sn structure becomes more stable than the diamond structure. The white-tin structure is a transition structure between diamond and more close-packed structures. The number of nearest neighbors is four, but the two next-nearest neighbors are only 5% more distant. The theoretical transition pressure where diamond transforms to β-Sn is near 10 GPa; this pressure is in good agreement with experiment. At higher pressures, other structures have lower energies than diamond or β-Sn.

Total-energy calculations predicted successfully that hexagonal-close-packed silicon would be stable at higher pressure, i.e., in the range of 40 GPa. Also, high-pressure superconducting forms of silicon were predicted using total-energy methods.

4. CHEMICAL TRENDS IN COHESION AND STRUCTURE

While total-energy, or cohesive-energy, computations are useful for predicting the most stable crystalline phase, these methods are computationally intensive. Empirical methods have been developed that provide a "global" perspective without the computational complexity. For example, the surface energy of an elemental metal, J, can be estimated by $J \approx E_{\text{cohesive}}/V_a^{2/3}$, where E_{cohesive} is the cohesive energy and V_a is the atomic volume. While this expression is only an estimate, it is probably as accurate as any experimental or computational method. Correlations of metallic properties such as surface segregation with these empirical surface energies have been quite successful (de Boer *et al.*, 1988).

Cohesive energies of elemental solids also correlate roughly with the melting points and the bulk moduli. Intuitively, this seems reasonable. High cohesive energies imply strong bonds. Concurrently with strong bonds one expects resistance to compression and thermal disruption. Examples of this are given in Table 1 where the melting points and the bulk moduli for elemental solids are compared to the cohesive energy. As extreme examples, osmium has a cohesive energy of 8.2 eV/atom, a melting point of 3306 K, and a compressibility of about 0.02×10^{-10} m^2/N; for neon the cohesive energy is 0.02 eV/atom, the melting point 25 K, and the compressibility 10.0×10^{-10} m^2/N.

Another example of how such chemical trends can be important involves the search for "superhard" solids. For example, carbon in the diamond structure is much harder than any other material. Corundum is the mineral ranked next below diamond on the hardness scale devised by Mho. Cubic boron nitride, a synthetic material, is at least as hard as corundum and is the second hardest material. Nonetheless, boron nitride is only half as hard as diamond (Bundy, 1974).

Such materials have great technological applications, e.g., making drill bits or protecting electronic devices with superhard films (Bundy, 1974; Sarin, 1987). Often superhard materials are very brittle, and the mechanical properties may be dominated by defects. A contemporary research topic is the use of modern computational methods for cohesive energies to predict the "hardness" of a hypothetical crystal (Sarin, 1987). An example of this effort is given by Liu and Cohen (1989). This work has centered on low-compressibility covalent solids such as diamond and boron nitride. A key relationship used in this study is that the compressibility scales with the nearest-neighbor distance, R, as $R^{3.5}$. Short bond lengths, which correlate with a large cohesive energy, also characterize solids with low compressibilities. Experimentally, there has been considerable interest in growing diamond films (Sarin, 1987; Moustakas, 1989) (see DIAMOND AND DIAMONDLIKE MATERIALS).

A related issue to understanding the chemical forces that lead to cohesion is to construct indices by which to judge whether two solids have similar chemical bonds. This approach is similar to the Phillips ionicity theory discussed in Sec. 1.6. If an index can be found that suggests that the bonding of one solid is "very similar" to another in some quantitative sense, then one would expect the properties of the two solids to be similar. For example, if the atomic volume and electronegativity of two atoms are similar, one expects the respective solids to have similar structures and cohesive properties. Pauling pioneered this effort by the development of electronegativity and atomic radius scales (Pauling, 1960).

Quantitative indices have been developed that accurately predict many structural properties of binary semiconductors and insulators. Many of them are based on a pseudopotential model of a solid. In this model, the valence and core electrons are treated separately. The tightly bound core states are considered to be inert. The pseudopotential reproduces only the valence charge densities of the solid. This type of potential can be used to determine orbitally dependent radii, i.e., radii are different for *s*, *p*, and *d* electrons. Correlations between the cohesive energies and structural energies of simple binary solids with orbital radii have been quite successful. In Fig. 6, we illustrate how the structural energies of binary solids can be systematized

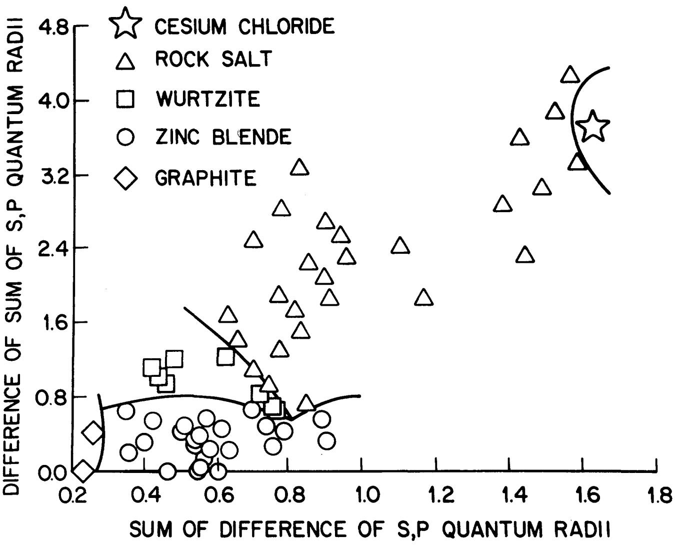

FIG. 6. Quantum structural diagram that systematizes the most stable crystals of simple binary solids. Orbital radii based on pseudopotentials are used as chemical indices to characterize the solid-state bonding. Five different crystal structures are separated on this diagram. The abscissa corresponds to the sum of the difference of the *s,p* radii, i.e., $|r_p - r_s|_A + |r_p - r_s|_B$, and the ordinate corresponds to the difference in the sum of the *s,p* radii, i.e., $|(r_p + r_s)_A - (r_p + r_s)_B|$. $(r_p, r_s)_A$ correspond to the *s*- and *p*-orbital radii for atom *A*. [St. John and Bloch (1974)].

by orbital radii. These types of plots are called *quantum-structural diagrams.* In Fig. 6, if two binary solids share similar combinations of ionic radii, the solids can be expected to have similar structures. One of the most surprising results of this diagram is that the wurtzite and zinc-blende structures can be separated into two domains. These structures differ only with respect to the third nearest neighbors. It would be very difficult to distinguish these two structures with *ab initio* total-energy calculations.

A similar scheme based in part on electronegativities, orbital radii, and the number of valence electrons has been applied to intermetallic binary, ternary, and even some quaternary compounds. It is possible to predict cohesion in hypothetical solids via such schemes. Many of these hypothetical solids have later been found to be stable (Villars and Calvert, 1985).

GLOSSARY

Born–Oppenheimer Approximation: The electronic and nuclear coordinates can be separated in a solution of the Schrödinger equation.

Cohesive Energy: The energy necessary to separate a solid into its constituent atomic species to free atoms at 0 K and 1 atm.

Covalent Bond: A bond formed by the sharing of two electrons with opposite spins.

Dielectric Theory of the Covalent Bond: A theory of the covalent bond based on the optical spectra of tetrahedral semiconductors. It is used to define an ionicity scale.

Exchange Interaction: A spin-dependent Coulomb energy. The spin nature of this Coulomb interaction arises from the Pauli principle.

Hydrogen Bond: A largely ionic bond in which a bare proton stabilizes an interaction between two negatively charged ions.

Ionic Solid: A solid that coheres through the electrostatic interaction of charged ions.

Ionicity: A measure of the charge transferred from one atom to another upon the formation of a chemical bond.

Lattice Energy: The energy necessary to separate an ionic solid into free ions at 0 K and 1 atm.

Lennard–Jones Potential: A pairwise potential commonly used to model the interactions between inert-gas atoms. The form of this interaction between two atoms is $U(R) = 4\epsilon[(\sigma/R)^{12} - (\sigma/R)^6]$, where R is the interatomic distance, ϵ is the binding energy, and σ is a parameter that characterizes the interaction range.

Madelung Constant: A structurally dependent constant determined by the summation of the Coulomb interactions in an ionic crystal.

Metallic Bond: A bond formed by the lowering of the kinetic energy of the conduction electrons.

Pauli Principle: A fundamental law of quantum mechanics: two electrons cannot have the same quantum numbers.

van der Waals Forces: Attractive interaction between closed-shell atoms or molecules. Arises from the interaction of dynamical dipoles.

Wigner–Seitz Method: One of the first methods for quantifying the cohesive energy of simple metals.

INTRODUCTION

The simplest model used to understand the properties of a solid is in terms of a collection of independent electrons and harmonic phonons. (See ELECTRONIC STRUCTURE OF SOLIDS; PHONONS IN CRYSTAL LATTICES.) When the interaction between pairs of particles is taken into account, a dichotomy ensues. On the one hand, the particles are turned into "quasiparticles." These quasiparticles have weak interaction between each other so that they can be treated like independent particles although the properties of each quasiparticle may not have the same numerical values as the individual electron or phonon. We use the field-theory term of the particle having been dressed or renormalized. For example, the low-temperature electronic contribution to the specific heat may still be considered as that of a collection of noninteracting fermions, with, however, a heavier mass than the free-electron mass. There is a large class of properties of a solid which may be understood on the

basis of these quasiparticles. On the other hand, there are phenomena which involve collective motion of the particles of the system, which are possible only because of the interaction between the particles. The aim of this article is to provide a physical understanding of both aspects of the consequence of the particle interaction. It is not a treatise on many-body techniques for computing the interaction effects, nor is it a complete catalog of all the collective phenomena in solids. It attempts to explain a few key concepts in the many-body theory upon which is built the understanding of the renormalization of the particle and of a number of important collective phenomena.

We begin with the introduction of the concept of exchange and correlation and of conceptual tools needed to describe the collective motion and the single-particle renormalization. An important tool is the linear response function, the change of a property of the interacting system to first order in the external perturbation. A collective mode is deduced from the resonance behavior of a linear response. The ground-state energy of a system contains the effects of interaction. The analysis of the contributions such as exchange and correlation is simplest to illustrate in the homogeneous electron gas, a model of a solid in which the crystal lattice is replaced by a uniform background of positive charges. To cope with the total energies in real solids, the density-function theory is introduced. How a quasiparticle in an interacting electron system is formed is described in terms of the linear response of the system to the addition or removal of an electron.

The collective excitations in a homogeneous electron gas (Sec. 2) provide an excellent introduction to the collective behavior in general and a good model for the simple metals where these modes have been observed. An examination of the linear density response yields the plasma oscillation and the Kohn effect in lattice vibrations. The Landau Fermi-liquid theory is a powerful phenomenological theory which treats the low-lying excited state of an interacting-fermion system. It is used to bring forth the quasiparticle properties and the low-energy collective modes such as the magnetoplasma waves and the spin waves formed in a sea of mobile electrons.

In a solid, the electronic structure consists of a number of energy bands. The transition of an electron from one band to another due to excitation by light is influenced by the interaction with the other electrons in the system. One interaction effect in an insulator or semiconductor may be described as the attraction between the excited electron and the "hole" left behind, forming a hydrogen atom-like object called the exciton. An intense light source can excite a large number of excitons which condense into a two-component plasma, termed the electron-hole droplet (Sec. 3.1). The collective modes in the electron-hole droplet illustrate excitations both in a two-component plasma and in a system of finite spatial extent. In a metal or a doped semiconductor, the conduction electrons react to the presence of the hole left behind by the optical excitation of an electron. Such a reaction leaves remarkable signatures (the Mahan singularities) in the optical spectrum. They are observed in metals and in doped semiconductor heterostructures in which the conduction electrons are confined to a two-dimensional layer (Sec. 3.2).

When nonlinear effects are taken into account, there are collective modes which cannot be described in terms of small disturbances as in the linear response theory. The solitary wave is an important example. Section 4 introduces the soliton solutions of two commonly occurring nonlinear equations, and physical examples in solids.

The ground state of the system upon which the edifice of collective phenomena is built is the "normal" state, which is close to the noninteracting particle state. Under different external conditions, such as temperature or pressure, a collective mode may become unstable, leading to the formation of a different ground state, such as the superconducting, magnetic, or ferroelectric state. For the properties of such states the reader is referred elsewhere in the *Encyclopedia* (see FERROELECTRIC DEVICES; FERROMAGNETISM AND FERRIMAGNETISM; HIGH-TEMPERATURE SUPERCONDUCTIVITY; SUPERCONDUCTIVITY, LOW-TEMPERATURE). The study of instabilities which presage the phase transitions is undertaken in Sec. 5 to introduce charge-density waves, structural transformations, spin-density waves, and the Wigner lattice, which in a two-dimensional system competes with the fractional quantum Hall state.

Each section begins with an overview of the subjects treated. Throughout the article, a few simple concepts have been used to describe a number of important collective modes, spanning one- to three-dimensional solids, as well as to provide an understanding of the idea of quasiparticles. These few important concepts and their illustrations are also meant to facilitate further pursuit in the literature of the collective phenomena not included here.

1. CONCEPTS IN INTERACTING SYSTEMS

For an independent particle, the potential determines its motion. The first approximation in an interacting system is to simulate the influence of the other particles by a potential. This is done first in the Hartree–Fock approximation. The effective potential then has two additional terms. The electrostatic potential due to the charge distribution of the other electrons is easy to understand. The second term is a nonlocal potential due to the exchange interaction of the electron with the others.

What the Hartree–Fock approximation misses is called the correlation effect. Although in principle it is possible to obtain the correlation with progressively more complicated many-electron wave functions, for solids this procedure has not been practical. It is also difficult to extract information on the collective excitations from further refinements of the wave function. A practical alternative for studying correlation effects and collective excitations is to use the idea of linear response. This concept is well known in circuit theory. One might, for instance, subject a circuit to a small ac voltage and measure the resulting change in current, from which some properties of the circuit may be deduced. In general, in responding to a weak external stimulus, a property of the system makes a small change. The ratio of the change to the external perturbation is, to the lowest order approximation, the linear response function, which is characteristic of the system. If the time dependence of the perturbation oscillates with a single frequency, a resonance behavior, i.e., a sharp rise in the response in the neighborhood of a particular frequency, signals the existence of a collective mode, which is self-sustaining without the external stimulus. From the frequency width of the resonance neighborhood, the lifetime of the collective mode may be deduced. A simple example is the plasmon (a quantum of plasma oscillation) as a resonance in the electron-density response to an oscillating electric field in a simple metal.

The total energy of a system is where the interaction effects are most easily delineated. The Hartree–Fock approximation represents a first step in including the interaction effects while maintaining the independent particle form in the ground state. To understand the correlation effect, a fruitful simplication is to remove the crystal lattice effect by replacing the lattice with a uniform positively charged background. In the resulting model, known as jellium (a shorter name for the homogeneous electron gas), the interaction energy is due entirely to the Coulomb interaction between electrons and may be separated into the exchange energy, which is due to the exclusion of electrons with the same spin and momentum, and the remainder called the correlation energy which includes the effect of repulsion between two electrons regardless of whether their spins are parallel or not. Analysis of the interaction energy in terms of the density response leads to the interpretation of the correlation energy partly as screening of the Coulomb potential in the exchange energy and partly as contribution from the zero-point energy of the plasma oscillations.

Quantitative computation of the correlation energy in jellium requires sufficiently draconian measures that extension of the same approach to real solids has only recently achieved acceptable accuracy for a couple of cases. The density-functional theory provides a widely used alternative approach for the real solids. The idea of the theory is to replace the role of the nuclear potential by the ground-state density distribution as the agent to characterize a system. Thus, one would specify a hydrogen atom not by the proton potential but by the electron density distribution of the 1*s* orbital. Then the philosophy of the Thomas–Fermi approximation may be used in approximating a small neighborhood of the system by jellium at the corresponding density. The important difference between the Thomas–Fermi approximation and the local-density approximation within the density-functional theory is that the latter applies the local approximation only to the local exchange and correlation energy and not to the kinetic energy, which provides a marked improvement in including the quantum effects.

Low-lying excited states of an interacting system may be enumerated by analogy with the independent-particle system. The entity corresponding to the independent particle is known as the quasiparticle, which possesses similar properties as the independent particle, such as mass, except that the values may be changed by the interaction effects. The concept of a quasiparticle is established by examining the response of the system to the addition or removal of an electron. The resonance pole in the response function as a function of energy yields the quasiparticle energy and the width of the resonance in energy gives the inverse lifetime of the quasiparticle. The particle in an excited state can decay by exciting other electrons. Phase-space restriction of the fermion system due to the Pauli exclusion principle causes the quasiparticles with energy near the Fermi energy (the smallest energy to add or remove a particle) to maintain their identity for a long time. The effect of all the other particles is lumped into the self-energy term, which is the extension of the Hartree–Fock potential to its most general form including velocity and time dependence (or, equivalently, spatially nonlocal and energy dependence) and the possibility of decay. The renormalized energy includes a term due to the electrostatic potential of all the particles and an exchange and correlation term.

The physical picture of exchange, correlation, the linear response, and collective excitations sketched here will be elaborated upon in the following sections.

1.1 Hartree–Fock Approximation

In adding interaction to a system of independent particles, the first approximation, both historically and conceptually, is to keep the role of the particles and to take into account the interaction effects by allowing each particle to be governed by an effective potential due to all the other particles. Thus, a wave function of a system of N noninteracting electrons is a Slater determinant of one-electron orbitals, which is an $N \times N$ determinant, with each row having the same orbital and each column having the same particle coordinates. The wave function vanishes if two orbitals are the same, thereby satisfying the Pauli exclusion principle. The Hartree–Fock approximation consists in finding the best set of one-electron orbitals in the Slater determinant representing the ground state. According to the variational principle, the best set is the one which yields the lowest total energy for the interacting system.

The resultant orbitals are given by a set of modified one-particle Schrödinger equations:

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + v(\mathbf{r}) + \int dr' \, \frac{e^2}{|\mathbf{r}-\mathbf{r}'|} \, n(\mathbf{r}') \right] \psi(\mathbf{r}) - \int dr' \, \frac{e^2}{|\mathbf{r}-\mathbf{r}|} \, n(\mathbf{r},\mathbf{r}')\psi(\mathbf{r}') = E\psi(\mathbf{r}), \tag{1}$$

where the spin summation is understood. Each electron moves under the combined influence of the external potential $v(\mathbf{r})$; the Hartree potential, which is expressed here as the electrostatic potential due to the electron density distribution $n(\mathbf{r})$ via the Coulomb interaction $e^2/|\mathbf{r}-\mathbf{r}'|$; and the nonlocal Fock exchange potential due to the one-particle density matrix $n(\mathbf{r},\mathbf{r}')$ as a consequence of the Pauli principle. Both the density and the density matrix are given by the N lowest energy orbitals of the above equation. The interactions of an orbital with itself in the Hartree and Fock terms cancels.

The total ground energy can be correspondingly classified as the kinetic energy term, the potential energy term due to the external potential, the Hartree term, and the exchange term. In addition to the ground state, the Hartree–Fock equations yield orbitals which can be used to construct excited states. The excitation energy over the ground state is simply the sum and difference of the single-particle Hartree–Fock energies of the orbitals added to or taken from the ground state.

Whatever in the total energy the Hartree–Fock approximation leaves out is termed the correlation energy. Similarly, if one is to focus on the motion of a single electron, the Hartree–Fock picture provides among the interaction effects the electrostatic interaction due to the other electrons and the exchange interaction with electrons of the same spin orientation due to the Pauli principle. Beyond these terms, the single determinant has no correlation between two electrons due to the Coulomb repulsion. The missing correlation effect can, as we shall see below, be pictured as due to interaction with collective excitations which the motion of the particle under examination excites. Before discussing correlation, we need a formalism for treating the collective excitations, which are also of interest on their own right.

1.2 Linear Response Functions

A powerful conceptual tool to treat the collective phenomena, taking into account the mutual interaction among the constituent particles of a system, is the linear response function. Suppose that the interacting system is subjected to a weak external probe which couples to the property $B(\mathbf{r})$ at the position $\mathbf{r}$ by a "potential" $\delta\phi(\mathbf{r},t)$ at time t. The perturbation to the Hamiltonian is given by

$$\delta H = \int d^3r\, B(\mathbf{r})\delta\phi(\mathbf{r},t). \tag{2}$$

The change of property A to first order in the external perturbation is of the form

$$\delta A(\mathbf{r},t) = \int d^3r' \int dt'\, \chi_{AB}(\mathbf{r},\mathbf{r}';t-t')\delta\phi(\mathbf{r}',t'). \tag{3}$$

The linear response function χ_{AB} is a property entirely of the system. The time dependence follows from the fact that the system itself has no time-dependent forces. Causality makes the response vanish if $t<t'$. The Fourier transform with respect to time of the response function, $\chi_{AB}(\mathbf{r},\mathbf{r}';\omega)$, measures the change of property A corresponding to a perturbation at an angular frequency ω (referred to hereafter as frequency for short).

As a simple example of how the dynamics of the interacting system determines the response function, consider the density response to an electric disturbance in the electron gas, keeping fixed the uniform background of compensating positive charges. Let the perturbing electric potential have a single wave vector $\mathbf{q}$ and a monochromatic frequency ω:

$$\delta\phi(\mathbf{r},t) = \delta\phi(\mathbf{q},\omega)e^{-i\omega t+i\mathbf{q}\cdot\mathbf{r}}. \tag{4}$$

Both the observables A and B are in this case the density distribution $n_{\mathbf{q}}$. In the classical approximation, each electron of charge $-e$ and mass m is set in oscillation with the displacement given by

$$\delta\mathbf{r} = -e\mathbf{E}/m\omega^2, \tag{5}$$

driven by the electric field which is composed of the external perturbation and the induced electric field:

$$\mathbf{E} = -i\mathbf{q}(\delta\phi+\delta\phi_i), \tag{6}$$

where the induced field is due to the change in the electron density:

$$\delta\phi_i = 4\pi\delta n_q/q^2. \tag{7}$$

The change in density is related to the displacement by the volume dilatation:

$$\delta n_q = -nei\mathbf{q}\cdot\delta\mathbf{r}, \tag{8}$$

where n is the uniform density of the unperturbed system. Elimination of the induced potential leads to an expression of the density response which is the ratio of δn to $\delta\phi$:

$$\chi_{nn}(\mathbf{q},\omega) = \frac{ne^2q^2}{m\omega^2}\left(1-\frac{\omega_p^2}{\omega^2}\right)^{-1}, \tag{9}$$

where

$$\omega_p^2 = 4\pi ne^2/m. \tag{10}$$

If the perturbing frequency ω is equal to the plasma frequency ω_p, the density response blows up. In other words, the system is able to sustain a density oscillation of this frequency without external disturbance. This response mode of the jellium is called the plasma oscillation. This example illustrates how microscopic dynamics (in this case a rather crude combination of Newtonian mechanics and electrostatic theory) leads to an expression for a response function and how its behavior yields the interpretation of a collective mode.

If the perturbation is adiabatically turned on or if a weak damping is introduced, a small imaginary number may be added to the frequency ω in the response function. Then the imaginary part of the response function, known as the spectral density, will peak in the neighborhood of the pole of the response function. The peak position gives the collective mode energy and momentum, and the width of the resonance gives the inverse lifetime of the collective mode.

Two concepts related to the density response which arise in the example above are the electric susceptibility function $\tilde{\chi}_{nn}$, which is the density response to the total potential in Eq. (6), and the dielectric function ϵ, which is the ratio of the perturbing potential to the total potential. These two quantities are the extension of the susceptibility and dielectric constant to finite wave vector and frequency. From these definitions and Eq. (6) the two quantities are related to the density response and to each other by the relations

$$\epsilon^{-1}=1+\frac{4\pi}{q^2}\chi_{nn}, \quad \epsilon=1-\frac{4\pi}{q^2}\tilde{\chi}_{nn}. \tag{11}$$

An approximation in which the proper polarization part is replaced by the density response of a noninteracting system is called the random phase approximation. This contains the long-range Coulomb interaction effects.

The spin density response with both A and B replaced by the spin vector σ, known as the magnetic susceptibility function, is a second-rank tensor related to the proper polarization part since the spin-density wave does not create long-range interaction as a charge-density wave does. In an isotropic system, the tensor is diagonal with elements identical to the proper polarization part of the density response.

1.3 Correlation Energy

Interaction plays an important role in the cohesion of a solid (see COHESIVE ENERGY), which is the difference between the total energy of the solid and the total energy of the constituent atoms isolated from one another. In metals, it is found that the correlation energy contribution to cohesion is as important as the Hartree and exchange terms.

An understanding of the essential physics of the correlation effects may be garnered by first neglecting the lattice potential. Thus, the properties of the jellium model (defined in Sec. 1.2) have been studied. Jellium is also a useful model for carriers in a doped semiconductor. (See ELECTRON STATES IN ZERO-, ONE- AND TWO-DIMENSIONAL STRUCTURES.) With the addition of the lattice pseudopotential as a perturbation, the jellium model describes the behavior of simple metals such as the alkali metals and aluminum quite well. (See ELECTRONIC STRUCTURE OF SOLIDS.) Quantitatively, it turned out not to be so straightforward to extend the methods developed for jellium to most of the other solids. Among the various approaches, the density-functional theory is the most widely used and, perhaps, the most successful. Its limitation lies in the inability to describe accurately the strong correlation of d or f electrons in narrow bands. This state of affairs brings us to the present-day research on strong correlation in narrow-band models such as the Hubbard model. (See METAL–INSULATOR TRANSITIONS; HEAVY-FERMION PHENOMENA.) Here we review the concepts arising out of the study of the interaction energy in jellium and the principles of the density-functional theory.

1.3.1 Total Energy in Jellium. The noninteracting part of the total energy is given by the kinetic energy of a single determinant of single-particle states, each of which, in jellium, is a plane wave, with wave vector **k** and spin state σ (± 1 for up and down states), and thus energy

$$\epsilon_{\mathbf{k}}=\hbar^2k^2/2m. \tag{12}$$

The determinant (and, hence, the state of the system) may be specified by the distribution function $n_{\mathbf{k},\sigma}$ which, at zero temperature, assumes the value of unity if the single-particle state $(\mathbf{k},\sigma)$ is occupied and the value zero otherwise. The lowest energy state of n electrons per unit volume has single-particle states occupied up to the wave vector with magnitude k_{F}, the Fermi wave vector. The total energy per particle in the noninteracting approximation is the average kinetic energy per particle:

$$\epsilon_s=\frac{3}{5}\,\epsilon_{k_{\mathrm{F}}}=\frac{2.21}{r_s^2}\ \mathrm{Ry}. \tag{13}$$

The last expression is expressed in terms of the mean electron radius in units of the Bohr radius a_{B} related to the electron density by

$$n=\left[\frac{4\pi}{3}(r_sa_{\mathrm{B}})^3\right]^{-1}. \tag{14}$$

Since the mean distance between two electrons is of the order r_sa_{B}, the Coulomb energy between them is r_s^{-1} Ry. The mean radius r_s is a measure of the ratio of the electron interaction energy to the average kinetic energy.

If the expectation energy is calculated for the single-determinant state, the approximation is the Hartree–Fock approximation (Sec.

1.1). The interaction-energy part is the exchange energy, which, per particle, is

$$\epsilon_x = -\frac{3}{4\pi} k_F = -\frac{0.92}{r_s}. \tag{15}$$

The remainder of the total energy per particle, the correlation energy, is denoted by ϵ_c, so that

$$\epsilon = \epsilon_s + \epsilon_x + \epsilon_c. \tag{16}$$

The exchange and correlation energies can be formulated in terms of the inverse dielectric function defined by Eq. (11) (Pines and Nozières, 1966). If the inverse dielectric function is taken to first order in the Coulomb interaction, the exchange energy is recovered. If the dielectric function is taken in the random phase approximation (see Sec. 1.2), then in addition a correlation-energy term results, which contains the correct logarithmic term in the high-density (or small-r_s) limit:

$$\epsilon_c = [0.062 \ln(r_s) - 0.096] \text{ Ry}. \tag{17}$$

Physically, there are two contributions, one being the static screening of the Coulomb interaction in the exchange due to the excitation of the electron-hole pairs at low energies and the other being the zero-point energies of the plasmon modes. The constant term is corrected by a second-order exchange to the random phase term.

The best expression for the correlation energy is obtained numerically by a Monte Carlo evaluation of the correlated wave function (Ceperley, 1978).

1.3.2 The Density-Functional Theory. Ever since the days of Thomas and Fermi, there had been attempts to formulate quantum mechanics in terms of density in place of the wave function. The advantage over the solution of the many-particle Schrödinger equation would be a more direct relation between the density and the potential and a better way to include the interaction effects. However, the methods remained semiclassical in nature and the quantum effects, such as the density oscillations, were not treated quantitatively. The modern density-functional theory (Hohenberg and Kohn, 1964; Kohn and Sham, 1965) is formally based on the density variable instead of the wave function, but the density is solved by an effective one-particle Schrödinger equation which in principle contains all the interaction effects. This theory avoids the shortcomings of the semiclassical theory and provides a formal framework for approximations for the interaction effects and for the gradient expansion including the Thomas–Fermi approximation as a special case.

Consider a class of systems of electrons. The electrons all have the same mass and interact with the same Coulomb potential. What determines a system in this case uniquely is the potential $v(\mathbf{r})$ due to the nuclei, aside from a trivial additive constant to the potential. In the Schrödinger approach, once $v(\mathbf{r})$ is given, solution of the many-electron Schrödinger equation determines all the properties of the system. In particular, the ground-state density distribution $n(\mathbf{r})$ can be determined. Thus, the density $n(\mathbf{r})$ is said to be a functional of the potential $v(\mathbf{r})$. The fundamental theorem in the density-functional theory due to Hohenberg and Kohn is the converse of the preceding statement. The external potential (to an arbitrary additive constant) and, hence, all the properties of a system are uniquely determined by the ground-state density $n(\mathbf{r})$.

With the help of this theorem, it is possible to write the ground-state energy of a system in the form

$$E = \int d^3r\, n(\mathbf{r}) v(\mathbf{r}) + T_s[n] + \frac{1}{2} \int d^3r \times \int d^3r'\, n(\mathbf{r}) \frac{e^2}{|\mathbf{r}-\mathbf{r}'|} n(\mathbf{r}') + E_{xc}[n]. \tag{18}$$

The first term on the right is the potential energy due to the external potential. The second is the kinetic energy of the noninteracting system with the same density as the interacting system. The notion of a noninteracting system with the same ground-state density as the real system is important to the reduction of the many-electron problem to the solution of a one-particle problem with an effective potential, as we shall presently see. The third term is the electrostatic energy of the electron charge distribution. The fourth term is the exchange-correlation energy. In the limit of constant electron density, these energy terms reduce to the corresponding ones already defined for jellium, with the electrostatic energy terms adding to zero.

A corollary to the Hohenberg–Kohn theorem is the variational principle with respect to the density. The change in the ground-state energy to first order in the density change is zero. This yields a variational equation for solving the density. It only remains to find the energy functional. Two series constructions are possible. One is the perturbation from jellium. The other is a gradient expansion in terms of the density and its derivatives to all orders. If the exchange and correlation energy $E_{xc}[n]$ is neglected, only the noninteracting kinetic energy functional needs to be expanded in Eq. (18). The leading terms without the gradients of the density, corresponding to the energy density of jellium at the local density, reproduce the Thomas–Fermi approximation. The gradient terms also correspond to some attempts to improve the Thomas–Fermi approximation. If the leading term in the gradient expansion of the exchange energy functional, corresponding to the exchange energy density of jellium at the local density, is kept, the Dirac correction to the Thomas–Fermi approximation ensues. In practical terms, computational results of the leading term in the gradient expansion, constituting the addition of exchange and correlation effect to the Thomas–Fermi approximation, provide a good asymptotic approximation, but the gradient corrections are more trouble than they are worth.

A key to the improvement over the Thomas–Fermi-type approximation is to keep the whole single-particle kinetic energy functional $T_s[n]$. For the corresponding noninteracting system, the variational equation in terms of the density variable is just the sum of the functional derivative of $T_s[n]$ and the external potential. The solution for the density can be obtained by solving the one-particle Schrödinger equation. The variational equation for the interacting system, from Eq. (18), has the same form as in the noninteracting case, except that the effective potential now includes the external potential, the Hartree potential (strictly speaking, the electrostatic potential due to the density distribution of all the electrons), and the exchange-correlation potential defined as the functional derivative of $E_{xc}[n]$, i.e.,

$$v_{\text{eff}}(\mathbf{r}) = v(\mathbf{r}) + \int d^3r' \, \frac{e^2}{|\mathbf{r}-\mathbf{r}'|} \, n(\mathbf{r}') + v_{xc}(\mathbf{r}). \tag{19}$$

Thus, solving the many-electron problem for the density is reduced to solving a one-particle Schrödinger equation. What remains is the construction of the exchange-correlation functional. There is a perturbation-theory expression for the functional (Sham, 1985). The most widely used is the local-density approximation, which is the leading term in the gradient expansion, i.e., the exchange-correlation part of the chemical potential of the electron in jellium. (See ELECTRONIC STRUCTURE OF SOLIDS; Schlüter and Sham, 1982; Cohen and Chelikowsky, 1988). An interpolated form of the electron-gas results of Ceperley (1978) is widely used.

The functional can be extended to include the spin density, to superconductors (Oliveira *et al.*, 1988), and to finite magnetic fields by extending the density variable to include the current density (Vignale and Rasolt, 1988).

1.4 Quasiparticles

In this section, we devote our attention to concepts arising out of consideration of one-particle properties. Clearly, an electron propagating in an interacting system has to push other electrons out of the way. Thus, the particle is "dressed." In the Hartree–Fock approximation, Eq. (1), the particle sees, besides the external potential, the electrostatic potential due to the electrons and the nonlocal exchange potential.

To include the correlation effect, the nonlocal and energy independent (or static) exchange term has to be replaced by a more general term, $\Sigma(\mathbf{r},\mathbf{r}',E)$, called the self-energy, which includes the exchange term and is now energy dependent (or dynamic) and complex as well as being nonlocal. An infinite perturbation series can be developed for the self-energy, which shows that the form adopted is the most general form. The energy dependence reflects the retardation effects or the finite energies of the density oscillations and other correlation effects excited by the motion of the electron. The complex self-energy allows for the decay of the electron state under study through exciting other electrons. The effective Schrödinger equation becomes

$$\left[-\frac{\hbar^2}{2m}\nabla^2+v(\mathbf{r})+\int d^3r'\,\frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\,n(\mathbf{r}')\right]$$
$$\times\psi_j(\mathbf{r},E)+\int d^3r'\;\Sigma(\mathbf{r},\mathbf{r}',E)\psi_j(\mathbf{r}',E)$$
$$=W_j(E)\psi_j(\mathbf{r},E). \qquad (20)$$

From the eigenvalues $W_j(E)$ and eigenfunctions $\psi_j(\mathbf{r},E)$, a Green's function can be constructed (see Mahan, 1990):

$$G(\mathbf{r},\mathbf{r}',E)=\sum_j \frac{\psi_j(\mathbf{r},E)\psi_j^\dagger(\mathbf{r}',E)}{E-W_j(E)}\,. \qquad (21)$$

The one-electron Green's function may be regarded as the response function to the addition or removal of an electron to the system. By analogy with the collective-mode concept in relation to the response function, a pole of the one-electron Green's function gives a self-sustaining mode which is identified as a state of the quasiparticle. The quasiparticle energy is given by the zeros of

$$E=\text{Re}\ W_j(E), \qquad (22)$$

where the right-hand side is the real part of $W(E)$. The imaginary part of $W(E)$ at the quasiparticle energy gives the reciprocal lifetime of the quasiparticle.

The quasiparticle state resembles that of an independent electron with its motion much modified by the interaction. If there is no interaction among the electrons, the eigenvalue $W_j(E)$ is real and independent of E (yielding infinite lifetime) and the residue of the pole, when integrated over all space for $\mathbf{r}=\mathbf{r}'$, is unity. The inclusion of interaction reduces the corresponding residue, known as the wave function renormalization. Thus, a quasiparticle is not completely equivalent to an electron including the interaction effects since there is a remaining piece of the Green's function besides the pole part. Nonetheless, for one-particle properties of the system, a simple picture of quasiparticles with one-to-one correspondence between the quasiparticle states and the independent-electron states is useful. The Fermi surface in momentum space which separates the unoccupied quasiparticle states from the occupied ones must enclose the same volume as the Fermi surface of the independent electrons. This is known as the Luttinger theorem. Quasiparticle states close to the Fermi surface are long-lived. Because of the phase-space restriction by the exclusion principle, the reciprocal lifetime of the quasiparticle close to the Fermi surface is proportional to the square of the energy difference from the Fermi energy. This follows from the process of decay of the particle coming primarily from the Auger process of exciting an electron-hole pair, which must remain within roughly the same energy range from the Fermi surface. The final state of the particle contributes no phase-space restriction since its state is determined by energy and momentum conservation from the initial state and the states of the electron-hole pair. The quasiparticle picture is, thus, valid for low-lying excited states.

For jellium, the self-energy can be constructed in the random-phase approximation in terms of the dielectric function. It is of a similar form to the exchange term with the Coulomb potential screened by the energy-dependent, nonlocal dielectric function. The physical picture is that of the Fock exchange term statically screened and with the addition of a correlation hole. At the Fermi level, because of the hindrance of the other electrons and of phonons, the speed of the quasiparticle is lower than that of a free electron at the Fermi level. The effective mass m^* of the quasiparticle at the Fermi surface is defined as the ratio of its momentum to its velocity. Thus, the interaction effects cause the effective mass to be larger than the bare electron mass m. This effect manifests itself in the enhanced density of states and, hence, the low-temperature specific heat. The isotropy of jellium means that the quasiparticle Fermi surface is spherical as is the one for the free electrons. Since both Fermi surfaces enclose the same volume of phase space, the Fermi momentum for the quasiparticles is equal to that of the noninteracting system with the same number of electrons. Without the isotropy of jellium, the shape of the Fermi surface (in general) is changed by the interaction effects.

For real solids, the simplest method to construct the self-energy is to start with the density-functional orbitals (see Godby *et al.*, 1987, and references therein). Calculations of the quasiparticle energies demonstrate that the band structure is not well given by the eigenvalues of the one-particle Schrödinger with the potential in Eq. (19), particularly the band gap. The discrepancy in the band-gap values can be understood in terms of the discontinuous jump of the exchange-correlation potential v_{xc} when one electron is added to the insulating ground state. On the other hand, for metals, the density-functional eigenvalues yield a good approximation for the Fermi surface although they cannot give the density-of-states enhancement.

2. COLLECTIVE EXCITATIONS IN THE ELECTRON PLASMA

In this section, we examine the collective modes due to interaction among the electrons, in which the band structure is of secondary consideration. Thus, the jellium model introduced in the last section serves admirably to explore the physics of a variety of collective oscillations of the electron system, which acts like a low-temperature degenerate plasma. The three-dimensional jellium model is a good approximation to simple metals, which are generally elements on the left-hand side of the periodic table although lead is included, and to the charge carriers in heavily doped semiconductors. Two-dimensional jellium is a good approximation to the confined layers to carriers in semiconductor heterostructures (see HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR). One-dimensional jellium can be used to glean some collective effects and instabilities of the linear conductors (see ELECTRONIC STATES IN ZERO-, ONE-, AND TWO-DIMENSIONAL STRUCTURES).

The collective excitations in the electron plasma are obtained by studying the linear response to a weak electric or magnetic field with a sinusoidal spatial variation (with wave vector $\mathbf{q}$) and a monochromatic time oscillation (with angular frequency ω). Allowing the heavy positively charged background to oscillate yields in addition a model for the long-wavelength lattice vibrations (phonons) in a simple metal. A revisit of the density response including the quantum effects at a finite wave vector and frequency yields the static screening of a charged impurity, the plasma oscillations at high frequencies, screening of the acoustic phonons at low frequencies, and the image of the Fermi surface in the Kohn effect at the wave vector equal to the Fermi diameter.

To treat low-energy charge- and spin-density oscillations under more complicated circumstances, such as in the presence of a strong static magnetic field, we use the Fermi-liquid theory due to Landau and Silin, which is a powerful phenomenological theory treating the low-lying excited states of the interacting system as a number of quasiparticles which have been described in Sec. 1, but now including the residual interaction between quasiparticles which is essential to the existence of the collective modes. Such a phenomenological theory has been justified from first principles starting with bare electrons and Coulomb interaction between electrons. To describe a nonequilibrium state of the interacting system, Landau's Fermi-liquid theory divides the position and momentum phase space of the quasiparticle into cells, with dimensions large enough for each cell to be a thermodynamic system but small compared with the corresponding variations of the external perturbation and, therefore, of the collective mode, and defines a quasiparticle distribution for all the cells. The time evolution of the quasiparticle distribution is governed by the kinetic theory. Knowledge of the quasiparticle distribution in thermal equilibrium leads to thermodynamic properties. Knowledge of the time dependence of the quasiparticle distribution leads to the collective modes. Moreover, the results delineate clearly for each property whether the interaction effects are due to the dressing of the quasiparticle or to the interaction between quasiparticles.

The difference between an uncharged Fermi liquid, such as ^{3}He, and the electron system is the existence in the latter of a long-range electrostatic potential due to the density variation of the quasiparticles. The long-range interaction, besides giving rise to the plasmon in the electron system, tends to shield from experimental observation some of the spin-independent collective modes which exist in the uncharged Fermi liquid. A good example is the zero sound which is due to the collective oscillation corresponding to an isotropic change of the Fermi surface. In the charged Fermi liquid, such a mode is coupled to the compressional part of the lattice vibration.

The effect of the quasiparticle interaction in the zero sound is submerged in the lattice effect.

The presence of a uniform and static magnetic field opens up the possibility of interesting collective modes which are not totally screened by the long-range interaction. There are two classes, those which owe their very existence to the quasiparticle interaction and those which exist because of the long-range electric potential but are modified by the quasiparticle interaction. The former are particularly important in extracting experimental information of the quasiparticle interaction. The cyclotron motion of the electrons is inaccessible by the electromagnetic field except in the surface region (the skin effect). With the magnetic field parallel to the metal surface, arrangement can be made to impart electromagnetic energy in the skin depth to electrons passing through it in their execution of the cyclotron motion. The resultant resonance is known as the Azbel'–Kaner resonance. The dielectric response to electromagnetic waves in a static magnetic field shows transverse plasmons at high frequencies, helicon waves at low frequencies with their polarization vectors winding along the static magnetic field in the same sense as the cyclotron motion, and branches of magnetoplasma waves around the cyclotron frequency or its harmonics. The magnetoplasma modes exist under the condition that they do not create a net density wave or a current, either of which will induce the long-range Coulomb interaction screening out the collective modes. Thus, the Fermi-surface deformation in such a magnetoplasma mode must be neither spherically symmetric (which would produce a density wave) nor a rigid displacement (which would produce a current). Spin waves in metals are truly collective modes in that they cannot exist without quasiparticle interaction. They are unlike the spin waves in a ferromagnet which are due to oscillations of localized spins from their equilibrium orientations. In a metal, the electrons which carry spins are highly mobile. It is their net spin density at each locality which oscillates in time and varies from locality to locality. Like the sound wave in a fluid, the individuality of the particles is lost, but unlike the sound wave, the spin wave in driven by particle interaction and not by collision.

2.1 Dielectric Screening and Plasma Oscillations

The procedure of obtaining the density response discussed in Sec. 1.2 is general and will be followed here. An external electric disturbance induces a change in electron density, which in turn creates an induced electric potential. The total electric potential seen by a charge is the sum of the external potential and the induced potential. The density response expressed as a linear coefficient to the total potential is the proper polarization part $\tilde{\chi}$ in Eq. (11). The only difference is that we forsake the classical treatment of the electron motion to obtain the density response to the total potential in Sec. 1.2, and use an approximation which is also reasonable for finite wave vector and frequency. In the so-called random phase approximation (RPA), the density response to the total potential is equated with the density response of the noninteracting system, which is easily obtained, known as the Lindhard expression:

$$\tilde{\chi}(\mathbf{q},\omega)=\sum_{\mathbf{k},\sigma}\frac{n_{\mathbf{k},\sigma}-n_{\mathbf{k+q},\sigma}}{\omega+i0+\epsilon_{\mathbf{k}}-\epsilon_{\mathbf{k+q}}}, \tag{23}$$

consisting of the excitations of all possible electron-hole pairs, with occupation function $n_{\mathbf{k},\sigma}$ and energy $\epsilon_{\mathbf{k}}$ from Eq. (12). The small imaginary part $i0$ is due to the adiabatic switching on discussed in Sec. 1.2.

Since the induced potential is related to the induced electron density change, it can be expressed in terms of the external potential via $\tilde{\chi}$. The result is that the total potential is given by the external potential divided by the dielectric function which can be expressed in terms of $\tilde{\chi}$ as in Eq. (11). The Lindhard expression for $\tilde{\chi}$ can be evaluated explicitly for the free-electron energy dispersion. In particular, the static dielectric function in three dimensions is

$$\epsilon(q,0)=1+\frac{4\pi e^2}{q^2}N_0\left[\frac{1}{2}+\frac{4k_F^2-q^2}{8k_F}\ln\left|\frac{2k_F+q}{2k_F-q}\right|\right], \tag{24}$$

where N_0 is the density of states at the Fermi level. In the long-wavelength or small-q limit, the polarization part reduces to the density of states and the dielectric screening is of the form

$$\epsilon(q,0)=1+4\pi e^2N_0/q^2. \quad (25)$$

In this Thomas–Fermi approximation, a static external Coulomb potential, e.g., due to a charged impurity, is screened to a short-ranged Yukawa potential.

When the wave vector is equal to Fermi surface diameter, there is a sharp decrease in the dielectric function (24). It has an $x \log x$-type singularity for q near $2k_F$, known as the Kohn singularity. The behavior may be understood by looking at the electron-hole pair contribution to the polarization. The most important ones are those nearly satisfying energy conservation (thus, making the denominator small). As q increases through the diameter of the Fermi surface, the number of such pairs drops sharply. The Kohn singularity is, therefore, an image of the Fermi surface. From this physical explanation, it is clear that the flatter the two pieces of the Fermi surface across one of its diameters are, the stronger the singularity. For two-dimensional or cylindrical Fermi surfaces (Brovman and Kagan, 1974) the Kohn singularity is stronger, being a square-root decrease. In one dimension or parallel plane sections of the Fermi surface, the Kohn singularity is stronger still, having a logarithmic divergence. The significance of the Kohn singularity is that it is reflected in the dispersion of any collective mode which involves the low-frequency density response in the neighborhood of the Fermi diameter. This is observable in the phonon dispersion in metals where the force constants between ions are screened by the electrons. In one dimension, the giant Kohn singularity sets up such a strong charge- or spin-density wave (Overhauser, 1965) that the normal ground state could become unstable. This is an alternative way of viewing the Peierls instability (see Sec. 5).

The Fourier transform to the three-dimensional coordinate space of the screened impurity potential due to the Kohn singularity has a power-law oscillation in space $\sim\cos(2k_Fr)/r^3$, known as the Friedel oscillation. The Friedel oscillation of the electron density in the presence of a charged impurity may be observed by the ensuing change in the hyperfine interaction.

A lattice vibration may be regarded as a collective mode (phonon) in the linear response of the nuclear displacement (see PHONONS IN CRYSTALS). As a simple model for the electron screening of the lattice vibration with a long wavelength, consider the oscillation of the positively charged background. The dielectric response can be analyzed in the same way as for jellium with a rigid positive background. We simply need to add the polarization contribution due to the oscillating positive background to Eq. (11), which in the long-wavelength limit is given by $-\Omega_p^2/\omega^2$, where Ω_p is the ion plasma energy given by Eq. (10) with the electron mass replaced by the ion mass M. Since the ion plasma frequency is much lower than the electron plasma frequency, the electron screening term should be taken at low frequency in determining the zero of the dielectric function which corresponds to the electron-screened ion plasma frequency, then given by

$$\omega^2=\Omega_p^2q^2/4\pi e^2N_0, \quad (26)$$

keeping only the leading term in q using Eq. (25). This is the acoustic branch of the phonon.

In the long-wavelength limit, the electron polarization at a finite frequency is, from the Lindhard expression,

$$\tilde{\chi}(\mathbf{q},\omega)=ne^2q^2/m\omega^2. \quad (27)$$

For small q, the number of electron-hole pairs is limited and this expression can be shown to exhaust the sum rule. Thus, the classical derivation given in Sec. 1.2 and the RPA both actually yield the right plasma frequency for three-dimensional jellium in this limit. In a two-dimensional system, the polarization expression is the same if n denotes the number of electrons per unit area. However, the Fourier transform of the Coulomb potential in two dimensions is $2\pi e^2/q$, yielding from the zero of the dielectric function the 2D plasma frequency for small q given by

$$\omega_p^2=2\pi ne^2q/m. \quad (28)$$

The oscillation of the heavy positively charged background changes the plasma frequency slightly, replacing m by the reduced mass.

In metals, the plasma oscillation is observed by energy loss of injected electrons (Schnatterly, 1979; Raether, 1980). Figure 1 gives an example in aluminum, which also shows the frequency dispersion of the plasmon. The quadratic dispersion can be deduced by keeping the next order term in q in addition to the zero-q limit in Eq. (27). In a

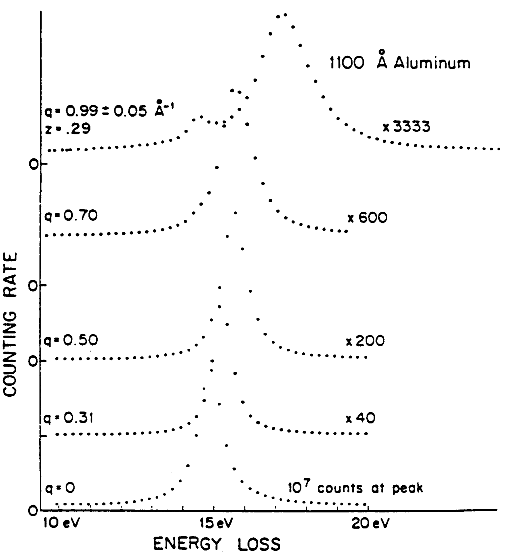

FIG. 1. Measured plasmon spectra of Al from $q=0$ to $1\ \text{Å}^{-1}$. [From Gibbons *et al.* (1976), Fig. 2; reproduced with permission.]

two-dimensional electron gas in a semiconductor heterostructure, the plasma frequency is in the infrared range and can be observed by light absorption (Heitmann, 1986). The problem is that the charge oscillation and, thus, the electric vector of light have to be in the plane of the electron gas and, therefore, the confining interface. The finite wave vector of the plasma oscillation is obtained by laying down metal wire gratings on the interface. Figure 2 shows the observed dispersion of plasma frequency, confirming the square-root wave-vector dependence. Equation (28) has to be modified by replacing the mass with the effective band mass and by making allowance for the dielectric function of the background heterostructure.

2.2 Landau–Silin Theory of Fermi Liquid

In Sec. 1.3, the single-particle properties are represented by quasiparticles which are electrons dressed by interaction with the other electrons. There is a residual interaction between quasiparticles. A phenomenological formulation due to Landau represents the low-energy excited states of the interacting system in terms of a number of quasiparticles and holes excited near the Fermi surface. By including the residual interaction between the quasiparticles as phenomenological parameters, Landau's theory is able to describe all the low-energy collective excitations. Although the Fermi-liquid theory was originally designed for the uncharged ^{3}He liquid, Silin extended it to the electron gas by including the effects of the long-range Coulomb interaction. In the limit of temporally and spatially slowly varying weak external perturbations, the Fermi-liquid theory has been derived from first principles by means of infinite perturbation series. (For reviews, see Pines and Nozières, 1966; Mahan, 1990; Abrikosov, 1972).

2.2.1 Quasiparticle Interaction. A low-energy excited state of the whole many-electron system may be described by the addition of quasiparticles to the ground state and removal of quasiparticles from it, resulting in a change of distribution:

$$\delta n_k(\mathbf{r},t) = n_{\mathbf{k}}(\mathbf{r},t) - \theta(\mu - E_k), \tag{29}$$

where k is short for the wave vector $\mathbf{k}$ and spin σ. It is a matter of convenience to describe the addition and removal of quasiparticles to and from, respectively, the ground state as a difference between two quasiparticle distributions, $n_k(\mathbf{r},t)$ for the excited state and the step function $\theta(\mu - E_k)$ for the equilibrium distribution of unity when the quasiparticle energy E_k is below the chemical potential μ and zero above. It is, however, misleading to think of the ground state as made up exclusively of quasiparticles. A quasiparticle distribution is well defined only if the quasiparticle lifetime

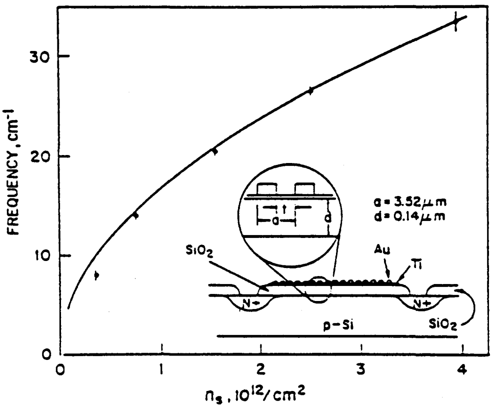

FIG. 2. Measured two-dimensional plasma spectrum of the inversion layer in Si MOSFET, compared with theory (solid curve). The inset shows the structure of the Si MOSFET with the metal gratings which produce the finite wave vectors. [From Allen *et al.* (1977), Fig. 2; reproduced with permission.]

is long, i.e., for energies close to the Fermi energy. For an external disturbance which is slowly varying in space and time (i.e., with wave vector $q \ll k_F$ and frequency $\omega \ll \mu$), we may think of a neighborhood around r with dimension larger than the Fermi wavelength as locally a homogeneous electron gas and, over a time interval around t much shorter than the period of the external disturbance, having a distribution $n_k(\mathbf{r},t)$ of quasiparticles. The excited state has a total energy in excess of the ground-state energy given by

$$\delta E[\delta n_k] = \sum_k \int d^3r\, v_{\text{ext}}(\mathbf{r},t)\delta n_k(\mathbf{r},t) + \frac{1}{2}\sum_{kk'} \int d^3r \int d^3r' \frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\delta n_k(\mathbf{r},t)\delta n_{k'}(\mathbf{r}',t)$$
$$+ \sum_k \int d^3r\, E_k \delta n_k(\mathbf{r},t) + \frac{1}{2}\sum_{kk'} \int d^3r \int d^3r'\, f(k,k')\delta n_k(\mathbf{r},t)\delta n_{k'}(\mathbf{r}',t) + O(\delta n^3). \quad (30)$$

The first two terms are familiar from Sec. 1.1, being the change due to the external potential directly and via the induced electrostatic potential (the Hartree term). In the next two terms, the coefficient to the first-order term in δn_k, E_k, is the quasiparticle energy in addition to the external potential; and the coefficient to the second-order term in δn_k, $f(\mathbf{k},\mathbf{k}')$, is the interaction between quasiparticles, which is a short-range interaction on top of the long-range Hartree term. In jellium, the Coulomb interaction is spin independent but the quasiparticle interaction is made up of a spin-independent and a spin-dependent term:

$$f(\mathbf{k}\sigma,\mathbf{k}'\sigma') = f_s(\mathbf{k},\mathbf{k}') + \sigma\cdot\sigma' f_a(\mathbf{k},\mathbf{k}'). \quad (31)$$

For low-energy quasiparticles close to the Fermi surface, the interaction functions depend only on the relative angle between the wave vectors on the Fermi surface. Each function can be written in the form

$$f_s(\mathbf{k},\mathbf{k}') = N_0^{-1} \sum_{l=0}^{\infty} A_l(2l+1)P_l(\hat{k}\cdot\hat{k}'), \quad (32)$$

in terms of the exact density of states N_0 at the Fermi level and the Legendre function P_l, where $\hat{\mathbf{k}}$ is the unit vector along $\mathbf{k}$. Thus, the set of parameters A_l specifies the spin-symmetric interaction $f_s(\mathbf{k},\mathbf{k}')$, and a similarly defined set, B_l, characterizes the spin-asymmetric interaction $f_a(\mathbf{k},\mathbf{k}')$.

2.2.2 Local Equilibrium Distribution. From the energy difference between the excited state and the ground state, Eq. (30), we can extract the energy of a single quasiparticle in the presence of others by taking the first functional derivative with respect to δn_k. In addition to the Hartree energy,

$$v_{\text{ext}}(r,t) + \sum_{k'} \int d^3r' \frac{e^2}{|\mathbf{r}-\mathbf{r}'|}\delta n_k'(\mathbf{r}',t), \quad (33)$$

which is shared by all the quasiparticles in the same locality and time, the energy of a quasiparticle in state k at $\mathbf{r}$ and t is

$$\tilde{E}_k = E_k + \sum_{k'} f(k,k')\delta n_{k'}. \quad (34)$$

It is sometimes convenient to specify the quasiparticle distribution as the deviation from the local equilibrium distribution,

$$\delta\tilde{n}_k(\mathbf{r},t) = n_k(\mathrm{r},t) - \theta(\mu - \tilde{E}_k), \quad (35)$$

with both the quasiparticle energy and the Fermi energy measured from the local Hartree value, Eq. (33). Comparison of this with the quasiparticle deviation from the global equilibrium, Eq. (29), yields the relation

$$\delta\tilde{n}_k(\mathbf{r},t) = \delta n_k(\mathbf{r},t) + \delta(E_k - \mu)\sum_{k'} f(k,k')\delta n_{k'}. \quad (36)$$

The delta function at the Fermi level arises from the small deviation from the step-function distribution. If we express the quasiparticle deviation in terms of the spherical harmonics about the Fermi surface,

$$\delta n_k = \sum_{lm} \delta(E_k - \mu)\delta n_{lm} Y_{lm}(\hat{k}), \quad (37)$$

then the spin-symmetric coefficients for the local and global deviations are related by

$$\delta\tilde{n}^s_{lm} = (1 + A_l)\delta n^s_{lm}. \quad (38)$$

The spin-asymmetric coefficients are related by

$$\delta\tilde{n}^a_{lm} = (1 + B_l)\delta n^a_{lm}. \quad (39)$$

2.2.3 Specific Heat and Magnetic Susceptibility. As an example of the use of the Fermi-liquid theory, consider the low-temperature thermodynamic properties. The entropy and, hence, the thermal distribution of the quasiparticles are derived in the same way as for the noninteracting Fermions:

$$n_k(T)=1/[1+\exp\{(\tilde{E}_k-\mu)/k_BT\}]. \qquad (40)$$

The difference lies in that this relation through Eq. (34) depends implicitly on the quasiparticle distribution on the right-hand side. At low temperatures, to the lowest order in the quasiparticle deviation, the interaction term to the energy may be neglected and the specific heat is given by the noninteracting expression with the effective mass of the quasiparticle in place of the free-electron mass.

In the presence of a constant and uniform magnetic field H, each quasiparticle with spin up or down, $\sigma=\pm 1$, has an additional Zeeman energy $-\mu_B\sigma H$, where μ_B is the Bohr magneton. Then, the local deviation is

$$\delta\tilde{n}_{k\sigma}=\mu_B\sigma H\delta(E_k-\mu). \qquad (41)$$

The global deviation, which is isotropic around the Fermi surface, is, by Eq. (39), the local one, divided by the factor $1+B_0$. The susceptibility of the interacting system is, therefore, that of the noninteracting Fermions (with the effective mass in the density of states) divided by the same factor.

2.2.4 Landau–Boltzmann Equation. The response of the system to external perturbations at low frequencies and long wavelengths is governed by the kinetic theory of the quasiparticles suitably modified to take into account the interaction between the particles. The rate of increase of the quasiparticle distribution at $(k,\mathbf{r})$ is equal to the scattering rate $I_k[n]$ into the same point of the phase space:

$$\frac{\partial n_k(\mathbf{r},t)}{\partial t}+\frac{\partial n_k(\mathbf{r},t)}{\partial \mathbf{r}}\cdot\frac{\partial \tilde{E}_k(\mathbf{r},t)}{\partial \mathbf{k}}$$
$$-\frac{\partial n_k(\mathbf{r},t)}{\partial \mathbf{k}}\cdot\frac{\partial \tilde{E}_k(\mathbf{r},t)}{\partial \mathbf{r}}=I_k[n]. \qquad (42)$$

The total rate includes the partial rate with respect to time, the partial rate of change with respect to position times the rate of change of position which is equal to the velocity of the wave packet, and the partial rate with respect to the wave vector times the rate of change of the wave vector which is equal to the acceleration and, therefore, the force on the quasiparticle. The quasiparticle energy here is that of Eq. (34) plus the Hartree energy, Eq. (33). To the first order in the deviation from equilibrium distribution, the Landau–Boltzmann equation becomes

$$\frac{\partial}{\partial t}\,\delta n_k(\mathbf{r},t)+\mathbf{v}_k\cdot\frac{\partial\delta\tilde{n}_k(\mathbf{r},t)}{\partial \mathbf{r}}-\mathscr{F}(\mathbf{r},t)\cdot\mathbf{v}_k\delta(\mu-E_k)$$
$$=I_k[\delta\tilde{n}], \qquad (43)$$

where v_k is the quasiparticle velocity and $\mathscr{F}$ is the total force due to the external field and the induced field. The quasiparticle interaction is hidden in the deviation from the local equilibrium $\delta\tilde{n}_k(\mathbf{r},t)$, related to the global deviation $\delta n_k(\mathbf{r},t)$ by Eq. (36). By neglecting this difference, Eq. (43) reduces to the usual Boltzmann equation.

The terms in the linearized Landau–Boltzmann equation may be given the following physical interpretation. The external force which drives the quasiparticle distribution away from equilibrium is coupled to the states in the thin shell around the Fermi surface. The ensuing time rate of change of the distribution gives the deviation from the global equilibrium. The rate of change of the distribution due to the spatial variation must be counted in terms of the deviation from the local equilibrium. Since the scattering events can only reduce the nonequilibrium state to a local equilibrium, the collision term involves only the deviation from local equilibrium. The difference between the global and local distributions is caused by the quasiparticle interaction. Thus, for a particular phenomenon, by examining the relative importance of the terms involving the two distributions, one can determine whether the residual quasiparticle interaction plays a role. For a low-frequency phenomenon such that $\omega \ll qv_F$, the first term on the left of the linearized equation is unimportant compared with the second term. The equation becomes just like the Boltzmann equation with the entire equation involving only the "renormalized" distribution $\delta\tilde{n}_k(r,t)$. Then the residual interaction plays no explicit role and cannot be measured. For a high-frequency phenomenon such that $\omega \gg qv_F$, because the time variation term involves $\delta n_k(r,t)$ and the collision term involves $\delta\tilde{n}_k(r,t)$, in principle the quasiparticle interaction is explicitly present. However, the theory is generally insufficiently accurate to distinguish between relaxation time with and without the residual interaction. It is in practice not possible to deduce the interaction from such high-frequency phenomena. Only from phenomena in which both the temporally and spatially varying terms are comparable can the Landau interaction parameters be deduced.

2.2.5 Density and Current Response. Density and current responses to the longitudinal electric field yield information on the transport properties. The collision term, which by restoring the local equilibrium plays an important role in transport, may be written in terms of relaxation times τ_l in the form

$$I_k[\delta\tilde{n}] = -\sum_{lm} \frac{\delta\tilde{n}_{lm}}{\tau_l}\,\delta(\mu - E_k)Y_{lm}(\hat{k}), \tag{44}$$

in terms of the spherical harmonic components, Eq. (37). In general, the relaxation-time expression is an approximation. In some cases, such as impurity scattering, this is exact. The $l=0$ term is absent, so that the spherical average of the linearized Landau–Boltzmann equation leads to the equation of continuity with the density and current density given by

$$\begin{aligned} \rho(q,\omega) &= -e\sum_k \delta n_k, \\ \mathbf{j}(q,\omega) &= -e\sum_k \mathbf{v}_k\delta\tilde{n}_k. \end{aligned} \tag{45}$$

Note the global and local distributions which go, respectively, into the density and current density expressions.

The density and current responses may be obtained by solving the Landau–Boltzmann equation in the spherical harmonic components. The proper polarization part (the density response to the total field) is given in terms of the spherically symmetric deviation of the quasiparticle distribution, yielding

$$\tilde{\chi}(q,0) = -e^2N_0/(1+A_0). \tag{46}$$

The modification of the Landau parameter is the counterpart of the spin susceptibility. (See Sec. 2.2.3.)

The current response to a uniform static field, which creates an $l=1$ type Fermi surface distortion, leads to the conductivity

$$\sigma(0,\omega) = ne^2\tau^*/(1-i\omega\tau^*), \tag{47}$$

where the relaxation time is given by

$$\tau^* = \tau_1/(1+A_1). \tag{48}$$

This is an example in which the Landau interaction parameter A_1 does enter into a transport coefficient but in which the inaccessibility of the unrenormalized relaxation time τ_1 makes it impossible to determine the Landau parameter.

2.2.6 Helicon and Magnetoplasma Modes. In an uncharged Fermi liquid, the Landau–Boltzmann equation leads to a variety of collective oscillations about the Fermi surface. However, in the electron gas, because of the long-range Coulomb interaction, these are masked by the strong screening due to the high plasma frequency or by the lattice vibrations. For example, zero sound in the Fermi liquid, corresponding to a spherical distortion of the Fermi surface, is excited by a compressional wave. In an electronic solid, this is inextricably bound with the lattice wave. A clean separation of the quasi-interaction effects is not possible (Sham, 1969). In this section we consider the collective excitations as first-order responses to a weak electromagnetic field in the presence of a strong uniform static magnetic field $\mathbf{H}_0$, which opens up new possibilities for collective modes. (See Kaner and Skobov, 1966; Platzman and Wolff, 1973.) The screening current which limits the electromagnetic wave to the skin depth is somewhat curtailed by the cyclotron motion of the electrons in the strong magnetic field, giving rise to windows for the propagation of electromagnetic waves along the magnetic field direction.

To the left-hand side of the Landau–Boltzmann equation, Eq. (43), a term corresponding to the Lorentz force due to the static field is added:

$$-\frac{e}{c}\,\mathbf{v}_k\times\mathbf{H}_0\cdot\frac{\partial}{\partial\mathbf{k}}\,\delta\tilde{n}_k(r,t). \tag{49}$$

The force $\mathscr{F}$ is now the Lorentz force due to the weak electromagnetic field.

Consider the propagation of a right-handed circularly polarized electromagnetic wave along $\mathbf{H}_0$. In the long-wavelength limit, the dispersion relation from the wave equation is

$$\omega^2\epsilon(0,\omega) = q^2c^2. \tag{50}$$

From the Landau–Boltzmann equation, the dielectric response is of the form

$$\epsilon(0,\omega)=1-\frac{\omega_p^2}{\omega(\omega-\omega_c-i/\tau)}, \tag{51}$$

where $\omega=eH_0/m^*c$ is the cyclotron frequency involving the effective mass of the quasiparticle at the Fermi surface.

At low frequency and weak magnetic field, with $\omega \ll \omega_c \ll 1/\tau$, the relaxation-time term dominates the dielectric function and the wave vector is complex,

$$q\equiv q'+i/\delta=(i\omega\tau)^{1/2}\omega_p/c. \tag{52}$$

An applied low-frequency electromagnetic wave is confined to a skin depth δ of the surface of the metal. For normal metals, the plasma frequency is much larger than the cyclotron frequency even for the largest magnetic field strength attainable nowadays. Thus, the uniform cyclotron resonance is screened by the plasma mode. The only possible cyclotron resonance is the Azbel'–Kaner resonance, in which the electron cyclotron radius is much larger than the skin depth and in which the resonance occurs when the applied electromagnetic wave is in synchronization with the electron passing through the skin depth. At high frequencies, $\omega \gg \omega_c, 1/\tau$, the dispersion relation for the transverse plasma waves is

$$\omega^2=\omega_p^2+q^2c^2. \tag{53}$$

For a high magnetic field so that the cyclotron term dominates in the dielectric function, $\omega_c\tau \gg 1$, there is a low-frequency mode:

$$\omega=q^2c^2\omega_c/\omega_p^2. \tag{54}$$

This is known as the helicon mode. The frequency is lower than ω_c. The propagation of the right-handed circularly polarized mode is made possible by the static magnetic field. The experimental arrangement is for the magnetic field to be normal to the metal surface and the applied electromagnetic wave incident normal to the surface. The helicon propagation provides an ac method to measure the Hall coefficient $R=1/nec$ since the coefficient in Eq. (54) is

$$\omega_c/\omega_p^2=RH_0/4\pi, \tag{55}$$

and the sense of the circular polarization is determined by the sign of the carrier charge. The Landau interaction term is unimportant in the helicon since it is at low frequency and high magnetic field.

In contrast to the helicon wave whose frequency is much lower than the cyclotron frequency, there are magnetoplasma modes with frequencies of the same order as the cyclotron frequency. We follow Mermin and Cheng (1968) in obtaining these modes from the Landau-Boltzmann equation, Eq. (43), which is rewritten in the form

$$(L-\omega)\delta n_k=-ie\mathscr{E}_{\text{ext}}\cdot\mathbf{v}_k\delta(\mu-E_k). \tag{56}$$

The operator L includes from Eq. (43) the spatial variation term, the cyclotron motion term, the collision term, and the induced driving-force term. The eigenfrequencies of the operator L are the frequencies of the magnetoplasma modes. We apply perturbation theory for small q in terms of the spherical harmonic components δn_{lm} of the quasiparticle distribution about $\mathbf{H}_0$ as the polar axis. From the expressions in Eq. (45), the induced current involves only the $l=1$ components and the induced density fluctuation only the $l=0$ component. Thus, the $l=0,1$ deformation of the Fermi surface would induce a strong screening current masking the collective modes. The magnetoplasma modes of interest have components with $l>1$. Consider separate cases of different orientations of the wave vector $\mathbf{q}$ relative to the magnetic field $\mathbf{H}_0$.

Case I, $\mathbf{q}\perp\mathbf{H}_0$: The frequency is given by

$$\omega=a_l m\omega_c+\frac{q^2v_{\mathrm{F}}^2}{\omega_c}\sum_{l'>1,m'}\frac{a_l|C_{l'm'}^{lm}|^2a_{l'}}{ma_l-m'a_{l'}}. \tag{57}$$

The Landau interaction parameter in $a_l = 1 + A_l$ splits the degeneracy in the modes at zero wave vector. These magnetoplasma modes are, therefore, strongly influenced by the quasiparticle interaction. The coefficient $C_{l'm'}^{lm}$ is the $3j$ symbol, i.e., the matrix element between the two spherical harmonics of $Y_{1,0}$ if the electric polarization vector is parallel to $\mathbf{H}_0$ and of $Y_{1,\pm1}$ if the electric vector is normal to $\mathbf{H}_0$. The former mode is known as the ordinary wave and the latter the extraordinary wave.

Case II, $\mathbf{q}\|\mathbf{H}_0$: The normal-mode frequencies are given again only for $l>1$ by

$$\omega=a_l m\omega_c+\frac{q^2v_{\mathrm{F}}^2}{\omega_c}\sum_{l'>1}\frac{a_l|C_{l'm}^{lm}|^2a_{l'}}{m(a_l-a_{l'})}, \tag{58}$$

where the coefficient $C_{l'm}^{lm}$ is the matrix element between the two spherical harmonics of $Y_{1,0}$. The contrast with Case I is that the sum here in the q^2 term is over the same m components. Hence, if the interaction parameters A_l are neglected, the q^2 term blows up. For noninteracting particles, the modes form a continuum with the dispersion

$$\omega=\omega_c+\mathbf{q}\cdot\mathbf{v}_k. \tag{59}$$

In contrast to Case I, the discrete modes exist only by virtue of the quasiparticle interaction.

Observations of both types of modes have been used to deduce the Landau parameters A_l for alkali metals.

2.2.7 Spin Waves. The spin waves considered here are the spin counterpart of the magnetoplasma waves in jellium, unlike the spin waves in magnetic materials. We follow the treatment of Platzman and Wolff (1967). A review of the experimental situation is given by Dunifer *et al.* (1974).

In order to include spin flip, the quasiparticle distribution $n_k(\mathbf{r},t)$ is now considered as a 2×2 density matrix. Its trace gives the density distribution considered for the magnetoplasma waves. Trace with the Pauli matrices yields the spin-density distribution $\mathbf{m}_\mathbf{k}(r,t)$. The corresponding Landau–Boltzmann equation is derived from the kinetic theory in the same way as above. Through the asymmetric part of the quasiparticle interaction in Eq. (31), the spin density creates an internal magnetic field:

$$\mathbf{h}=\sum_{\mathbf{k}'} f_a(\mathbf{k},\mathbf{k}')\mathbf{m}_{\mathbf{k}'} \tag{60}$$

which also relates this deviation of the spin distribution from global equilibrium to the deviation from local equilibrium, $\tilde{\mathbf{m}}_\mathbf{k}(r,t)$. To the driving force is now added the precession of the electron spin acted upon by the magnetic field.

If the magnetic field is taken to be in the z direction, the longitudinal component $m_{z,\mathbf{k}}(r,t)$ yields the spin susceptibility as above. The transverse component

$$m_+=m_x+im_y \tag{61}$$

yields information on spin precession. The Landau–Boltzmann equation for m_+ may be solved in terms of the spherical harmonic components of its $\mathbf{k}$ orientation on the Fermi surface, in much the same way as the density fluctuation. The crucial difference is that the spin-density distribution creates no screening current. Thus, the dominant spherical harmonic components are $l=0,1$, which, when summed over $\mathbf{k}$ space, yield, respectively, the magnetization and magnetization current:

$$M_+=\sum_\mathbf{k} m_{+,\mathbf{k}}, \qquad \mathbf{J}_+=\sum_\mathbf{k} v_\mathbf{k} m_{+,\mathbf{k}}. \tag{62}$$

If the $l>1$ components of the spin distribution are neglected, the Landau–Boltzmann equation reduces to a closed set of equations for the magnetization and current:

$$\begin{aligned} &-i(\omega-\omega_s)M_+ + i\mathbf{q}\cdot\mathbf{J}_+ = i2\mu_\mathrm{B}M_0H_+,\\ &-i\left(\omega-\omega_s\frac{b_1}{b_0}\right)\mathbf{J}_+ + i\mathbf{q}\,\frac{1}{3}\,v_\mathrm{F}^2 b_0 b_1 M_+\\ &\qquad + \frac{1}{\tau}\,\mathbf{J}_+ + b_1\omega_c\times\mathbf{J}_+ = 0, \end{aligned} \tag{63}$$

where $b_l = 1 + B_l$ involves the spin part of the quasiparticle interaction, $\omega_s = 2\mu_\mathrm{B}H_0$ is the spin precession frequency in terms of the Bohr magneton μ_B, H_+ is the rf field normal to the static magnetic field, and ω_c is the cyclotron frequency due to the static field, directed along the same direction.

The terms in the two equations may be interpreted as follows. The terms $-i\omega M_+ + iq\cdot\mathbf{J}_+$ equated to zero would give the equation of continuity. However, the magnetization M_+ precesses about $\mathbf{H}_0$ with frequency ω_s and is driven by the rf field $\mathbf{H}_+$. The first equation shows no relaxation of the magnetization M_+ because the scatterings due to quasiparticle interaction (characterized by the relaxation time τ) which appear in the second equation do not change the spin component. The equation could be supplemented by a term M_+/T on the left if spin-flip scatterings with a characteristic time T are included. The first two terms in the second equation have a similar physical meaning, with the precessing spin current driven by the gradient of the magnetization. The term $\mathbf{J}_+/\tau$ is the current relaxation due to non-spin-flip particle scattering. The last term, $\omega_c \times \mathbf{J}_+$, represents the cyclotron motion of the current. The factors of the interaction parameters b_l come from the terms in the Landau–Boltzmann equation which appear as deviation from the local equilibrium.

An approximate solution of these equations yields the transverse spin response:

$$\chi_+(\mathbf{q},\omega+i0)\equiv\frac{M_+}{H_+}=\frac{\chi_+(0,0)\omega_s}{P(\mathbf{q},\omega+i0)}\,. \tag{64}$$

The denominator has the form

$$P(\mathbf{q},\omega+i0)=\omega_s+\alpha q^2-\omega-i/T, \tag{65}$$

where the coefficient of the dispersion is

$$\alpha=b_0b_1\,\frac{v_\mathrm{F}^2}{3}\left[\frac{\cos^2\Delta}{\tilde{\omega}_s+i/\tau}+\frac{(\sin^2\Delta)(\tilde{\omega}_s+i/\tau)}{(\tilde{\omega}_s+i/\tau)^2-b_1^2\omega_c^2}\right], \tag{66}$$

Δ being the angle between $\mathbf{q}$ and $\mathbf{H}_0$, and $\tilde{\omega}_s = \omega_s(1 - b_1/b_0)$.

In the strong-scattering limit, $\tilde{\omega}_s\tau\ll 1$, the denominator assumes the form

$$P(\mathbf{q},\omega+i0)=\omega_s-iD_sq^2-\omega-i/T, \tag{67}$$

with the diffusion coefficient

$$D_s=b_0b_1\,\frac{v_\mathrm{F}^2}{3}\left[\cos^2\Delta+\frac{\sin^2\Delta}{1+(b_1\omega_c\tau)^2}\right]. \tag{68}$$

The diffusion coefficient and the spin-flip relaxation time give the Dysonian line shape (Dunifer *et al.*, 1974) for the conduction electron spin resonance at the frequency ω_s, unrenormalized by the interaction parameters.

In the weak scattering limit $\tilde{\omega}_s\tau\gg 1$, the coefficient α is real and the poles of χ_+ give the spin waves with the dispersion $\omega=\omega_s+\alpha q^2$. These spin waves cannot occur without the presence of the interaction parameters B_l. Figure 3(a) shows the frequency dispersion for three directions of the wave vector $\mathbf{q}$ relative to the static magnetic field, normal, parallel, and at the critical angle Δ_c where the two terms in α cancel each other. Only the $\sin^2\Delta$ term in α depends on the field strength H_0. The reason is that only the component of the magnetization current parallel to the wave vector influences the magnetization M_+ and that the cyclotron motion of the current vector is about the static magnetic field. If $\mathbf{q}$ is parallel to $\mathbf{H}_0$, the cyclotron motion of the current vector has no influence on the magnetization. If $\mathbf{q}$ is perpendicular to $\mathbf{H}_0$, $\mathbf{J}_+\cdot\mathbf{q}$ precesses with frequency $b_1\omega_c$, thus modifying the spin current precession with frequency $\tilde{\omega}_s$. Figure 3(b) shows typical spin-wave signals in relation to the conduction electron spin resonance line. The wave vector $q=n\pi/L$ is determined by the standing waves confined by the thickness L of a thin-film sample.

3. COLLECTIVE EFFECTS ASSOCIATED WITH INTERBAND TRANSITIONS

In a solid, the electronic structure consists of a number of energy bands. In the ground state of the system, a completely filled band is known as a valence band and a partially filled or empty band is known as a conduction band. Optical processes which involve interband transitions may incur collective effects through the particle interaction. These phenomena are clearly outside the scope of the jellium model even though the model has been shown in the last section to be extremely useful in illustrating the collective effects of electrons in a single conductor band.

In an insulator or semiconductor, the conduction bands are all empty. Light can excite the transition of an electron to a conduction band leaving behind a hole in the valence band. The electron-hole pair binds into a hydrogen-atom-like entity, known as an exciton, which survives from a nanosecond to a microsecond before the electron deexcites giving out a photon (see EXCITONS; Rashba and Sturge, 1982). With a sufficiently intense light source, the density of excitons can increase so much that Keldysh predicted that they would form a new metallic phase, known as the electron-hole liquid (see Rice, 1977; Hansel *et al.*, 1977; Jeffries and Keldysh, 1983), with a number of new collective phenomena, which we shall examine in Sec. 3.1. The phase diagram is like that of the gas–liquid transition. The collective modes include the two branches of the plasma oscillations and the analog of the helicon wave in a neutral plasma known as the Alfvén wave which has a different frequency dispersion from the helicon and which can now have either circular polarization about the magnetic field axis.

In a metal or a doped semiconductor, with one or more partially filled conduction bands, the appearance of a valence hole following the interband transition causes the conduction electrons to react (Sec. 3.2). If the valence hole is localized, the reaction of the conduc-

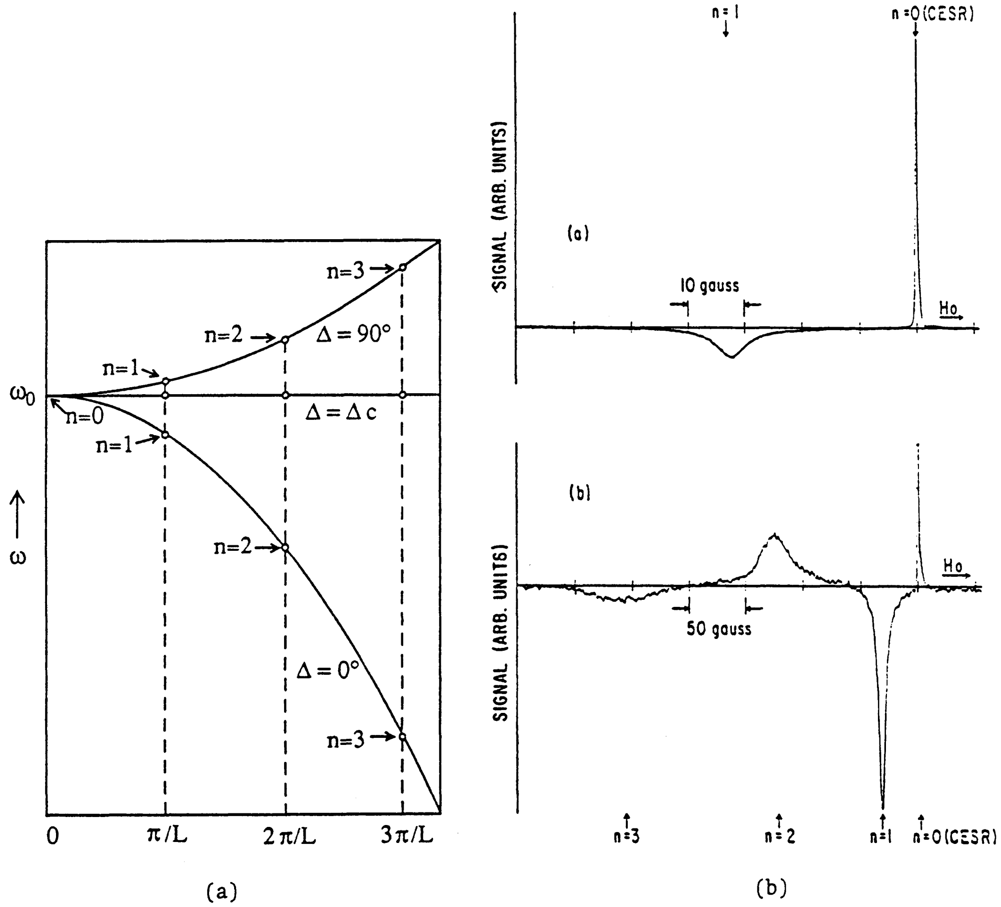

FIG. 3. (a) Schematic spin-wave dispersion for three values of the angle between the wave vector and the magnetic field normal to a metal film of thickness L. (b) Typical spin wave signals for $\Delta=90°$ sweeping the static magnetic field, showing the conduction electron spin resonance line and the spin waves at three wave vectors $q=n\pi/L$, L being the thickness of the Na film. "CESR" stands for conduction electron spin resonance. [From Dunifer *et al.* (1974), Figs. 1 and 6(b); reproduced with permission.]

tion electrons creates a large number of density waves around the Fermi surface, leading to a threshold singularity at the Fermi level in the optical spectrum. In x-ray emission, the hole is deep in the core of an atom and is well localized. Mahan predicted that an edge singularity should be seen. The relevance of the edge singularity in the experimental x-ray emission and absorption spectra and in x-ray photoemission is surveyed below. The strength of the edge singularity in the optical spectrum of a doped semiconductor quantum well varies with samples, seemingly dependent on whether the hole is localized or is mobile with a finite mass. The theory of the finite mass effect of the valence hole on the edge singularity is discussed below.

3.1 Excitons and the Electron-Hole Liquid

In a semiconductor, an electron and a hole created by the absorption of a photon relax, respectively, to the bottom of the conduction band and the top of the valence band. There, they are bound by the mutual Coulomb attraction mediated by the dielectric constant of the medium to form a hydrogen-like entity called the exciton. As Keldysh (Jeffries and Keldysh, 1983) puts it, the exciton resembles more the positronium than the hydrogen atom in that after a time the electron-hole pair recombines emitting a photon. Two excitons have the tendency to form a biexciton molecule. A large number of excitons may form a liquid phase of electrons and holes, called the elec-

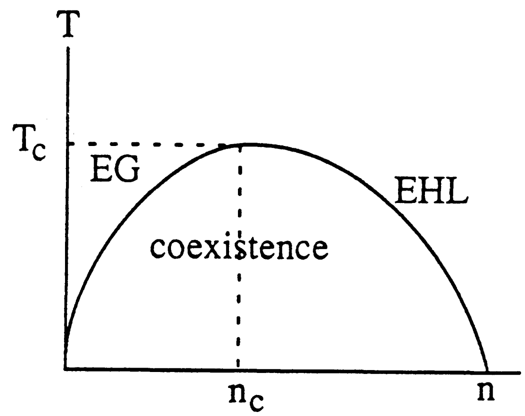

FIG. 4. Schematic phase diagram of the electron-hole liquid (EHL) and exciton gas (EG) in the temperature T and density n plane.

tron-hole liquid (EHL), in which the individual electron and hole are no longer bound to each other. Such a system may be considered in quasiequilibrium because the relaxation times of the carriers to the conduction-band valley and the valence-band peak, of the order of picoseconds, are shorter than the recombination time of the electron-hole pair, which is of the order of nanoseconds in a direct bandgap semiconductor such GaAs and of the order of microseconds in an indirect gap material such as Ge or Si.

3.1.1 The Phase Diagram. Figure 4 shows a schematic phase diagram of equal numbers of electrons and holes as a function of density n and temperature T. At low density and high temperature they form a gas of excitons (EG), and at high density and low temperature they form an electron-hole liquid (EHL). The phase transition between the two phases is first order except, of course, at the critical point (n_c, T_c). Thus, there is a coexistence region, in which the liquid phase is composed of droplets. The calculation of the phase boundary requires a careful comparison of the total energy of the exciton gas with that of the two-component plasma, including the kinetic energy, exchange, and correlation, as well as the dependence on the bulk electronic structure of conduction valleys and the valence band peak. (See Rice, 1977; Vashishta, *et al.*, 1983.) Strain in some instances favors the formation of the liquid phase and has been utilized in Ge to produce very large drops (see Wolfe and Jeffries, 1983).

The quasiequilibrium properties of EG and EHL are observed by the luminescence spectra due to electron-hole recombination after the semiconductor is excited by a light source. (See Westervelt, 1983.) Figure 5 is an excellent example. The top panel shows the spectrum of the exciton gas phase. Since Ge has an indirect band gap, recombination of an electron-hole pair must be accompanied by the emission of a phonon to conserve momentum. In this case, the phonon assistance is rendered either by the longitudinal acoustic branch (the luminescence peak labeled LA) or the transverse optical branch (the peak labeled TO). With the increase of the intensity of the excitation light, at a well-defined threshold, a broad peak marked EHD appears below the free-exciton (LA) peak, marked FE in the lower panel of Fig. 5. The broad peak is due to the recombinations in the electron-hole drop, with the width of the peak being a measure of

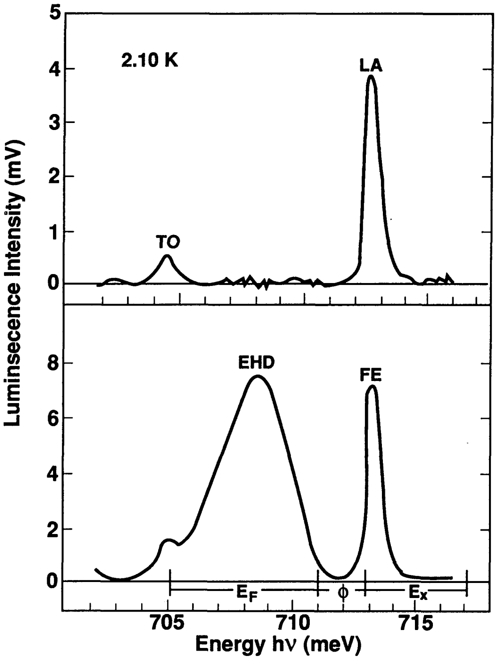

FIG. 5. Upper panel: Luminescence spectrum of the free excitons (FE) in Ge at 2 K. The phonon replicas are marked by LA and TO. Lower panel: Luminescence of the electron-hole drop (EHD) when the excitation light power is twice as high as above. The LA replicas are marked FE and EHD. [Taken from Westervelt, (1977), Figs. 1.3 and 1.4; also published in Jeffries and Keldysh (1983), p. 196, Fig. 6; reproduced with permission.]

the sum of the Fermi energies of the electrons and holes in the liquid.

3.1.2 Plasma Oscillations and Alfvén Waves in EHL. The electron-hole liquid is a two-component neutral plasma, analogous to jellium with a mobile positive background. The plasma oscillation, therefore, has two branches, a high-frequency branch with the long-wave limit frequency $\omega_p^2 = 4\pi ne^2/m$ with m being the reduced mass of the electron-hole pair, and an acoustic branch with frequency dependent linearly on the wave vector. The energy scale is, however, different from that in the simple metals. Since the Fermi energy in an EHL is of the order 10 meV, the collective excitation is in the infrared range. (See Markiewicz and Timusk, 1983.)

The electrons in jellium form a light-mass mobile component, the restriction of whose motion by the magnetic field allows the propagation of helicon waves. The counterpart in EHL, in which the two components of the plasma have comparable masses and are both mobile, is the Alfvén wave. In the wave equation (50), the dielectric function for the positively circularly polarized wave is changed from Eq. (51) to

$$\epsilon(0,\omega) = 1 - \sum_{j=e,h} \frac{\omega_{pj}^2}{\omega(\omega - \omega_{cj} - i/\tau_j)}, \qquad (69)$$

where the index $j=e,h$ denotes the quantity for the electron or hole component. The hole cyclotron frequency is $\omega_{ch} = eH_0/cm_h$, whereas the electron one is $\omega_{ce} = -eH_0/\mathrm{c}m_e$. In the high frequency regime we retrieve the plasma oscillation. In the high-field regime, with $\omega_{cj}\tau_j \gg 1$, the cancellation of the first-order term in ω on the left-hand side of the wave equation (50) leads to the low-frequency mode being linear instead of quadratic in the wave vector q:

$$\omega^2 = q^2 H_0^2/4\pi(m_e + m_h). \qquad (70)$$

The other difference between the helicon wave and the Alfvén wave lies in the sense of the circular polarization, which in the former can be in only one sense dependent on the charge of the active component of the plasma but which can be both right- and left-handed in the neutral EHL.

Other interesting phenomena in the light scattering of the EHD arise out of the finite size of the droplets. See Jeffries and Keldysh (1983) for further details.

3.2 Dynamical Response of the Fermi Sea to Interband Transition

During an interband optical transition, the presence of a hole in a valence band causes the Fermi surface to respond dynamically. The most dramatic manifestation of this is in the power-law singularities in energy at the Fermi level in the emission and absorption spectra and in the asymmetric line shape of the photoemission spectrum. (For reviews see Mahan, 1990; Almbladh and Hedin, 1983.) Here we shall examine the effects which occur in the soft x-ray range of core-level transitions in metals and in the optical range of valence- to conduction-band transitions in semiconductor quantum wells. The basic cause is the sudden perturbation by the appearance or disappearance of the core hole, which provides a charged-impurity-like potential (Hopfield, 1969). That the initial and final states of the system are under the influence of different potentials, and thus differ by more than a single-particle transition, resembles the Franck–Condon effect. The edge singularity arises out of the high density of states of the electron-hole pair density fluctuations at the Fermi level. We first explain the principle of the phenomenon before detailing the experimental observations in the x-ray range in metals and in the optical range in modulation-doped semiconductor quantum wells.

3.2.1 Principle of the Mahan or MND Effect. The effect of the dynamical response of the Fermi sea to the core hole is known as the Mahan or MND effect, in honor of the originator, Mahan (1967), and of Nozières and de Dominicis (1969), who gave a more complete theory, thereby elucidating the subtle competing factors which determine the power-law indices. Here, we shall first give a qualitative description of their theories and then use the boson model to supply a somewhat more quantitative understanding of the phenomenon. In this subsection, the core level is taken to have no dispersion or, equivalently, the core hole is assumed to be localized.

In the state of the system with a core hole, a conduction electron in the Fermi sea and the hole attract each other with a Coulomb interaction screened by the other electrons. The change of the electron state is limited by the available phase space because of the presence of the Fermi sea. In addition, the tendency to excitonic formation is countered by the ability of the core hole to excite electron and (conduction-band) hole pairs in the Fermi sea. The net result is the elimination of the formation of an exciton in the metal above the Fermi level, placing sufficient oscillator strength in the neighborhood of the Fermi level to cause the absorption or emission spectrum to have a power-law singularity, $|E-E_F|^{-\alpha}$. So far, the consideration has not included the fact that all the conduction-band states are changed in the presence of the core potential. When this is taken into account, the overlap matrix element of the many-electron state in the presence of the core hole and the state in its absence is vanishingly small as the number of electrons tends to infinity. This effect is known as the infrared catastrophe (Anderson, 1967). The orthogonality between the two many-electron states tends to lower the oscillator strength for the transition and to reduce the power-law singularity. The existence of a Fermi edge singularity is the delicate net result of these three competing factors (electron-core-hole attraction, production of conduction-band electron-hole pairs, and the infrared catastrophe).

The appearance or disappearance of the core hole between the initial and final states creates a sudden perturbation in time. Its effect is very different from a perturbation which is adiabatically turned on, even if the strength of the sudden perturbation is weak. The response of the system to a small adiabatic perturbation is adequately described by the linear response (Sec. 1.2). To illustrate the difference between the two types of perturbation, consider the example of a harmonic oscillator of frequency ω in the ground state at time $t=0$ subject then to a weak force

$$F_0(1-e^{-t/\tau}), \tag{71}$$

with a time constant τ. What is the probability of finding the oscillator in the first excited state after a long time? In the adiabatic limit $(\tau \gg 1/\omega)$, the probability is $|F_0 x_{10}/\omega^2\tau|^2$, where x_{10} is the matrix element of the displacement. The probability of exciting the oscillator from its ground state goes to zero with the rate of the adiabatic switching on. In the sudden limit $(\tau \ll 1/\omega)$, the probability is $|F_0 x_{10}/\omega|^2$. A sudden perturbation of the same strength as the adiabatic perturbation can make the system leave its ground state.

Now consider a boson model more relevant to the optical transition problem and justify its relevance to the Fermi system after we have seen the results of the boson model. Suppose that the system in state a with energy E_a is uncoupled to the bosons but in state b with energy E_b is coupled linearly to the bosons of frequency ω_q by the Hamiltonian

$$H_1 = \sum_q V_q(b_q + b_q^\dagger), \tag{72}$$

in terms of the linear coefficient V_q and boson creation and destruction operators. If H_r denotes the light excitation with frequency ω, the absorption spectrum $P(\omega)$ for the transition from state a to state b is given by the Fourier transform of the correlation function,

$$P(t) = \langle H_r(t) H_r(0) \rangle_a, \tag{73}$$

the ensemble average being over the bosons with the system in state a. For simplicity, the excitation matrix element is taken to be independent of the boson states; then $P(t)$ is proportional to the correlation function

$$S(t) = \langle e^{iH_b t} e^{-i(H_b + H_1)t} \rangle, \tag{74}$$

where H_b is the boson Hamiltonian and $\hbar = 1$. The matrix element with respect to the state a has been evaluated [a factor of $\exp\{i(E_b - E_a)t\}$ is understood] and only the boson ensemble average remains. This correlation function is easily evaluated in the same way as the derivation of the Debye–Waller factor for harmonic phonons (Maradudin *et al.*, 1963):

$$S(t) = e^{-i\delta E t + g(t) - 2M}, \tag{75}$$

where

$$\delta E = -\sum_q |V_q|^2/\omega_q \tag{76}$$

represents the change in the transition energy to $E_t = E_b - E_a + \delta E$ due to the reaction of the bosons,

$$2M = \sum_q (2n_q + 1)|V_q|^2/\omega_q^2 \tag{77}$$

is the Debye–Waller factor, n_q being the boson distribution, and

$$g(t)=\sum_q [n_q e^{i\omega_q t}+(n_q+1)e^{-i\omega_q t}]|V_q|^2/\omega_q^2 \tag{78}$$

is essentially the boson propagator. Note that if the boson perturbation H_1 were turned on adiabatically the terms $g(t)$ and $2M$ would be absent.

The spectrum $S(\omega)$ has two types of behavior at threshold depending on whether M is finite or not. The Debye–Waller factor is from Eq. (77) expressed in frequency terms at zero temperature as

$$2M=\int_0^\infty d\omega N(\omega)|V(\omega)|^2/\omega^2, \tag{79}$$

where $N(\omega)$ is the boson density of states. The Debye–Waller factor is finite, e.g., for phonons with deformation-potential coupling

$$N(\omega)\propto\omega^2;\quad V(\omega)\propto\omega^{1/2}. \tag{80}$$

If the coupling V is weak, a series expansion of the spectrum yields

$$S(\omega)=\delta(\omega-E_t)e^{-2M}+e^{-2M}\sum_q\left|\frac{V_q}{\omega_q}\right|^2 \times\delta(\omega-E_t-\omega_q)+\cdots. \tag{81}$$

The first term is the no-phonon line and the second term is the one-phonon side band, etc. The reduction in strength by the Debye–Waller factor can be understood as the overlap between the initial and final states reduced by the change of the final state by the presence of the phonons.

The Debye–Waller factor is infinite for the example of phonons with piezoelectric coupling,

$$V(\omega)\propto\omega^{-1/2}, \tag{82}$$

or for the more relevant example of the density waves in a fermion system:

$$N(\omega)\propto\omega;\quad V(\omega)\propto\omega^0. \tag{83}$$

In this case, the no-phonon line disappears and the spectrum has a power-law singularity at the threshold.

This simple boson model has a diverse range of applications: infrared spectrum of electronic transitions in impurities coupled to phonons in insulators (see the review by Duke and Mahan, 1965), Doppler shift in the Mössbauer effect (Maradudin, 1966), and paraelectric resonance (Sander and Shore, 1970). We shall now adapt it to the fermion system in place of the bosons.

We follow the treatment of Schotte and Schotte (1969) as being the most physical approach. The sudden introduction of a core-hole potential creates electron-hole pairs in the vicinity of the Fermi surface or density waves:

$$b_k^\dagger=c_{k_>}^\dagger c_{k_<}. \tag{84}$$

The right-hand side depicts the creation of an electron outside the Fermi surface at $k_>$ and destruction of one inside at $k_<$. The creation of the density wave at $k=(k_>,k_<)$ is approximately a boson operator. The density wave has energy

$$\omega_k=\epsilon_{k_>}-\epsilon_{k_<}. \tag{85}$$

The density of states of the density waves is given by the convolution of the electron-hole pair densities of states, which for small energy difference from the Fermi level yields

$$N(\omega)=\omega N_0^2, \tag{86}$$

where N_0 is the electron density of states at the Fermi level. The linear ω dependence of the boson density of states and the coupling constant V from the Coulomb interaction between the core electron and the density waves means that the Debye–Waller factor diverges. The evaluation of the two exponents in Eq. (75) together gives for large t

$$g(t)-2M=-(\delta/\pi)^2\ln|\omega_F t|, \tag{87}$$

where N_0V has been replaced by the s-wave phase shift and ω_F is the cut-off energy for the density waves of the same order as the Fermi energy.

The correlation function $S(t)$ may be thought of as that of the core hole after photoemission, which after a long time behaves like

$$S(t)\sim e^{-iE_t t}(\omega_F t)^{-(\delta/\pi)^2}. \tag{88}$$

The photoemission spectrum near the threshold E_t is, therefore,

$$S(\omega)=\left(\frac{\omega-E_t}{\omega_F}\right)^{(\delta/\pi)^2-1}. \tag{89}$$

Physically, this is what has happened. Photoemission from the core level leaves behind a core hole which provides a sudden attractive potential creating density waves in the conduction-band Fermi sea. The number of such waves is large $[N(\omega)\sim\omega]$, compared with the low-energy phonons $[N(\omega)\sim\omega^2]$. The sheer number of density waves makes the excitation of the system out of the ground state very probable, so much so that the overlap of the current state with the old ground state is zero. Hence, the "zero-phonon" line disappears. The effect of the sudden perturbation of such a large number of density waves persists a long time, like the grin of the Cheshire cat, causing the power-law divergence of the spectrum at the threshold.

The x-ray absorption (or emission) spectrum involves the transition of a core electron to the conduction band and is given by

$$P(t)=\sum_{kk'}\langle e^{iH_b t}c_k e^{-i(H_b+H_1)t}c^\dagger_{k'}\rangle, \tag{90}$$

where, as in the boson model, H_b is the Hamiltonian for the density waves and H_1 couples the density waves to the core hole. By comparing the commutation relation with that for the density wave b_k, one obtains the boson approximation for the fermion operator:

$$\sum_k c_k\sim\exp\left\{\sum_k (b^\dagger_k-b_k)/\omega_k N_0\right\}. \tag{91}$$

The difference between the absorption spectrum P here and the photoemission spectrum S above is that now after the introduction of the sudden perturbation a conduction electron is added in the same locality as the core hole, as given by the operator in Eq. (91). Since this is just a linear displacement operator of the harmonic oscillator, the correlation function $P(t)$ can be evaluated in a similar way to that for $S(t)$. The threshold behavior is

$$P(\omega)\sim\left(\frac{\omega-E_t}{\omega_F}\right)^{[(\delta/\pi)-1]^2-1}. \tag{92}$$

The presence of the conduction electron changes the phase shift δ by $-\pi$.

3.2.2 Experimental X-ray Spectra in Metals.

Transitions from deep core levels in metals fit the localized core-hole model discussed in the previous section very well. In x-ray photoemission (XPS), we expect the spectrum of a deep core level, which would be a sharp line in the independent-particle model, to become a broadened asymmetric line when the power-law singularity in Eq. (89) is rounded off by phonons and by decay through excitation of the Fermi sea. Such asymmetry is indeed observed in the XPS of Na, Mg, and Al from 1*s*, 2*p* levels (Citrin *et al.*, 1977). Quantitative fit of the power law yields indices in good agreement with theory.

The x-ray absorption and emission spectra, involving electron transitions from the core level to states near the Fermi level, should also have power-law singularities with the same index, different from that of the XPS. This is confirmed by observation in Na, Mg, and Al. (See a comprehensive analysis of the power-law fit to the experimental data by Citrin *et al.*, 1979.) Figure 6 clearly shows that in the emission and absorption spectra of Na, both peak structures near the Fermi level are observed. One exception is Li, where the broadening by phonons dominates over the dynamical response of the Fermi sea (Mahan, 1990).

3.2.3 Optical Spectra in Doped Semiconductor Quantum Wells.

Thin layers of different semiconductors with very sharp interfaces can be grown epitaxially (see HETEROSTRUCTURES AND SUPERLATTICES, SEMI-

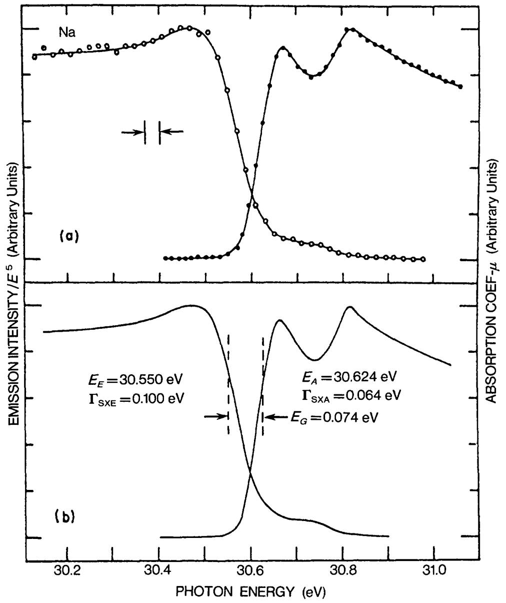

FIG. 6. Soft x-ray emission and absorption spectra with $L_{2,3}$ shell in Na: (a) spectral curves fitted to original data; (b) after correction for instrumental broadening. [From Callcott *et al.* (1978), Fig. 7; reproduced with permission.]

CONDUCTOR). If a semiconductor, such as GaAs, is sandwiched between two layers of another with a larger band gap, such as AlGaAs, electrons released by doping in the AlGaAs layers will be confined in the GaAs layer (see ELECTRON STATES IN ZERO-, ONE-, AND TWO-DIMENSIONAL STRUCTURES). Hence, the structure is called a quantum well. Quantization of the electron motion normal to the interfaces yields a set of subbands. In an undoped quantum well, the optical excitation of an electron from the topmost valence subband to the lowest conduction subband yields an exciton with a binding energy much stronger than the three-dimensional counterpart, such that the exciton line may be seen in the optical spectrum even at room temperature. Doping in the quantum well to produce a Fermi sea of electrons unbinds the excitons, not so much through screening of the attractive Coulomb potential as through the phase-space exclusion by the Fermi sea (Schmitt-Rink *et al.*, 1989). In a doped quantum well, are the Fermi edge singularities seen in the absorption and emission spectra for transitions between the conduction and high lying valence subbands?

Observations vary with samples (Fig. 7). In both InGaAs/InAlAs and GaAs/AlGaAs quantum wells, some samples (Skolnick *et al.*, 1987; Lee *et al.*, 1987) show the edge singularity behavior in both absorption and emission while others (Soorykumar *et al.*, 1987; Livescu *et al.*, 1988; Zhang *et al.*, 1990) show the edge singularity in absorption but not in emission.

The theory of the edge singularity reported above assumes that the valence electron energy has no dispersion. Thus, it has been assumed that when the edge singularities are seen in the quantum wells, the transition is not from the valence subband but from a localized state due either to the alloy fluctuations or to the interface roughness. A finite dispersion rounds off the power-law singularity (Müller-Hartmann *et al.*, 1971). In the last section, the singularity is shown to arise out of the density of states of the electron-hole pair being linear in the energy ω from the Fermi level. If the valence-band dispersion is taken into account, the density-wave energy is modified to be

$$\omega_k=\epsilon_{k_>}-\epsilon_{k_<}+(k_>-k_<)^2/2m_h, \qquad (93)$$

where m_h is the valence-hole mass. Then the density of states is quadratic in ω for $\omega < 4E_F m_e/m_h$ and linear in ω for larger ω. Thus, in the valence correlation function the power law is depressed to zero accompanied by the rise of the zero-phonon line if $\omega < 4E_F m_e/m_h$.

A more careful treatment of the finite valence-hole mass (Uenoyama and Sham, 1990) shows that, while the finite valence-band dispersion rounds off the power-law singularity in both the absorption and emission spectra, it also allows for the Boltzmann distribution of the valence hole before recombination which decreases the intensity of emission as the energy increases towards the Fermi level. This effect is clearly seen in the luminescence spectrum of a GaAs quantum well [Fig. 7(c)]. The roundoff is apparently not sufficient to remove the peak at the Fermi level in the absorption spectrum altogether.

4. SOLITONS

So far in this article, we have relied entirely on the concept of linear response to understand the collective excitations in solids. Consequently, these collective excitations are small oscillations of a property about its equilibrium value. A characteristic of the linear theory is that the collective modes of a particular kind can be superposed on one another without changing their properties. There are nonlinear couplings of these excitations, such as the anharmonic coupling of the phonons and the electron–phonon interaction. If the nonlinear corrections are treated as perturbations, the results are renormalization of the excitation dispersion (energy vs momentum) relations, modification of lifetime, and generation of harmonics or sum and difference frequencies (Nakajima *et al.*, 1980). Perturbation treatment of nonlinearity, however, misses important nonlinear effects, among them the collective excitation known as the soliton. We shall first study the soliton solutions of two important nonlinear equations and then survey their applications in solids.

When nonlinear interaction is taken into account there are collective modes which cannot be described in terms of small disturbances. The solitary wave is an example of a collective mode in which the deviation from

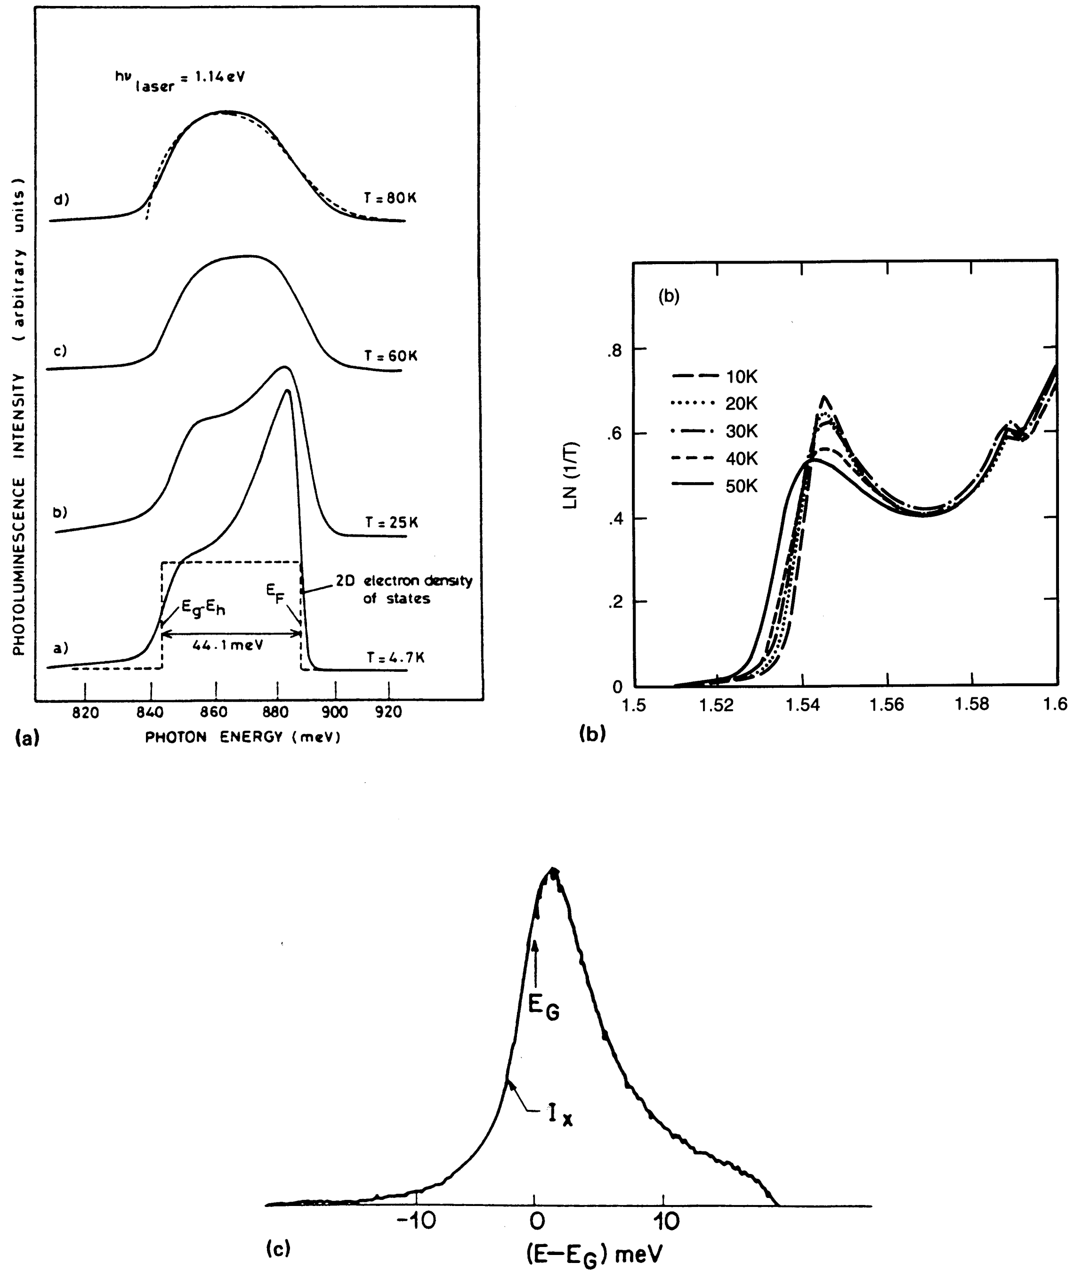

FIG. 7. (a) Emission spectra of an *n*-doped InGaAs/InP quantum well with an electron density of 9.1×10^{11} cm^{-2} at various temperatures. The dashed curves show the spectra calculated without the interaction effects. equilibrium is large and yet which has a long lifetime. A wave packet of linear waves will in time disintegrate if different components of the linear waves move with different speeds. The soliton keeps its shape. In this section we describe the soliton solutions of two ubiquitous nonlinear equations in one dimension: the sine-Gordon and the nonlinear Schrödinger equations. The former solution is more accurately depicted as a kink, i.e., a finite deviation from the equilibrium value in one-half of the one-dimension system and no deviation in the other half of the system. The soliton solution of the nonlinear Schrödinger equation is truly an isolated wave of finite extent which moves through the system without changing its shape. The occurrence (or nonoccurrence in one instance) of the solitons in solids is surveyed. A particularly important role played by the soliton is domain formation near a phase transition, be it a transition from a paramagnetic solid to ferromagnetic, from a commensurate to incommensurate charge-density wave, or from a normal to superconducting metal. Soliton propagation of electromagnetic waves in a dispersive optical fiber may have important potential application in fiber-optic telecommunications.

4.1 The Sine-Gordon and the Nonlinear Schrödinger Equations

There is a large class of nonlinear differential equations with soliton solutions. We shall not discuss the method of solving such nonlinear equations and refer the reader to Eilenberg (1981) and Newell (1985), which are readable by a physicist with a normal mathematical background. We concentrate here on describing the soliton solutions to two nonlinear differential equations which appear in a great number of areas of solid-state physics.

The first is the sine-Gordon equation:

$$\frac{\partial^2\psi}{\partial t^2}-c^2\,\frac{\partial^2\psi}{\partial x^2}+\omega_p^2\,\sin\psi=0. \tag{94}$$

If ψ is small so that the sine term can be replaced by the argument, the solution is a harmonic wave with the frequency wave vector relation given by

$$\omega^2=\omega_p^2+q^2c^2, \tag{95}$$

which we have seen in the case of the transverse plasma oscillations in Sec. 2.2.6. In the linear approximation, a superposition of the waves can make up a wave packet localized in space. However, the components are dispersive so that after a time the width of the packet grows and the wave packet begins to unravel. The nonlinear term in the sine-Gordon equation acts to counter that tendency. A suitably localized wave packet can maintain its shape forever (or for as long as damping, which has not been included in the equation, does not come into play). Such a soliton solution is given by

$$\psi=4\,\arctan[e^{(x-x_0-vt)/\xi}]. \tag{96}$$

The solution changes from 0 to 2π in the neighborhood of x_0+vt within a width of the order ξ, where

$$\xi=\frac{c}{\omega_p}\,\sqrt{1-\frac{v^2}{c^2}}\,. \tag{97}$$

It is a rounded step propagating with speed $v<c$, not otherwise dependent on the parameters ω_p and c of the differential equation. Although the equation is nonlinear, a characteristic of the solitons is that two solitons can pass through each other with no change in shape. A more apt description is the term "kink" solution. Superposed on the soliton can be small oscillations (see Krumhansl in Bishop and Schneider, 1978).

The second nonlinear equation which appears frequently in solids is the nonlinear Schrödinger equation:

$$i\,\frac{\partial\psi}{\partial t}+\frac{\partial^2\psi}{\partial x^2}+|\psi|^2\psi=0. \tag{98}$$

The soliton solution is

$$\psi=\operatorname{sech}(x)e^{it/2}. \tag{99}$$

This is indeed a solitary wave peaked about the origin.

4.2 Some Applications in Solids

The soliton solution of the sine-Gordon equation occurs in a number of areas in solids (Bishop and Schneider, 1978; Davydov, 1985). The most direct application is in the Josephson junction transmission line (see also Superconductivity, Low-Temperature), which is composed of two superconducting metal strips separated by a thin insulating barrier permitting Josephson tunneling of Cooper pairs between the metal strips. The superconducting order parameter is given by ψ.

Close to the second-order phase transition, the Landau theory for the free energy quartic in the order parameter (see PHASE TRANSITIONS) yields a static version of the nonlinear equation with the sine term replaced by the first two terms of its power series. The quartic term is temperature dependent. Above the transition temperature, the free energy has only one minimum, which corresponds to the normal state. Below the transition temperature, the quartic polynomial develops two minima. The ground state is given by one of the two minima of the quartic free energy. A soliton solution is an excitation which connects one order parameter value in one spatial region of the system to the other order parameter value in another region. This applies to all second-order transitions with complex order parameters, including superconductivity, order–disorder, magnetism, and charge-density waves. For a quasi one-dimensional superconductor, the soliton is the counterpart of the vortex structure in three dimensions. In a ferromagnet, it is a domain wall. The soliton solutions are important to the statistical mechanics of critical phenomena around the transition.

In a one-dimensional charge-density-wave state commensurate with the lattice, such as the Peierls distortion (see the next section), the soliton connects two equivalent distortions in different sections of the linear chain and provides an excited state lying in the energy gap of the semiconductor. (See the review by Heeger *et al.*, 1988.) The kink solution in this case does not share the soliton property of two of them being able to pass through each other without changing shape. It has an unusual charge and spin relation. With the soliton, there appears near midgap a single electronic state. The unpaired electron gives a 1/2 spin but the whole complex is neutral (charge zero). If the midgap electronic state is empty, or is occupied by two electrons if their Coulomb repulsion is insufficient to put one of them above the gap, then the soliton is charged but its spin is zero. Such states are seen in the optical spectra of the conducting polymers. In a one-dimensional charge-density-wave state incommensurate with the underlying crystal lattice, e.g., in $NbSe_3$, the excited state of the sliding charge-density wave obeys the sine-Gordon equation. (See the review by Grüner, 1988.) The sliding charge density gets pinned by defects and, consequently, its effects on the transport show up not in the dc conductivity but in the ac and nonlinear conductivity. Tunneling through a pinning center is possible (Bardeen, 1986). Claims of solitons playing a role in the charge-density transport (Rice in Bishop and Schneider, 1978) were disputed by Grüner (1988). Near a commensurate–incommensurate phase transition, the incommensurate phase consists of large commensurate regions separated by domain walls, which have been shown to be solitons of the sine-Gordon equation (Bak in Bishop and Schneider, 1978).

Hasagawa and Tappert (1973) first suggested the possibility of soliton propagation of light in an optical fiber. Provided that the optical medium is dispersive (i.e, the frequency–wave-vector relation is nonlinear), the electromagnetic pulse propagation is governed by the nonlinear Schrödinger equation, in which $x \rightarrow t - x/v$ and $t \rightarrow x$ with the new distance and time variables expressed as dimensionless quantities in units of the critical length and time scales, which are dependent on the medium parameters. Mollenauer *et al.* (1986) have verified experimentally that such soliton propagation in a fiber is possible. They suggest that the inevitable slight loss be compensated by energy boosting with Raman scatterings at periodic intervals of the long fiber. This is potentially of great importance in optical communications.

5. PHASE TRANSITION FROM COLLECTIVE-MODE INSTABILITY

In the foregoing, we have, with the exception of the electron-hole drop, mostly described collective excitations from a "normal" state: resistive as opposed to superconducting, paramagnetic as opposing to magnetic, and high crystal symmetry as opposed to lower symmetry. The excitation of a collective mode increases the free energy of the system in a stable state. If it is found in theory to decrease the free energy of the system, then the assumed ground state is unstable against a finite distortion of the collective mode, resulting in a phase transition. This can come about by varying a system parameter, such as temperature, pressure, density, or magnetic field. The instability presages a phase transition. This view is taken here to introduce a model ferromagnetic transition, the charge- and spin-density-wave states and concomitant structural distortions, and the Wigner lattice, which, in a two-dimensional system, competes with the fractional quantum Hall effect.

The finite change of the collective-mode coordinate serves as the order parameter of the new phase. In solids, such a phase transition is accompanied by a change in symmetry. The change from high to low symmetry is often called broken symmetry. In the new phase, there is often a collective mode associated with the broken symmetry tending to restore the old phase. Notable examples not treated here are the collective mode of the superconducting order parameter and spin waves in antiferromagnets. For more detailed expositions of the consequences of such phase transitions, we refer to Anderson (1984) and Nakajima *et al.* (1980). In this section, we survey the possible unstable collective modes as preludes to phase transitions.

5.1 Itinerant-Electron Ferromagnetism

The simplest example of an instability is the spin-density response to a uniform and static magnetic field in jellium. The spin susceptibility given in Sec. 2.2.3 has a denominator $1+B_0$. The Landau parameter B_0 is negative. As the density is lowered, it reaches the value of -1. Then the paramagnetic ground state of equal populations of up and down spins of electrons becomes unstable against the state which has more electrons in one spin direction than the other. The new state possesses a spontaneous magnetization. From the total-energy point of view, the kinetic energy of the system is raised if, instead of the electrons being distributed equally in two spin states, more electrons are put in one spin state than in the other. On the other hand, this act would increase the exchange and correlation of the electrons, thereby lowering the total energy of the system since the exchange and correlation energy of the system is negative. Since the ratio of the exchange and correlation energy to the kinetic energy is r_s, which is inversely proportional to the cube root of the density (see Sec. 1.3.1), in the small-r_s or high-density limit the state is paramagnetic, and in the large-r_s or low-density limit the state is ferromagnetic. Ceperley and Alder (1980) have computed the density at which the transition of jellium to the ferromagnetic state occurs.

The above is a modern rendering of Bloch's theory of itinerant-electron ferromagnetism. The actual cause of ferromagnetism in real metals is more complicated. In *d*-electron ferromagnets, such as iron, cobalt, and nickel, the *d* orbitals are considered partly to provide localized spins and partly to provide itinerant spins. We refer to the article on MAGNETIC ORDERING IN SOLIDS for a proper discussion. We note in passing that the density-functional theory, in the local spin-density approximation, which describes the local exchange-correlation effect as that of an electron gas with the same local density and local spin density, produces magnetization or its absence for the 3*d* and 4*d* transition-metal series in good agreement with observation.

An example of a transition analogous to the ferromagnetic transition in jellium is provided by a quasi two-dimensional electron system in silicon metal-oxide-semiconductor field-effect transistors (MOSFETs), in which the role of the conduction valleys replaces the role of spins in the ferromagnetic transition. In a silicon MOSFET, a layer of electrons is trapped at the silicon interface with the oxide. If the silicon surface is in the (111) crystalline direction, there are six conduction valleys which contribute to the layer. At high density, the layer is made of equal populations from the six valleys. At low density, the splitting of the valley degeneracy has the same origin as the ferromagnetic transition of the electron gas (Bloss *et al.*, 1979). The exchange-correlation energy is stronger in a two-dimensional system than in a three-dimensional system because of the confinement in one direction. Thus, the valley transition in a quasi-two-dimensional system may be observed at a more accessible density.

5.2 The Wigner Crystal

In jellium at a sufficiently low density, the kinetic energy of the electron is small compared with the interaction energy. The Coulomb repulsion between pairs of electrons keeps the electrons apart from one another so that they form a lattice, known as the Wigner lattice. In the calculation by Ceperley and

Alder (1980) of the total energy for jellium, as the density decreases, the system first transforms into a ferromagnetic state, and, at still lower density, the electron gas is unstable against the Wigner crystal formation. The lattice of positive ions is, however, not favorable for the formation or observation of the Wigner crystal, nor is the density range in simple metals for which jellium is otherwise a successful model for many collective modes.

A more suitable system is the two-dimensional electron gas confined in a semiconductor heterostructure (Sec. 3.2.3) and under a strong magnetic field normal to the layer. The effect of the background semiconductor lattice is negligible. The appropriate electron density may be obtained by the design of the heterostructure system. The kinetic energy may be lowered relative to the interaction energy by increasing the magnetic field. In two dimensions, the electronic structure is composed of sets of Landau levels broadened by the impurities. As the magnetic field is increased, the number of Landau levels occupied by the electrons decreases. Although there are localized states between the Landau levels due to the two-dimensional disorder, they do not contribute to the Hall voltage. Thus, the famous plateaus are observed (von Klitzing *et al.*, 1980) in the Hall measurement around integral occupations of the Landau levels as the magnetic field is varied. (See QUANTUM HALL EFFECT, or Prange and Girvin, 1987.) The Hall plateaus are also observed (Tsui *et al.*, 1982) at fractional occupation of a Landau level. The state of a fractionally occupied Landau level is a new phase of an incompressible fluid with a gap in its excitation spectrum (Laughlin in Prange and Girvin, 1987). The fractional quantum Hall states compete with the two-dimensional Wigner crystal, which has been claimed to be observed at very low density (Etienne *et al.*, 1988).

5.3 Charge- and Spin-Density-Wave States

A collective mode of oscillating charge or spin density at a finite wave vector may become unstable. Then the ground state of the system develops a static charge- or spin-density distribution with a finite wave vector. The Wigner lattice may be regarded as a linear combination of density waves.

The giant one-dimensional Kohn anomaly which occurs in both the charge- and spin-density responses (Sec. 2.1) causes instability in the charge- and spin-density waves. Whether the system adopts the charge- or spin-density-wave state depends on the interaction energy. In the case of the charge-density state, the lattice of charged ions distorts with the electron-density wave because of the enormous Coulomb attraction between the ions and the electrons. In one-dimensional conductors (see the review volume edited by Devreese *et al.*, 1978), the Kohn anomaly thus causes the phonon at the Fermi diameter $2k_F$ at low temperatures to become unstable, creating a charge-density-wave state.

The formation of the charge-density wave may alternatively be viewed via consideration of the total energy of the system. In the simple example of a linear chain, such as polyacetylene, in which each molecule contributes one conduction electron, the half-filled conduction band of an evenly spaced chain is unstable against dimerization of the chain (displacement of every other molecule, known as the Peierls distortion) opening up a gap in the electron band structure at the Fermi level, transforming the ground state to a semiconductor. If u denotes the displacement of every other molecule, the increase in elastic energy of the chain is proportional to u^2 but the decrease of the total electron energy at zero temperature due to the gap formation is proportional to $u^2 \ln u$, as can be seen by summing the electron energies $-\sqrt{(\epsilon^2+\Delta^2)}$ of the occupied states near the gap where ϵ is the energy measured from the Fermi level in the absence of the distortion and Δ is the half-gap, proportional to u. The balance of the two energy terms yields a minimum of the total energy at a finite lattice distortion, u. In this example, the wavelength of the charge-density wave bears a simple rational ratio to the lattice constant and the charge-density wave is known as a commensurate state. It is possible to have the charge-density wavelength incommensurate with the lattice constant. In that case the static charge density may slide over the periodic lattice potential, yielding a new collective mode. This happens in $NbSe_3$ (see Sec. 4.2; Bardeen, 1986; Grüner, 1988).

In two- or three-dimensional systems, parallel sections of the Fermi surface will also give rise to the giant Kohn anomaly and, hence, a charge- or spin-density-wave instability. These states are common in the layer compounds of transition-metal dichalcogenides, e.g., $NbSe_2$ (Wilson *et al.,* 1975), where the quasi two-dimensional Fermi surface often has parallel sections. A famous example of the spin-density wave in a three-dimensional solid is the explanation of antiferromagnetism in Cr (Fawcett, 1988).

Phonon modes in solids driven unstable by the electron-density response sometime precipitate structural phase transitions. The structural distortion in the quasi one-dimensional conductor potassium cyanoplatinate, at low temperatures, and the soft-phonon modes at the corresponding wave vector above the transition temperature have both been observed (Devreese *et al.,* 1978). A number of the quasi two-dimensional transition-metal dichalcogenides show soft phonons above the charge-density-wave transition temperatures. In some of the A15 compounds, such as Nb_3Sn (reviewed by Sham, 1978), the Sn atoms form a body-centered lattice and the Nb atoms form chains running on the cube crystal planes in all three $\langle 100 \rangle$ directions. Charge-density waves along the chains cause the C_{11}–C_{12} shear to become unstable at low temperatures, accompanied by a Γ_{12} optical-mode distortion, creating a cubic-to-tetragonal transformation.

In this article, we have not touched on diplacive transitions which are not caused by the electron response, as occur in ferroelectric crystals (see DIELECTRIC PROPERTIES OF INSULATORS).

GLOSSARY

Fermi Liquid: A system of particles obeying Fermi statistics and having pairwise interactions. Liquid ^{3}He is an example of an uncharged Fermi liquid and an interacting electron system is an example of a charged Fermi liquid.

Functional Derivative: If a quantity E is determined by a function $n(k,r)$ of variables k and r, an infinitesimal change of the function $\delta n(k,r)$ brings about a change in E of the form

$$\delta E = \int dk \int dr\, f(k,r)\delta n(k,r),$$

where $f(k,r)$ is known as the functional derivative, denoted by $\delta E/\delta n$.

Incommensurate Charge-Density-Wave State: A state with a sinusoidal spatial variation of the electron density of a wavelength not bearing a simple rational ratio to the lattice vector.

MOSFET: Metal-oxide-semiconductor field effect transistor. The MOS forms a capacitor which can confine a layer of electrons on the semiconductor side.

INTRODUCTION

Over millennia, combustion has provided society with much of its practical energy production. From the fire that cooked food for cavemen, to the forges that enabled prehistoric man to emerge from the Stone Age, to the gunpowder that transformed relations between societies in the Middle Ages, and to the boilers and furnaces that drove the Industrial Revolution, combustion has been intimately interwoven with the technological factors that have moved civilization. Even today, although alternative sources of energy production are being intensively pursued, a large fraction of practical energy production is the result of combustion of hydrocarbon fuels.

Combustion has also been responsible for many of the environmental problems associated with modern civilization. The killer fogs and smogs of the past century and the problems of modern air pollution and acid rain are products of the use of combustion for practical energy production. Even more recently, the production of carbon dioxide, an apparently benign product of complete combustion, is now being associated with global warming and the so-called greenhouse effect. (See AIR POLLUTION: COMPONENTS, CAUSES, AND CURES.)

Combustion interacts with society in many ways, influencing economics, foreign policy, and other political and sociological problems. The import and export of hydrocarbon combustion fuels has an enormous impact on the balance of payments for many countries, and access to fuels has played a large role in many foreign policy decisions over the past hundred years.

1. COMBUSTION FUNDAMENTALS

Combustion consists of the reaction of one or more chemical species to produce other species, together with the release of heat. As stated by Strehlow (1984), combustion occurs when "...weak molecular bonds are broken and replaced by stronger bonds and the excess

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

bond energy is liberated to the system, usually causing a very large increase in temperature." This heat can then be used to do work in a thermodynamic sense, driving a practical system such as an internal combustion engine or a furnace.

1.1 Fuels

In most familiar systems, combustion takes place between a fuel, often a hydrocarbon species, and an oxidizer, usually air. The physical properties of the hydrocarbon fuel can vary considerably. Many fuels exist as gases under normal conditions. For example, natural gas consists primarily of methane (CH_4) with small amounts of ethane (C_2H_6), propane (C_3H_8), and other trace species, all of which are gases at room temperature and pressure. Automobile gasoline and diesel fuel are complex mixtures of larger hydrocarbons, with components as large as toluene (C_7H_8), octane (C_8H_{18}), and dodecane ($C_{12}H_{26}$), all of which are liquids at room temperature. Familiar fuels such as firewood, paper, gunpowder, and many others are solids under normal conditions. Fuel storage and distribution, as well as the configuration of the combustion system that consumes them, will then depend on the nature of the fuel.

The fuel need not consist of a hydrocarbon species; one simple fuel is a mixture of molecular hydrogen and carbon monoxide. Other fuels can include N-H species such as ammonia (NH_3) or hydrazine (N_2H_4), sulfur-bearing species such as hydrogen sulfide (H_2S) and carbon disulfide (CS_2), and mixed species such as hexyl nitrate ($C_6H_{13}NO_2$) and hydrogen cyanide (HCN).

In the familiar case of toxic waste incineration, the "fuel" can consist of any of a wide variety of chlorinated hydrocarbon species. Some of the most common of these are methyl chloride (CH_3Cl), vinyl chloride (C_2H_3Cl), and trichloroethylene, TCE (C_2HCl_3). Combustion of such species leads to carbon dioxide, water, and hydrogen chloride (or hydrochloric acid), HCl.

1.2 Oxidizers

Similarly, in the most common combustion situations, the fuel reacts with oxygen, either that present in air (which includes 21% O_2) or in the form of pure oxygen. From a historical point of view, combustion has been nearly synonymous with oxidation of these fuels in air, and this is still the basis of most practical combustion. However, when higher combustion temperatures are desirable, it is possible to use pure oxygen as an oxidizer, and other species such as N_2O_4 and ozone (O_3) are sometimes used as oxidizers for specialized applications. The key to all of these systems is that the reaction of the fuel with the oxidizer releases a significant amount of thermal energy.

1.3 Concept of Stoichiometry

The final product temperature and composition of a combustible mixture, and often the overall rate of combustion, depend on the ratio of fuel to oxidizer. A *stoichiometric* mixture is defined as one in which there is exactly the correct amount of oxidizer present to convert all of the fuel to final products. For example, if propane (C_3H_8) is the fuel, five oxygen (O_2) molecules are required to convert each propane molecule to CO_2 and H_2O:

$$C_3H_8+5O_2=3CO_2+4H_2O. \tag{1}$$

Therefore, a stoichiometric mixture of propane and oxygen would consist of $\frac{1}{6}$ propane and $\frac{5}{6}$ oxygen. If the oxidizer in the same example is air instead of oxygen, then the overall reaction is given by

$$C_3H_8+5O_2+18.8N_2=3CO_2+4H_2O+18.8N_2, \tag{2}$$

since the ratio of N_2 to O_2 in air is approximately 3.76, and a stoichiometric mixture of propane and air would include approximately 4% propane [i.e., one molecule of propane in the 24.8 molecules on the reactant side of reaction (2) above]. The same number of chemical bonds are broken and made in reactions (1) and (2), and so the total heat release is equal in the two reactions. Since that heat must be shared by more product molecules in reaction (2), the product temperature in reaction (1) will be considerably higher than that of reaction (2).

A given fuel-oxidizer mixture can include more or less fuel than a stoichiometric amount. The ratio of the fuel concentration actually present to that which would be the stoichiometric amount is termed the *equivalence ratio*, usually indicated by the symbol Φ, and a mixture with more than a stoichiometric amount of fuel (fuel-rich) has $\Phi > 1$, whereas a mixture with less than a stoichiometric amount of fuel (fuel-lean) has an equivalence ratio $\Phi < 1$.

The importance of the equivalence ratio can be illustrated by showing the variation in product temperature for a methane-air mixture in Fig. 1. The product temperature is defined as the final temperature achieved by a mixture of fuel and oxidizer at a particular equivalence ratio when all of the heat released by the reaction is used to heat the reaction products. This condition is also known as the *adiabatic* condition, and the product temperature is known as the *adiabatic flame temperature*, T_{ad}. The maximum value of T_{ad} is achieved for values of the equivalence ratio close to stoichiometric, falling quite rapidly as Φ moves towards lean or rich. Values of T_{ad} for many fuel-oxidizer mixtures have been collected and tabulated by Lewis and von Elbe (1987) and by Gaydon and Wolfhard (1979). Generally speaking, fuel-oxygen mixtures have much higher values for T_{ad} than fuel-air mixtures, but for both fuel-air and fuel-oxidizer mixtures maximum product temperatures are achieved at nearly stoichiometric values of the equivalence ratio. One result of this trend is that the greatest rate of combustion and the highest power production are achieved for stoichiometric conditions. Unfortunately, for combustion in air (which contains nearly 80% molecular nitrogen), production of nitric oxide (NO), a major chemical pollutant caused by combustion, grows very rapidly with increasing temperature, so that the rate of NO production is also greatest for stoichiometric conditions. This results is one of the great conflicts in much of practical (i.e., air-breathing) combustion: the greatest efficiency and power production occurs at $\Phi = 1$, but the greatest rate of pollutant production also occurs at $\Phi = 1$. One must often sacrifice some degree of performance in order to reduce the unwanted pollutant emissions.

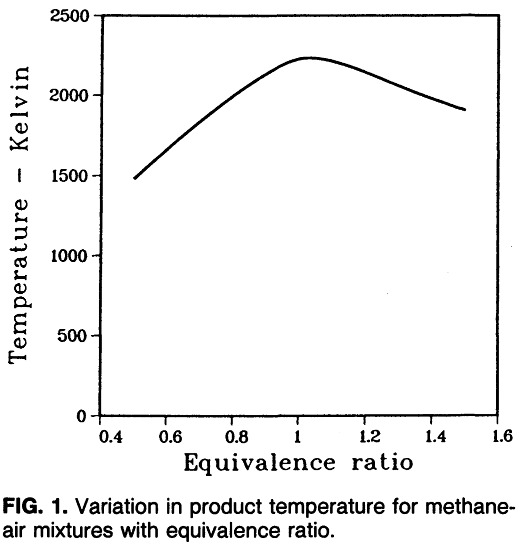

FIG. 1. Variation in product temperature for methane-air mixtures with equivalence ratio.

In addition to the final temperature, the product chemical composition depends strongly on Φ. In particular, on the fuel-rich side of stoichiometric, insufficient O_2 results in incomplete oxidation of the fuel, and products such as carbon monoxide and soot will result.

2. MIXING OF FUEL AND OXIDIZER

In order for combustion to occur, the fuel and oxidizer must interact on a molecular level. There are two general situations that can be used to characterize most combustion environments, based on the mechanism by which the fuel and oxidizer are combined. In the first limit, the fuel and oxidizer are already mixed prior to combustion, whereas in the opposite limit the fuel and oxidizer are initially separated and must be mixed during the combustion process.

2.1 Premixed Systems

In so-called premixed systems, molecular-scale mixing is accomplished prior to combustion. For example, in the familiar case of a laboratory Bunsen burner, the fuel and air are first mixed and stored in a single container, from which the combustible mixture flows into the burner itself. Another perhaps less obvious premixed system is found in the conventional internal combustion engine, where the initially liquid fuel is vaporized and mixed with air in the carburetor immediately prior to being introduced into the engine combustion chamber.

2.2 Laminar Burning Velocity

Premixed combustion represents an instructive limiting condition, and many fundamental combustion properties are defined in terms of premixed processes. For example, if a stoichiometric premixed fuel-air mixture is confined in a linear tube, and the mixture is ignited at one end of the tube, a flame will propagate down the tube. If the gas mixture is initially quiescent, and heat and mass transport processes take place on a molecular level (the laminar limit), then the rate of propagation of this flame is a fundamental combustion characteristic of the fuel, termed the laminar burning velocity, S_u. The laminar burning velocity is found experimentally to depend on the equivalence ratio, on the gas pressure, and on the unburned gas temperature. It also depends on the chemical properties of the fuel, so that S_u varies from one fuel to another. In Fig. 2, taken from Westbrook *et al.* (1983), the laminar burning velocity of an ethylene-air mixture is plotted as a function of equivalence ratio at two different pressures. The shapes of these curves are seen often in combustion problems, having maximum values for mixtures close to stoichiometric and falling for both rich and lean conditions.

Different fuels and oxidizers can be compared by noting their respective laminar burning velocities. Because heat release rates and adiabatic flame temperatures are higher for fuel-oxygen mixtures than for fuel-air mixtures, fuel-oxygen mixtures are found to have larger laminar burning velocities. The laminar burning velocities for a variety of stoichiometric fuel-oxidizer mixtures are shown in Table 1.

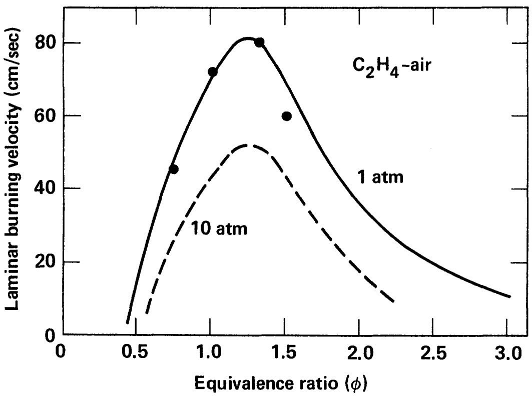

FIG. 2. Variation in laminar burning velocity of ethylene-air mixtures with equivalence ratio at atmospheric pressure and at 10-atm pressure.

Table 1. Laminar burning velocities for different stoichiometric mixtures of fuel and oxidizer.

Fuel-oxidizer mixture	S_u (cm/s)	Fuel-oxidizer mixture	S_u (cm/s)
H_2-air	310	H_2-oxygen	1100
Methane-air	38	Methane-oxygen	450
Propane-air	40	Acetylene-oxygen	1140
Ethylene-air	70	Ammonia-oxygen	115
Methanol-air	44		
Octane-air	40		

2.3 Flammability Limits

In Fig. 2, as the equivalence ratio differs from nearly stoichiometric for either lean or rich conditions, the laminar burning velocity decreases steadily from its maximum value. Extrapolating this curve in either direction suggests that S_u will fall to zero for a critical lean value Φ_L and a critical rich value Φ_R of the equivalence ratio. Experimentally, it is observed that for fuel-oxidizer mixtures outside these values of equivalence ratio, flame propagation is impossible to achieve. These limiting values Φ_L and Φ_R represent the lean and rich flammability limits for premixed flame propagation and are often used as fundamental parameters for combustion of different fuels. Lean and rich flammability limits for a variety of fuel-oxidizer mixtures are given in Table 2. Extensive studies of lean and rich flammability limits have been made by Simon (1951) and by NACA (1959).

2.4 Detonations

In a manner similar to laminar flame propagation, it is found that a detonation wave can propagate down a linear tube filled with a premixed fuel-oxidizer mixture. The detailed properties of detonations are quite complex (e.g., Fickett and Davis, 1979; Nettleton, 1987), but the fundamental feature of a detonation is that combustion is caused by the propagation of a shock wave into the reactive mixture (see EXPLOSIVES).The shock wave compresses and heats the premixed gases to a point where they react rapidly, releasing heat and reinforcing the propagating shock wave. The structure of such a detonation wave is characterized by the existence of cell-like structures that can be recorded as the detonation proceeds down the tube. A typical record of detonation cells is shown in Fig. 3. The sizes of these cells depend

Table 2. Lean and rich flammability limits; values shown are percentages of fuel in the total mixture.

Fuel-oxidizer mixture	Lean limit	Rich limit
Hydrogen-air	4.0	75.0
Methane-air	5.0	15.0
Propane-air	2.1	9.5
Ethylene-air	2.7	36.0
Hydrogen-O_2	4.0	95.0
Methane-O_2	5.1	61.0
Ammonia-air	15.0	28.0
Methanol-air	6.7	36.0
Acetylene-air	2.5	100.0

on the fuel-oxidizer equivalence ratio and on the unreacted mixture temperature and pressure. As in the case of laminar flame propagation, there are lean and rich limits to detonability that represent fundamental combustion properties of a given fuel.

2.5 Turbulent versus Laminar Combustion

The fluid mechanical features of combustion systems depend very strongly on the magnitude of gradients of various quantities, including the temperature, pressure, or fluid velocity field. When these quantities vary slowly throughout the physical domain of interest, then the fluid flow is laminar, and momentum, mass, and heat transport are controlled by molecular properties of the medium. However, when there are significant gradients, particularly in fluid velocity, then fluid mechanical instabilities are observed in which the flow system is found to break up spontaneously into chaotic, statistically random motions. Under such conditions, the fluid system is made up of three-dimensional structures often called turbulent eddies that move and interact among themselves, exchanging heat, mass, and momentum while retaining their identity as eddies for relatively long periods of time. These eddies are much larger than characteristic length scales encountered in laminar systems, and net transport of heat, mass, and momentum is found to be much more efficient and rapid than in laminar environments.

The most reliable quantitative measure that divides laminar from turbulent regimes is the *Reynolds number*, denoted as *Re*. The Reynolds number of the fluid is defined (Williams, 1965) in terms of the fluid velocity V, a characteristic length scale L of the system being studied, the gas density ρ, and the viscosity μ, as

$$Re = LV\rho/\mu = LV/\nu, \tag{3}$$

where ν is the kinematic viscosity, $\nu = \mu/\rho$. The Reynolds number can be interpreted as the

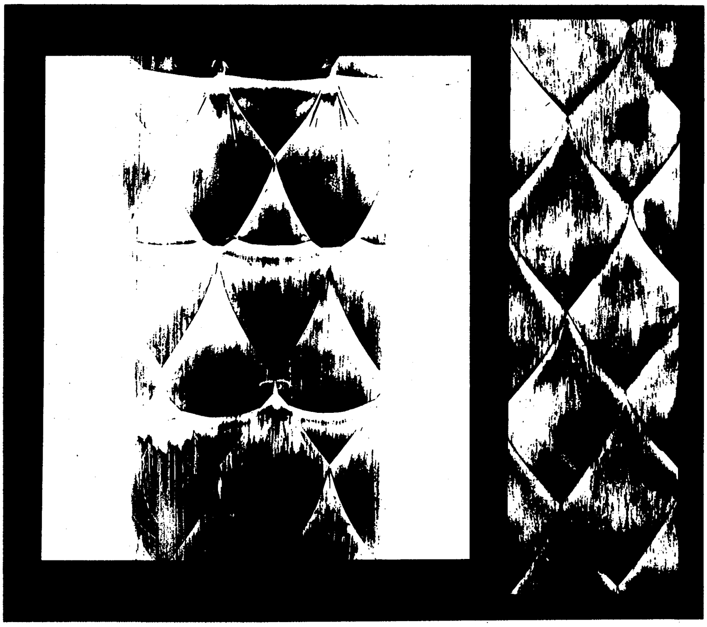

FIG. 3. Detonation cells observed using smoked foils in a detonation tube. Picture provided by Prof. R. A. Strehlow, University of Illinois.

ratio of inertial fluid forces to viscous forces in the fluid, with the inertial forces driving the system unstable and viscous forces trying to restore stability to the flow. When *Re* is small, laminar conditions are observed, and when *Re* is large, turbulent regimes are observed. Between these limits, the flow is found to be intermittently unstable. Values of *Re* in typical laminar flows are generally less than 100, values in fully turbulent flows are often 10^3 or greater, with the intermittent regime characterized by values of *Re* between these values.

In turbulent premixed combustion, the turbulent unburned fuel-oxidizer mixture produces a highly wrinkled flame surface. These wrinkles vary randomly in time and magnify the total amount of surface area between burned and unburned gases, thereby increasing dramatically the overall rate of heat release that can be achieved.

2.6 Diffusion Flames (Nonpremixed)

In contrast with premixed combustion systems, often the fuel and oxidizer are initially separate and then mixed together as they burn. This is actually the case in the great majority of practical combustion systems. For example, in a common gas-burning kitchen stove, jets of pure fuel gas emerge from the burner, where the fuel mixes with the air in the room. If an ignition source is present (e.g., a match or pilot flame), an essentially stationary flame is established, and the location of this flame coincides very closely with the position where fuel and oxidizer exist in stoichiometric proportions.

This type of flame is thus characterized by a high-temperature flame zone in which fuel and oxidizer react rapidly. Fuel approaches the flame from one side and oxidizer from the opposite direction. The physical process by which the reactants approach the flame and mix is diffusion, resulting in the term *diffusion flame* for this type of flame. Diffusion flames can be either laminar or turbulent. In *laminar* diffusion flames, molecular diffusion of fuel and oxidizer is the dominant transport process, and the features of these flames are controlled by molecular quantities. In *turbulent* diffusion flames, the mixing is dominated by the fluid mechanics of the combustion environment.

In addition to gas stoves, some other familiar diffusion flames include furnaces, gas turbines, and large-scale industrial burners. A forest fire and the combustion of a fireplace log are diffusion flames, as are a candle flame and a simple wooden match.

In spite of the ubiquity and enormous economic importance of turbulent diffusion flames, and the fact that they have been studied in one form or another for thousands of years, there is still a great deal of theoretical activity being devoted to these systems, and there is considerable controversy as to their controlling physical and chemical factors. The mathematics of turbulence phenomena is very complex, and these systems are very "stiff" (Gear, 1971)—that is, the characteristic time and space scales vary over many orders of magnitude, from a molecular level to the size of a gas furnace, and from a chemical reaction time scale of a fraction of a microsecond to the time required for a turbulent flame to cross an engine chamber. These problems cannot be resolved with current computational techniques, and a thorough theoretical understanding of turbulent combustion is still not available.

2.7 Spray Combustion and Diffusion Flames

Many hydrocarbon fuels are liquids at room temperature and pressure. Since rapid combustion requires the fuel to mix with oxidizer at a molecular level, it is necessary for such fuels to evaporate at the time of combustion, and the most common means of vaporizing the fuel is to disperse it into the combustion environment in the form of a spray. There are a considerable number of practical combustion systems in which the fuel is initially present in the form of a spray of liquid droplets. For example, in a diesel engine (Heywood, 1988), a liquid fuel spray is injected into the combustion chamber where the fuel spray droplets begin to evaporate. The vaporized gaseous fuel then diffuses away from the droplet surface into the surrounding air. At some distance away from the droplet, the ratio of fuel to oxygen achieves a stoichiometric value, and a flame zone will be established there (see DIESEL ENGINES). Subsequently, this diffusion flame is supplied by fuel evaporating from the surface of the droplet and diffusing out to the flame zone. Of course, in situations where the spray has enough time to vaporize completely and mix with the air prior to combustion, premixed conditions will prevail, but in most practical systems, the sequential processes of evaporation, diffusion, and oxidation all occur during the combustion process.

3. COMBUSTION CHEMISTRY

It is often convenient to write a simple expression for the overall reaction in a combustion system. This was done above as reaction (2) for the combustion of propane in air. However, on a molecular level the actual chemistry of combustion is very much more complex. For example, in the case of methane (CH_4), oxidation begins by removing a single hydrogen atom from the methane molecule. The resulting CH_3 species then can be consumed by any of several possible reactions, leading ultimately to CH_2O, which then produces HCO, CO, and finally CO_2. A complete chemical kinetic description of methane oxidation requires a detailed reaction mechanism with approximately 30 distinct chemical species, including both stable and radical species, and approximately 200 elementary chemical reactions between these species (Warnatz, 1984). For fuels with more carbon and hydrogen atoms, reaction mechanisms can be much larger; for heptane C_7H_{16}, a reasonably complete reaction mechanism must consider 350 chemical species and 2000 elementary chemical reactions (Westbrook *et al.*, 1991).

Combustion chemistry is best understood as a classical chain reaction (Semenov, 1959), in which the chain carriers are radical species. In hydrocarbon systems these radical species include, roughly in order of importance, OH, H, O, HO_2, CH_3, CH_3O_2, and other less significant radicals. In other systems radicals of importance can include NH_2, NH, N, HS, CN, NCO, and many others. Chain-propagation reactions maintain the total number of radical species, such as in the reaction of H_2 with OH:

$$H_2+OH=H_2O+H, \tag{4}$$

which consumes OH and produces H radicals. Termination reactions reduce the size of the so-called radical pool, as in the reaction

$$H+OH=H_2O. \tag{5}$$

In reaction (5) two radical species are consumed and none produced, resulting in a net loss of radicals to the combustion system. Chain termination can also result from nonkinetic processes such as molecular diffusion of radicals away from a flame zone.

Perhaps most important in understanding the chemistry of combustion are the chain-branching reactions, including

$$H+O_2=O+OH, \tag{6}$$

$$CH_4+O=CH_3+OH, \tag{7}$$

and numerous others in which the number of radical species increases. Reaction (6) is of particular significance for hydrocarbon combustion, and many practical combustion phenomena can be understood by the ways they interact with it. Reactions and processes that produce H atoms lead to accelerated rates of combustion because they promote reaction (6), whereas reactions that consume H atoms tend to retard combustion.

For illustration, it is well known that addition of small amounts of halogenated species to flammable mixtures dramatically reduces the rate of combustion and often makes them nonflammable (Westbrook, 1980, 1982). For example, the active chemical in commercial flame extinguishers is often CF_3Br. Chemical kinetic analysis of the influence of such additives show that they inhibit flame propagation through a sequence of reactions such as

$$HBr+H=H_2+Br, \tag{8a}$$

$$H+Br_2=HBr+Br, \tag{8b}$$

$$Br+Br=Br_2, \tag{8c}$$

where bromine is the inhibitor. Most often, HBr is the form in which Br is present as an inhibitor, but even when molecular bromine (Br_2) is used, the above reactions rapidly establish an equilibrium among the Br-containing species so that these reactions proceed in the directions shown here. The net result of these reactions is the conversion of two H atoms into one H_2 molecule, and each H atom that is consumed in this way is therefore not able to react with molecular oxygen in reaction (6) and provide chain branching to the reaction mechanism.

Another illustration is provided by the observation that the laminar burning velocity S_u decreases with increasing pressure. An important part of the analysis of this effect is that a reaction that competes with reaction (6) for H atoms is

$$H+O_2+M=HO_2+M, \tag{8d}$$

where M refers to any so-called third-body species required to conserve energy and momentum in the reaction. Since this reaction depends on the cube of the density and converts three reactants into two products, its rate increases more rapidly with density than the rate of reaction (6). Reaction (8d) is a chain-propagation step, producing one HO_2 radical for each H atom radical consumed. In addition, HO_2 radicals are considerably less reactive than the O and OH products of reaction (6). For these reasons, increasing the rate of reaction (8d) relative to the rate of reaction (6), which happens as the pressure and density increase, results in overall inhibition of the overall rate of combustion.

In some environments, a sequence of several reactions is responsible for chain branching, as in the intermediate-temperature pair of reactions

$$CH_4+HO_2=CH_3+H_2O_2, \tag{9}$$

$$H_2O_2+M=OH+OH+M, \tag{10}$$

which consumes one HO_2 radical and produces three radicals, including one CH_3 and two OH radicals.

In combustion chain reactions, as in nuclear and other chain reactions, a constant level of chain carriers (radical species) results in a steady rate of reaction, whereas a net loss of radicals due to termination will extinguish the reactive system, and a net increase in radical levels due to chain branching can lead to very rapid reaction or explosion.

The reactions in a detailed mechanism fall into several general classifications, consisting of initiation, abstraction, radical decomposition, and radical recombination (Westbrook and Dryer, 1984).

3.1 Initiation Reactions

A fuel molecule can decompose thermally to produce two radical species. Examples of such reactions are

$$C_3H_8=C_2H_5+CH_3, \tag{11}$$

$$C_5H_{12}=C_2H_5+C_3H_7, \tag{12}$$

for propane and pentane. These reactions require strong bonds to be broken and are therefore very slow except under high-temperature conditions. Their primary task in combustion is to provide a small number of radical species, following which other reactions carry out the process of fuel consumption.

3.2 Abstraction Reactions

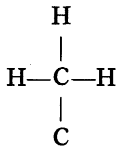
Most fuel consumption is accomplished in combustion systems through reactions with the radical species listed previously. Radicals remove (abstract) a single H atom from a hydrocarbon fuel species, as in the case of ethane reacting with OH or O:

$$C_2H_6+OH=C_2H_5+H_2O, \tag{13}$$

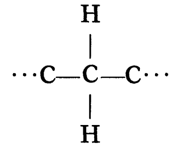
$$C_2H_6+O=C_2H_5+OH. \tag{14}$$

Abstraction reactions can function as either chain-propagating, as in reaction (13), or chain-branching reactions, as in reaction (14).

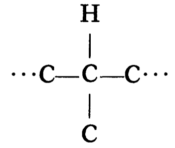
There are three types of C–H bonds in hydrocarbon fuels, varying according to the structure of the fuel molecule and termed primary, secondary, and tertiary bonds. In primary C–H bonds, the carbon atom is connected to only one other carbon atom; in secondary C–H bonds, the carbon atom is bonded to two other carbon atoms; and in tertiary C–H bonds, the carbon atom is connected to three other carbon atoms. Primary C–H bonds are strongest and tertiary bonds are the weakest. These can be shown as



primary
C atom is connected
to only one
other C atom

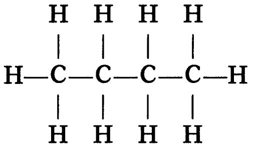


secondary
C atom is connected
to two other
C atoms



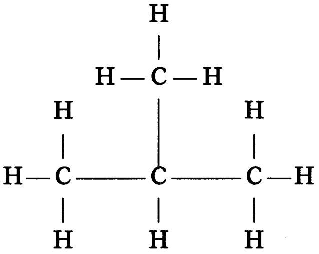
tertiary
C atom is connected
to three other
C atoms

Abstraction of H atoms from primary C–H bonds is slower than abstraction from secondary C–H sites, and both are slower than abstraction from tertiary sites. These distinctions are responsible for variations in ignition and combustion rates among fuels that differ only in their molecular structure. For example, two isomeric forms of butane each consisting of 4 carbon atoms and 10 hydrogen atoms, differing only in the way they are put together, are *n*-butane and iso-butane, shown as



$$\begin{array}{ccccccccccc} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \\ & & | & & | & & | & & | & & \\ \mathrm{H} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{H} \\ & & | & & | & & | & & | & & \\ & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \end{array}$$

n-butane



iso-butane

Iso-butane has nine H atoms at primary sites and is therefore more resistant to H-atom abstraction than *n*-butane with only six such primary H-atom sites. As a result, iso-butane ignites more slowly than *n*-butane in combustion environments.

3.3 Radical Decomposition

After an H atom has been abstracted from the fuel, the resulting large radical species will in most cases decompose to produce smaller radical and stable species. The product radical species then decompose further until only small radical and stable species remain. Thus even for large hydrocarbon fuels, this process quickly produces small species with one to three carbon atoms. In this sense, a large fraction of the combustion chemistry of virtually all hydrocarbon fuels eventually is reduced to the reactions of small-fragment hydrocarbon species. Many of these decomposition reactions produce H atoms, including the following in the cases of the ethyl, iso-propyl, and formyl radicals:

$$C_2H_5 = C_2H_4 + H, \qquad (15)$$

$$iC_3H_7 = C_3H_6 + H, \qquad (16)$$

$$HCO = H + CO. \qquad (17)$$

The H atoms that are produced in these decomposition reactions can then react with O_2 via reaction (6) to provide chain branching to the overall reaction system.

3.4 Radical Recombination

Rather than decomposing, radical species can recombine to produce larger, more stable hydrocarbon species. Perhaps the most important of these recombination reactions involves the recombination of two methyl radicals to produce ethane:

$$CH_3 + CH_3 = C_2H_6 \qquad (18)$$

This process reduces the number of radical species by two and provides chain termination, slowing the overall rate of reaction.

3.5 Pollutant Chemistry and Emissions

In addition to desirable products such as heat and radiation, combustion processes also generate unwanted and harmful products. These emissions can include products of incomplete combustion such as carbon monoxide, soot, and hydrocarbon species, as well as combustion by-products such as oxides of nitrogen or sulfur. Finally, there is some concern that an otherwise benign product of complete combustion, carbon dioxide, may be leading to global warming through the greenhouse effect and may ultimately be the most serious combustion problem to be considered.

Incomplete combustion results either when insufficient oxidizer was supplied to the fuel or when the fuel-oxidizer mixture was given inadequate time to complete its reaction. Fuel-rich hydrocarbon combustion produces carbon monoxide, even with ample time to achieve chemical equilibrium, and some CO is produced even under stoichiometric and lean conditions. In nonpremixed systems, if the time for mixing of fuel and oxidizer is not considerably shorter than the residence time in the combustion zone, then a variety of partially oxidized species will result. Coal combustion produces flyash and larger particulates, and many combustion systems produce particulates loosely referred to as soot.

Production and destruction of soot particles in combustion are controlled by both chemical kinetics and transport processes (Harris and Weiner, 1983; Frenklach *et al.*, 1986). Gas-phase kinetic processes lead to production of large aromatic hydrocarbon species that are often termed soot precursors. The chemistry involved in production of soot precursors is a current research topic and apparently involves reactions of both neutral and ionized chemical species, leading to species with molecular weights of nearly 10 000. At this size, these molecules are almost large enough to be considered particles, and they form nuclei upon which small hydrocarbon species begin to collect, eventually growing by many orders of magnitude in mass over time scales of milliseconds.

Soot can be both harmful and necessary. In furnaces and boilers, soot is an essential element in transferring heat of combustion to the metal surfaces that in turn heat the working fluid, usually air or water. Much of the energy released by combustion is absorbed by soot particles in the flame and then radiated from the luminous soot particles to the walls of the combustor. Without soot, the hot product gases are much less efficient in providing this transfer of heat. The soot is intended to be oxidized to CO_2 and water later in the combustion process, downstream from the luminous flame zone. However, soot that is not consumed or is produced unintentionally and then emitted along with the other exhaust gases can be a source of visible smoke, odor, and toxic and carcinogenic chemical species.

Chemical species that are present in the fuel in small amounts often lead to pollutant emissions. The best example of this is provided when liquid hydrocarbon fuels and coal and coal-derived fuels contain quantities of sulfur. Combustion temperatures and the presence of oxygen then convert whatever sulfur is present into oxides of sulfur, particularly SO_2, with small fractions of SO_3, denoted collectively as SO_x. If these species are allowed to escape into the air, they combine with water in the atmosphere and lead to acid rains. To remove SO_x from combustor exhausts, the most common strategy is to provide calcium carbonate or lime with the exhaust and produce $CaSO_4$ that can be collected in the solid phase.

The other common constituent of acid rain consists of oxides of nitrogen or NO_x. Some NO_x is produced from nitrogen that is present in the fuel, as in the case of SO_x above. However, the majority of NO_x production from combustion results from the oxidation of N_2 in the air via the catalytic series of reactions called the Zel'dovich mechanism,

$$N_2 + O = NO + N, \tag{19}$$

$$N + O_2 = NO + O. \tag{20}$$

Since both reactions require breaking strong chemical bonds, especially the triple bond between the two N atoms, these reactions proceed rapidly only at elevated temperatures, and their rates are strongly temperature dependent. Thus most NO_x production in a typical combustion system takes place only in the very highest temperature parts of the system.

Combustors can be modified to reduce the production rate of NO_x by removing or limiting the regions of high temperature. Based on the variability of product temperature with equivalence ratio as shown in Fig. 1, the most common strategy is to carry out the combustion in two or more stages, none of which is stoichiometric with its associated high temperature. In industrial burners and furnaces, often the first combustion zone is fuel-rich ($\Phi > 1.3$), resulting in temperatures considerably lower than the peak value at $\Phi = 1$, together with large fractions of CO and other products of incomplete combustion. Then, downstream from this rich combustion zone, additional air is injected into these gases in what is effectively a fuel-lean combustion zone, completing the oxidation of the fuel and the overall heat release process, but again avoiding high temperature that would promote production of NO_x.

Another strategy used to reduce NO_x emissions is to dilute the reactant gases with inert gases, a process called exhaust-gas recirculation (EGR). The principle involved was noted earlier, where it was observed that product temperatures in fuel-O_2 mixtures are considerably higher than in fuel-air mixtures because the additional N_2 in air dilutes the mixture and must be heated by the reaction along with the chemical products. In exactly the same way, other inert species such as H_2O and CO_2 can also be added to combustible reactants and will result in lower combustion temperatures. These lower product temperatures will then result in lower production rates of NO_x. This process is often very simple to implement, since the combustion exhaust consists of mixtures of N_2, H_2O, and CO_2, all of which are suitable as noncombustible diluents. This strategy is used in virtually all modern automobile engines to lower NO_x production.

Most of these techniques for NO_x control focus on temperature reduction to limit the rate of NO production during combustion. However, it is also possible, under tightly controlled conditions, to consume some of the NO that has already been produced. Several chemical kinetic schemes consume NO and produce N_2 by addition of nitrogenous species such as ammonia (NH_3) (Lyon, 1976), urea, and cyanuric acid (Perry and Siebers, 1986) to the product gases of a combustor. The details of these processes are chemically quite complex and have only recently become reasonably well understood (Miller and Bowman, 1989).

Finally, even the products of chemically complete combustion are now suspected of having serious harmful effects as leading to the greenhouse effect and causing long-term warming of the earth's climate. Worldwide rates of use of hydrocarbon fuels and their resulting production of CO_2 have risen steadily since the Industrial Revolution and are still increasing at present. Some computer simulations of the results of ever-increasing CO_2 emissions suggest a direct connection between such emissions and global warming, although many of the details of CO_2 circulation throughout the earth's land, ocean, and atmospheric systems are still extremely uncertain.

4. PRACTICAL COMBUSTION SYSTEMS

Although at first glance very different from each other, essential elements of most practical combustion systems are often quite similar.

4.1 Internal Combustion Engines

The fuel generally consists of a mixture of liquid hydrocarbons (Heywood, 1988). Both premixed and diffusion combustion operation can be utilized. In carbureted engines, the fuel is vaporized and mixed with air in the carburetor and then drawn into the combustion chamber. This mixture is ignited by means of localized deposition of energy, usually a spark plug. However, other ignition systems can and are used, including plasma and laser discharges. The mixture must be within the flammability limits or ignition and flame propagation are not possible. A premixed turbulent flame then propagates across the combustion chamber. The turbulence is the result of fluid-dynamic instabilities caused by the large Reynolds number of the inlet flow into the combustion chamber. This situation is illustrated in Fig. 4, showing the combustion flame front in a typical engine chamber (Cowart *et al.*, 1990), both from above and in a side view. In the top view, the circle at the left indicates the inlet and exhaust valve, while the circle at the right indicates the location of the spark plug. Heat release from the rapid chemical reactions causes a large pressure increase within

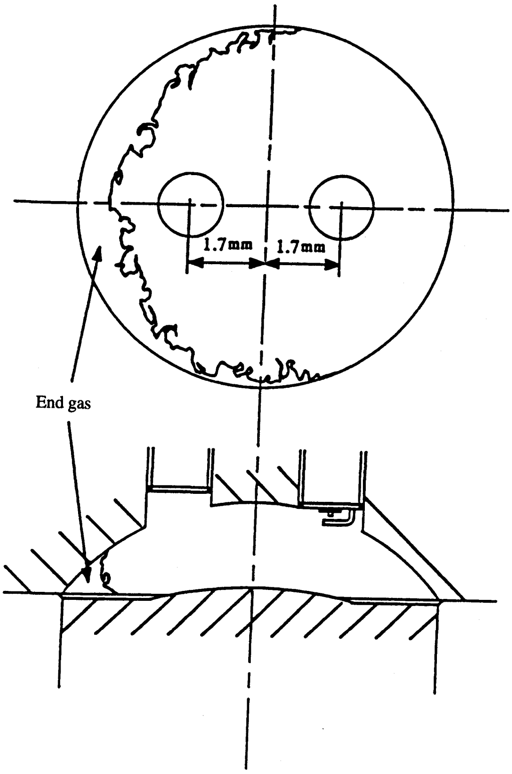


FIG. 4. Side view and top view of an automotive engine chamber, showing the flame propagating away from the spark plug where the spark ignition started the flame. The end gases are also indicated.

the combustion chamber that results in a strong force exerted on the piston, creating torque and driving the motor.

As the flame propagates across the combustion chamber, the Zel'dovich reactions produce NO from the nitrogen in the combustion air. In modern automobile engines, cold exhaust gases, consisting almost entirely of water, carbon dioxide, and nitrogen from previous combustion cycles, are recirculated into the combustion chamber together with the reactant gases, and this dilution, by exhaust gas recirculation (EGR), lowers the combustion temperatures in order to reduce the production rate of NO_x. Carbon monoxide and unburned hydrocarbon species that are present in the exhaust gases pass through a catalytic treatment that completes their oxidation at low temperature, reducing the hydrocarbon emissions without producing further NO_x.

In other cases the fuel is injected directly into the air already present in the combustion chamber. Most often this fuel is normally a liquid and is injected as a spray that then vaporized and mixes with air, creating a mixture in which the local equivalence ratio varies as a function of position in the combustion chamber. If there were sufficient time, eventually all of the liquid fuel would vaporize and the entire combustion chamber would consist of a homogeneous mixture of fuel and air very much like the carbureted engine. However, in the fuel-injected engine, ignition occurs quite early in the cycle, again generally by means of a spark plug. A difficulty in this type of operation is that the spark plug must "see" a flammable mixture when it discharges; otherwise no stable flame will result and an engine misfire will result.

A motivation for this type of engine configuration is its potential for fuel economy and lower NO_x emissions. The quantity of fuel to be injected can be matched accurately to the power needs of the engine, and by confining the fuel to a subvolume of the combustion chamber in which some combustion will take place under rich, and at other places, under lean conditions, the higher temperatures of stoichiometric combustion can be avoided, lowering NO_x production.

Under these conditions all of the flammable mixture burns very quickly, long before all of the remaining fuel spray has evaporated and mixed with air. There is then an extended period during which this remaining fuel burns as a diffusion flame, with fuel and air approaching the relatively stationary flame zone from opposite sides. Otherwise, combustion in this system is very much the same as in the carbureted engine. The heat release drives the piston, NO_x is produced via the Zel'dovich mechanism and controlled with EGR, and unburned hydrocarbons and CO are consumed in a catalyst.

4.1.1 Engine Knock. During the combustion cycle illustrated in Fig. 4, a premixed turbulent flame crosses the combustion chamber. The unreacted gases farthest from the spark plug, called the "end gases," are therefore the last gases to be consumed by the flame. These end gases, shown in Fig. 4, are steadily compressed and heated both by the motion of the piston and by the heat release of the propagating flame. As a result, although they are not in contact with the flame front, these end gases begin to react and, given sufficient time, would spontaneously ignite. Under normal operating conditions, the flame front arrives at the end gases and consumes them, resulting in smooth combustion. However, if these end gases are sufficiently reactive, or if the flame propagation is slow, then the end gases will explode. This explosion, and the pressure wave that results, produce the characteristic ringing phenomenon known as engine knock.

Engine knock can be very destructive if permitted to persist. An example of an engine piston damaged by prolonged knocking is shown in Fig. 5. Therefore, it is desirable to avoid operating conditions that encourage knocking performance. Two of the engine variables that influence knock are the compression ratio and the chemical nature of the automotive fuel. The compression ratio CR is the ratio of the combustion chamber volume at its greatest value [when the piston is at the bottom of its cycle, called *b*ottom *d*ead *c*enter (BDC)] to its smallest value at *t*op *d*ead *c*enter (TDC). The overall efficiency of engine combustion is known to increase steadily with increasing compression ratio, and so there is motivation to operate at as high as possible a value of CR. However, the rate of end-gas ignition also increases rapidly with CR, even-

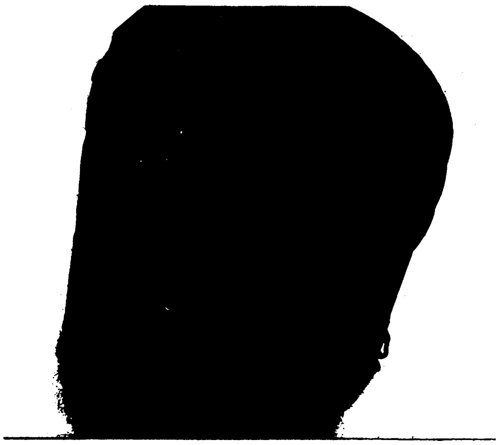

Fig. 5. Photograph of an automobile engine piston which has been severely damaged by engine knock. (Courtesy of P. Jessup, UNOCAL.)

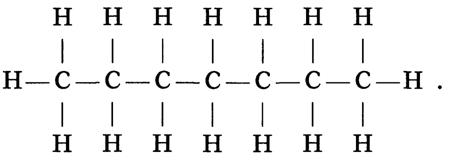
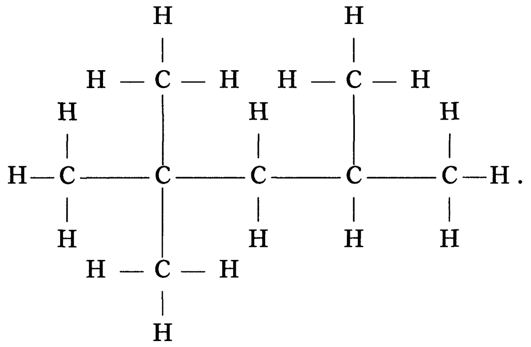
tually providing a limit to the increase in efficiency that could otherwise be achieved. The use of antiknock additives slows the rate of end-gas ignition, permitting the engine to increase its compression ratio further and to achieve a higher practical efficiency.

The chemical nature of the fuel also has a great influence on its tendency to knock (Lovell, 1948). That tendency is measured by the octane number of the fuel, with high values of octane number signifying resistance to knock and low values indicating significant tendency to knock. Straight-chain hydrocarbon species, with large percentages of secondary C–H bonds, have very low octane ratings. For example, the fuel that has, by definition, an octane rating of zero, is the straight-chain species *n*-heptane, indicated schematically as



$$\begin{array}{ccccccccccccccccc} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \\ & & | & & | & & | & & | & & | & & | & & | & & \\ \mathrm{H} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{H}\,. \\ & & | & & | & & | & & | & & | & & | & & | & & \\ & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \mathrm{H} & & \end{array}$$

In contrast, highly branched fuels with large numbers of primary C–H bonds are extremely knock resistant and have large octane numbers. The fuel that has, again by definition, an octane number of 100, is iso-octane:



Although the octane numbers and knock tendencies of pure-component fuels have been known for many years and some structural trends related to knocking are recognized, only very recently have these properties been placed on a quantitative and predictive basis (Westbrook *et al.*, 1991). Other factors can influence engine knock, including carbon deposits on engine chamber walls and fluid mechanical details in the flow patterns in the engine, but the above mechanism is the most important factor leading to engine knock in modern spark-ignition engines.

4.1.2 Diesel Engines. From a point of view of combustion principles, the diesel engine is very similar to the spray-injection spark-ignition engine above. One obvious difference is that ignition is accomplished by compression, much like in engine knock, rather than by means of a spark plug. Combustion is believed to take place in a combination of partially premixed, partially diffusion regime. It has been suggested that a diffusion flame exists around each fuel droplet, but it has not been possible to observe the phenomenon in sufficient detail to determine for certain the structure of the combustion zone in a diesel engine.

Diesel engines operate at much higher compression ratios than spark-ignition engines. This is possible because compression ignition or knock is effectively encouraged in the diesel engine. Desirable diesel fuels are denoted with high values of the *cetane* number, indicating good compression ignition tendency. As a result, often fuels with poor or low octane numbers have good or high cetane numbers.

4.2 Burners, Boilers, and Furnaces

A great number of practical combustors consist of stationary systems (as opposed to mobile systems such as automobiles), each of which can produce an enormous amount of thermal energy. These systems heat product gases that then heat a working thermal fluid, usually water, which in turn does the work desired.

All of these systems consist of diffusion flames, although the fuel can be gaseous natural gas, liquid fuel oil, or solid coal particles. Some systems in fact burn mixed fuels such as coal slurries, solid coal particles suspended in a liquid. Most such systems are turbulent, including virtually all of the industrial-scale combustion systems. This is because turbulent systems are able to produce much greater overall rates of heat release per unit volume than any laminar system of comparable combustor volume.

Because the combustion system is large and stationary, it is possible to apply a wider variety of pollution control equipment and technologies to these larger systems than to smaller units such as automobile engines. This includes scrubbing units, precipitators, and other devices to remove SO_x, NO_x, and burned hydrocarbons from exhaust gases.

4.3 Novel Combustion Systems

In addition to the familiar combustors already described, there are many other types of systems that employ the same combustion principles but have different boundary and other operating conditions. In supercritical water oxidation (SCWO), the fuel and oxidizer are dissolved in water at pressures well above the critical point of the water. Under such conditions of approximately 250 atm, water is strictly neither a liquid nor a gas, and such a closed environment has been used to consume toxic waste materials that must not be released into the atmosphere.

Pulse combustion systems have been used for many years, but only recently have the principles of pulse combustors become understood. In such systems, combustion in a chamber forces product gases out through a tailpipe assembly, and a rarefaction wave in the combustion chamber then sucks fresh fuel and air in through flapper valves. These fresh reactants then mix with hot combustion products from the previous combustion event, leading to a spontaneous ignition of the fresh mixture. This then drives a new cycle, and the process repeats itself continuously. Pulse combustors are now used in propulsion systems, in industrial processes, and in home heaters.

4.4 Incineration and Toxic Wastes

There are a wide variety of chemical species that are closely related to hydrocarbon fuels, but in which one or more of the H atoms have been replaced by chlorine atoms. These species, many of which are poisonous or carcinogenic, are used widely in industrial processes. Examples of such species are vinyl chloride, trichloroethylene, and chlorobenzene. When compounds containing these species, such as excess plastic pipe, used transformer fluids, and many others, are no longer needed, there is a need to consume them in an environmentally safe way. A simple method of consumption is combustion, in which the hydrogen and carbon constituents are oxidized to water and carbon dioxide, and the chlorine atoms are converted to HCl. The HCl products can then be dissolved in water and the acid water then concentrated and removed to be treated in a sensible and safe way.

The difficulty with this process of combustion, or incineration, is that all combustion processes are subject to the same problems noted above for simple hydrocarbon combustion. Specifically, incomplete combustion, which in the case of hydrocarbon fuels leads to soot production, in the case of toxic species can produce very harmful toxic wastes such as dioxin and phosgene (mustard gas). Thus the combustion devices intended to consume toxic species are much less tolerant to incomplete combustion than simple hydrocarbon fuels, and the environmental penalties for combustion problems are very severe. The thermochemical product of chlorine atom combustion is definitely HCl, but the necessity of producing only HCl and the opportunities for producing much-less-desirable other products make incineration a problematical science.

5. SUMMARY

Combustion is a part of everyday life, from the production of home heating and home cooking, through the energy required to propel the automobile, the bus, the truck, the train, and the airplane, to the firing of electricity generating plants, industrial boilers, and furnaces. In addition, combustion produces much of our air pollution and other environmental problems.

It is likely that combustion will continue to be an important source of energy and power production for many years, and it is very important to understand the fundamental processes, chemical and physical, that control combustion and its associated processes.

GLOSSARY

Cetane Number: Comparative rating of ignition for fuels under diesel conditions. Higher cetane numbers indicate greater ease of ignition; small cetane numbers indicate a fuel difficult to ignite.

Compression Ratio (CR): Ratio of the combustion chamber volume at its greatest value, at bottom dead center, to its volume at its smallest value, at top dead center.

Detonation: Reactive shock wave.

End Gases: The last fuel-air charge to be consumed in the combustion chamber; the reactants that can explode to produce engine knock.

Equivalence Ratio (Φ): Ratio of fuel concentration actually present to that required to consume exactly the available oxidizer.

Exhaust Gas Recirculation (EGR): Practice of dilution of reactants with reaction products, generally consisting of CO_2, H_2O, and molecular nitrogen, usually employed to reduce product temperatures and slow production of NO_x.

Laminar: Combustion regime in which transport of heat and mass occurs via molecular diffusion and conduction.

NO_x: Nitrogen oxides ($NO+NO_2$).

Octane Number: Relative measure of susceptibility to knocking behavior. Fuels with large octane numbers resist knock; fuels with small octane numbers are likely to knock.

Stoichiometric: Conditions in which the ratio of fuel to oxidizer is exactly correct to produce complete oxidation.

Turbulent: Combustion regime in which transport of heat and mass occurs via unstable large-scale motions of the fluid.

INTRODUCTION

History of Composite Materials

Since the earliest of times it has been recognized that certain combinations of different materials produce a composition whose properties are superior to those of the constituents alone. An ancient example is the use of straw to reinforce mud to produce reinforced bricks for construction purposes. Another important structural composite material was concrete developed and used by the Romans in the 2nd or 3rd century B.C. The Romans developed an extensive knowledge of the chemistry of cementitious limes as recorded in the writings of Vitruvius (Murdok and Brook, 1979). The Roman concrete was a combination of volcanic ash, lime, sand, gravel or crushed rock, and water. This composition, when properly mixed and dried, produced an extremely strong composite material that made possible the construction of truly massive structures. Another advantage of concrete was the ability to cast it into any desired shape to

digital Encyclopedia of Applied Physics

produce the great arches, domes, and vaults characteristic of much of Roman architecture. The great aqueducts, the dome of the Pantheon, and the Colosseum are examples of the large-scale application of man-made composite materials.

The use of concrete declined with the fall of the Roman Empire and did not reappear on a similar scale until the late 19th century, when the addition of steel reinforcing bars to concrete provided a major advancement. The steel reinforcement extended the use of concrete to areas such as beams, columns, and floor slabs subject to bending loads that place the structural element in a state of tension on one side and compression on the other. The tensile load is transferred to the steel reinforcement, which has a much greater tensile strength than the unreinforced concrete.

Another example of an early man-made composite material is paper, invented by the Chinese over 1800 years ago. The early Chinese papers were composed of pulp from the bark of mulberry trees, hemp, and cloth fibers. The pulp and fibers were mixed together in water, precipitated on a cloth screen, and dried to form the paper sheet. More recent examples since the middle of the 20th century include wood laminates such as plywood, directionally solidified eutectics, fiber-reinforced polymers such as fiberglass, and fiber-reinforced concrete, ceramics, and metals.

Constituent Materials and Properties of Composites

Composites encompass an extremely wide variety of constituent materials, as illustrated in the brief historical introduction. This extreme diversity makes it difficult to develop an acceptable definition of a composite material. In this article we will limit the scope of our definition of a composite material to those materials that are man-made by combination of two or more constituent materials to form a third material that has specific properties not possessed by the constituent materials individually. Thus we will not consider, for example, naturally occurring composite materials such as wood. This still leaves an almost unlimited range of combinations of constituent materials that could be considered as composite materials. In spite of this great diversity, the commonly used constituents in composites fall into three basic categories: reinforcements, fillers, and matrix materials. The reinforcing constituents are usually fibers, particulates, or flakes, which provide the principal structural properties of the composite. The matrix material provides the means of encapsulating and binding the reinforcing constituents, giving the composite material its bulk shape and form. Filler constituents are usually added to the matrix material to provide specific engineering, functional, or processing properties.

The properties of the composite material are derived from

1. the basic properties of the constituents,
2. their geometrical arrangement, and
3. the resulting complex interactions between the constituents.

The central idea encompassing all composite materials development is that different constituent materials can be combined to produce a material having specific properties or combinations of properties that are different from those of the constituents. As a simple example, consider a fiber-reinforced composite in which the fiber is unidirectionally oriented in an isotropic matrix material. The tensile strength of the composite measured along the fiber direction will in general be greater than that of the matrix and representative of the fiber, assuming that we use a fiber whose tensile properties are greater than those of the matrix. The matrix transfers the load to the fibers that support the applied load. In structural composites, the fibers form the majority phase, uniformly distributed and separated from one another by a thin layer of the matrix that serves to maintain the fibers in a fixed orientational relationship and to distribute the load uniformly over the fibers. Continuous-fiber–reinforced composite materials are in general anisotropic; properties measured along the fiber direction are different from those measured perpendicular to the fiber direction. An interesting and important aspect of fiber-reinforced composites is the ability to design the composite to make use of the anisotropy and tailor the properties of the composite to carry increased loads along specific directions. The properties of the composite ultimately depend on the constituents and the orientational relationship of the reinforc-

FIG. 1. ing fiber relative to the direction of the applied load. Figure 1 compares the specific strength (ultimate strength divided by density) and specific modulus of elasticity (Young's modulus divided by density) for a variety of commonly used structural and composite materials. Composite materials constructed from light-weight, high-performance fibers and polymeric matrix materials can exhibit specific strength and stiffness 3 to 4 times higher than those of commonly used structural materials such as steel and aluminum.

1. TYPES OF COMPOSITE MATERIALS

Composite materials can be classified (Schwartz, 1984) in several ways, such as by the type of matrix material, by the distribution of the reinforcement, e.g., continuous or discontinuous, or according to the functional purpose such as high-temperature, structural, or conductive composite materials. Composites can be most broadly classified according to the nature of the structural constituent. There are three basic categories of composite materials, as illustrated in Fig. 2. The three

FIG. 2. An illustration of the three basic categories of composite materials: fiber-reinforced, particulate-reinforced, and dispersion-strengthened matrices.

categories are (1) fiber-reinforced composites, (2) particulate-reinforced composites, and (3) dispersion-strengthened composites. The effect of the size of the reinforcing agent on the composite strength is illustrated in Fig. 3 for particulate- and fiber-reinforced composites (Broutman and Krock, 1967). In each case very different mechanisms are responsible for strengthening and stiffening of the matrix material. In the case of fiber-reinforced composites, the fiber must have an aspect ratio (length divided by diameter) that is at least ~10 and preferably > 100 to transfer the load from the matrix to the fiber completely. The three categories of composite materials are discussed in the following section and are readily distinguished by the range in size and volume concentration of the reinforcing phase.

1.1 Fiber-Reinforced Composites

In the area of structural composites, fibers are the most important class of reinforcement. This is driven by the necessity to produce ever stronger, stiffer, and more lightweight materials. Fibers provide a unique opportunity to obtain the ultimate mechanical properties of a given type of material. In general, materials when made in fiber form tend to exhibit more nearly intrinsic tensile properties than do bulk forms. The reasons for this will be discussed in Sec. 2. Glass fibers, for example, have much higher tensile strength than bulk glass plates. Similar statements can be made for metal, carbon, ceramic, and polymeric fiber forms. The most weight-efficient method for using the large Young's modulus and tensile strength of fibers is to combine them in a matrix of a lightweight material usually, but not necessarily, having lower tensile strength and modulus. Glass-fiber–reinforced resin is one of the first modern structural composites and has been devel-

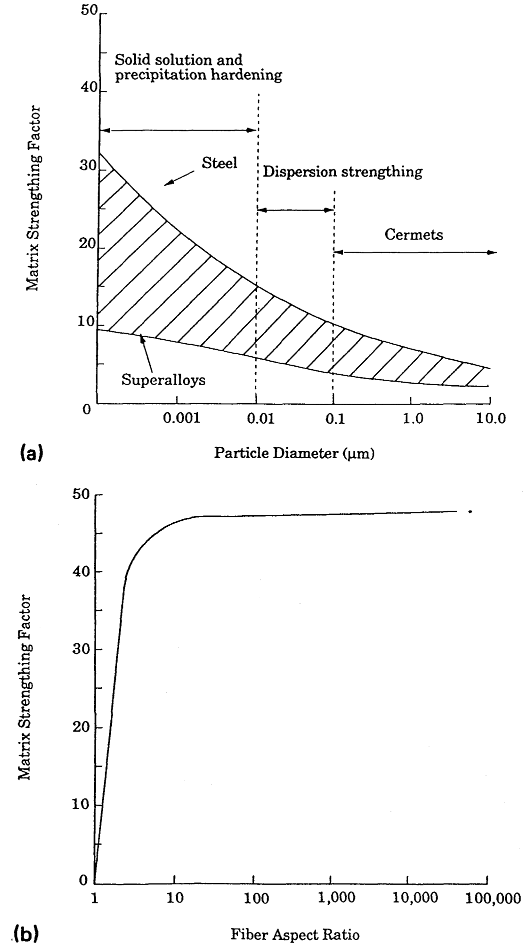

FIG. 3. Effect of the size of (a) particulates and (b) fiber aspect ratio (aspect ratio is defined as the ratio of fiber length to diameter) on the composite strength; after Broutman and Krock (1967).

oping an ever-increasing scope of utilization since the end of World War II. There have been significant developments since the 1960s in the area of carbon fibers and carbon-fiber–reinforced composites, resulting in some of the highest-strength lightweight materials. Carbon fibers have been used to reinforce a variety of polymeric resins and lightweight metals such as aluminum and magnesium. Besides reinforcing lower-modulus matrix materials, there has also been significant progress in using fibers to provide toughness to brittle matrix materials such as ceramics and glasses.

The performance of fiber-reinforced composites is determined by many variables such as

1. fiber orientation, length, shape, and composition,
2. composition of the matrix material,
3. the volume fraction of the reinforcing phase,
4. the interaction between the fiber and the matrix, and
5. the presence of any additional filler materials (Weeton *et al.*, 1987).

The mechanical properties of the composite are highly anisotropic and depend on the orientation of the fiber in the matrix. The strength and modulus of a uniaxially oriented fiber-reinforced composite will be largest along the direction of the fiber. If the applied load is at an angle that is not along the fiber direction, the strength and modulus of the composite will be dramatically reduced. Figure 4 illustrates the directional dependence of the tensile modulus as a function of angle between the applied load and the fiber direction for a carbon-fiber–reinforced epoxy composite. Since in actual applications structural elements are rarely subject to pure uniaxial loads, it is necessary to combine different fiber orientations in a single composite. This is typically done by forming a laminate made up of uniaxial plies oriented at various angles to one another. A typical laminate construction is illustrated in Fig. 5. The ability to tailor the mechanical properties of the composite to accommodate complex loads is a major advantage of composite materials over isotropic materials. The directional selectivity available with composite material design allows for more mass-efficient structures. The stiffness and strength of a uniaxial fiber-reinforced composite are directly proportional to the volume fraction of the fiber in the composite and can be described in a first-order approximation by a simple rule-of-mixtures expression such as

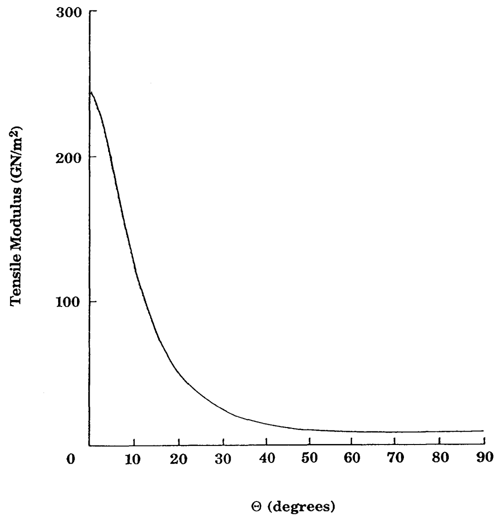

FIG. 4. Variation of the tensile modulus of a uniaxial composite as a function of the angle between the fiber direction and the applied load. After Hull (1981).

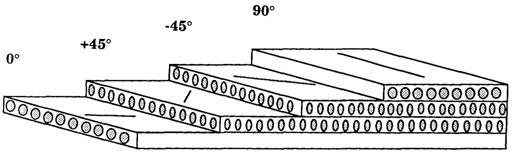

FIG. 5. Example of an angle-plied laminate; the angles indicate the amount of rotation of the fiber orientation in each lamina from the uniaxial direction.

$$E_c = E_f V_f + E_m V_m,$$

where E_c, E_f, and E_m are the moduli of elasticity of the composite, fiber, and matrix, respectively, and V_f and V_m are the volume fractions of the fiber and matrix in the composite. Similar expressions also can be written for the strength, density, Poisson's ratio, etc., of the composite.

1.2 Particulate and Flake-Reinforced Composites

1.2.1 Particulate Composites.

Particulate composites include cermets, metal and ceramic particles in metal, and plastic- and ceramic-matrix materials. Particulate composites differ from fiber-reinforced composites in that the reinforcing constituent does not have a shape anisotropy. The particulate can be viewed in a first approximation as spherical in shape, although in actuality the particulate may be spherical, disk shaped, cubic, or polyhedral. In cases where the particulate is randomly distributed in the matrix and lacks shape anisotropy, the properties of the resulting composite material are isotropic. Since the particulate composite does not have a homogeneous composition, the properties depend on the size, shape, concentration, and composition of the particulate as well as the strength of the interfacial bond with the matrix.

An important class of particulate-reinforced composites intended for use at high temperatures is comprised of cermets, a combination of the words ceramic and metal. Cermets are usually composed of ceramic particles 10%–97% by volume, supported in a metal matrix. Examples are cobalt-cemented tungsten carbide, nickel-cemented titanium carbide, alumina-reinforced chromium, and uranium-plutonium cermets. Cermets are usually produced by powder metallurgical techniques. The bonding between the particulate and the metal matrix is usually due to partial solubility of the two phases in one another. The properties of the cermets are variable over a wide range through variation of the ceramic-to-metal ratio in the starting powder mixture and the processing conditions. There are two commercially important classes of cermets, based on

1. metal carbide and
2. metal oxide particulates.

Many other cermet materials have been produced on a laboratory scale for applications as diverse as selective optical absorbers for solar collector panels.

1.2.1.1 Metal Carbide Cermets. A commonly used metal carbide cermet is cemented tungsten carbide, which finds broad application as a cutting-tool material. The most commonly used binder metal is cobalt. Cobalt-cemented tungsten carbides in general are abrasive and have high compressive strength, hardness, and rigidity. These properties can be varied through changes in the amount of cobalt binder used. Typically the amount of cobalt ranges from 1% to 35% by volume. Increased cobalt content results in increased toughness and ductility and decreased hardness, rigidity, and abrasiveness. Most commercial tungsten carbide cutting tools have small amounts of TiC, NbC, and TaC powders (0%–1%) to improve the high-temperature mechanical properties and the chemical wear resistance of the tool (North, 1987). Typical particle sizes are on the order of 1–10 μm, although new fine-grained tungsten carbide cobalt cermets are being developed that have superior properties. Titanium-carbide-particulate–reinforced nickel or nickel-alloy–matrix cermets have high stiffness and strength at temperatures in excess of 2200 °C.

1.2.1.2 Metal Oxide Cermets. Besides the carbide cermets, metal oxide cermets also find wide commercial application. Oxide cermets find use as high-speed cutting tools, low-friction mechanical seals, nuclear reactor fuel elements, and selective solar absorber coatings. The oxide cermets have the unique property that the metal and the ceramic may be interchanged as either the particulate or the matrix material. A typical metal oxide cermet composition is 72% Cr, 28% Al_2O_3; the properties of the cermet can be controlled by altering the ratio of metal to ceramic. The oxide cermets are typically formed by powder metallurgical manufacturing methods.

1.2.1.3 Dispersion-Strengthened Systems. Dispersion-strengthened composite materials consist of a matrix material that has fine particles of a second phase, typically 0.01–0.1 μm in diameter, dispersed uniformly throughout the matrix. In contrast to the particulate or fiber-reinforced composites, the dispersed particles constitute only a small fraction of the total volume of the composite, usually less than 3%. The strengthening mechanism in dispersion-strengthened systems is very different from that in either fiber- or particulate-reinforced materials. The fine particles reinforce the matrix by restricting the motion of dislocations. An excellent example of a dispersion-strengthened (DS) metal is commercial DS copper, which consists of pure copper that contains fine Al_2O_3 particles (Boyer and Gall, 1985). The effects of varying the Al_2O_3 content on the mechanical and electrical properties of the copper are shown in Fig. 6. The DS copper alloys provide excellent high-temperature stability over pure copper and copper alloys. Other metals in which dispersion strengthening has been successfully employed include

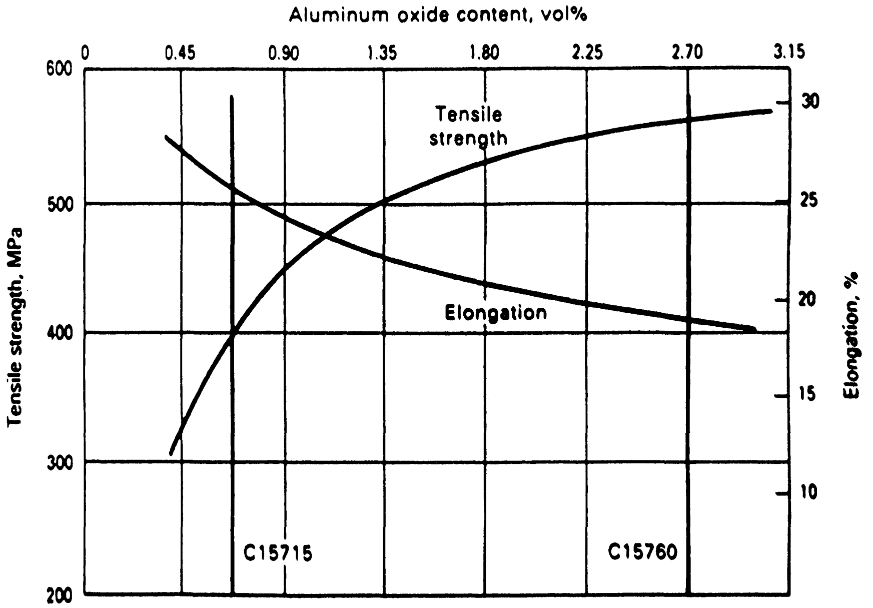

FIG. 6. The effect of aluminum oxide content on the mechanical properties of dispersion-strengthened copper. Reproduced from Boyer and Gall (1985) with permission from ASM International.

sintered aluminum powder alloys, thoria dispersed in tungsten, and thoria dispersed in nickel.

1.2.2 Flake-Reinforced Composites. A special case of a particulate-reinforced composite occurs when the particulate is in the form of a flake. A flake is a particulate that exhibits two-dimensional shape anisotropy, most easily visualized in the form of a plate. In the plane of the flake the shape is isotropic, and perpendicular to the plane of the flake the shape is highly anisotropic, resembling a fiber. The aspect ratio of the flake (diameter divided by thickness), just as in the case of fiber-reinforced materials (Fig. 3), is an important variable that determines how effective the flake is at supporting the load applied to the composite. The two-dimensional shape anisotropy of the flake leads to interesting composite properties provided

1. the aspect ratio is large (~ 100) and
2. the flakes can be incorporated into the composite such that they orient parallel to one another.

An oriented flake-reinforced composite exhibits isotropic mechanical properties in the plane of the flakes, in contrast to fiber-reinforced materials where special laminating or filament-winding procedures must be used to realize in-plane isotropic properties. The two-dimensional shape anisotropy allows the flakes to pack more closely together in the composite, yielding a higher volume fraction of reinforcement and increasing the modulus and strength. The most commonly used flakes are metal, graphite, glass, and mica. Metal flakes are typically used to increase the electrical and thermal conductivity of a polymer matrix material. Mica and glass flakes are used to provide high-temperature insulation properties. Flake-reinforced materials also find use as impermeable barrier materials because of the high packing densities and overlapping of the flakes, preventing fluids and gases from penetrating the composite.

2. FIBERS AND MATRIX MATERIALS

2.1 Fiber Types

A variety of materials can be produced in fiber form and used as reinforcing agents in a composite material. Consequently, fibers come in many sizes, shapes, and structures that usually reflect the manufacturing method. The range of structures commonly found in fibers is illustrated in Fig. 7, ranging from amorphous to single-crystalline to multiphase. Fibers are commonly classified according to material type such as glass, polymer, inorganic, metallic, or carbonaceous. Since many materials can be produced as continuous fibers, this section will describe some commonly used fibers for structural composite materials and recent trends in fibers for high-temperature composite applications.

2.1.1 Glass Fibers. The most frequently used material for manufacturing fibers for structural composite applications is glass. Glass fibers consist primarily of silica (SiO_2) with varying amounts of other metal oxides such as calcium, boron, sodium, aluminum, and iron. There are four major types of glass fiber:

1. A-glass (high alkali content) for good chemical resistance,
2. C-glass (chemical) for extremely good resistance to chemical attack,
3. E-glass (electrical) for high electrical resistivity for insulation purposes (also, because of its strength and resistance to attack by water, it is the most frequently used

glass fiber for structural purposes), and

4. S-glass for structural applications where higher strength is needed.

S-glass also has higher strength at elevated temperatures. The compositions of the major types of glass fibers are shown in Table 1.

Glass fibers are produced by melting mixtures of the appropriate oxides. The molten glass is extruded under the action of gravity through a heated die containing many small-diameter holes; see Fig. 8. The purpose of the die is to ensure that the fibers have a uniform and well-defined diameter. The extruded glass is drawn away from the die at high speed, resulting in a large number of small-diameter fibers. The fibers are then given a coating of a sizing agent and taken up on a winder. This produces a continuous roving that is used to make yarns, tapes, and various forms of fabrics used for composite material fabrication. Other methods disrupt the flow of molten glass through the heated die using a gas jet to produce short discontinuous staple fibers. Such fibers are used in making fiber mats and nonwoven materials.

Glass fibers produced by spinning processes have an amorphous structure that exhibits no long-range order typically characteristic of crystalline solids. The glass structure consists of a random network of silicon atoms covalently bonded to oxygen atoms. The randomness of this arrangement results in a completely isotropic structure whose properties are independent of direction, i.e., parallel or perpendicular to the fiber axis. The modulus of the glass fiber is primarily determined by the silicate network. Addition of other metal oxides can disrupt or strengthen the silicate network as illustrated in Table 2. Glasses having modulus and strength values comparable to or greater than S-glass have been produced using beryllium oxide additions (Diefendorf, 1985); however, because of toxicity concerns, these glasses have not received wide utilization.

2.1.2 Carbon Fibers.

Over the course of the past 30 years, carbon fibers have gone from being a laboratory curiosity to a major industry. Carbon-fiber–reinforced composites are used in a variety of applications ranging from advanced military fighter aircraft to sporting equipment such as fishing rods, tennis racquets, and golf clubs. Carbon fibers have unsurpassed specific strength and stiffness that make them attractive for applications where mass efficiency is important. Commercially available carbon fibers are produced by controlled pyrolysis, carbonization, and graphitization of one of several precursor fibers:

1. polyacrylonitrile (PAN),
2. petroleum or coal-tar-pitch–based precursors, or
3. rayon (cellulose).

Of these precursors, PAN is the most widely used for commercial carbon-fiber production. A schematic diagram of the manufacturing process is shown in Fig. 9 for both the PAN- and pitch-based fibers. In the PAN process, a starting fiber of polyacrylonitrile is subjected to a stabilization heat treatment during which the fiber is stretched, orienting the polymer chains parallel to the fiber axis. During the oxidative stabilization process, the linear carbon-nitrogen backbone of the polymer is converted to a ladder polymer of aromatic hexagonal rings. The stabilization process produces a fiber whose glass transition tem-

perature is well above its decomposition temperature. The stabilized fiber can then maintain the orientation of the ladder polymer structure during the subsequent carbonization process. The carbonization heat treatment drives off hydrogen, oxygen, and nitrogen, leaving behind a partially oriented graphitelike network of carbon atoms. The alignment and crystalline perfection of the carbon network are substantially improved by giving the fibers a high-temperature heat treatment, frequently termed the graphitization heat treatment. Fibers manufactured from PAN precursors in a strict sense do not actually develop a fully three-dimensional graphite lattice until heated to temperatures on the order of 3000 °C.

Pitch-based carbon fibers are produced by conversion of a petroleum or coal-tar-pitch-based precursor fiber into a carbon fiber through a series of heat-treatment processes similar to the PAN process. The pitch-based precursor fiber is produced by first extracting a liquid-crystalline mesophase that is melt-spun into a precursor fiber. The precursor fibers have a high degree of orientation of large platelike aromatic hydrocarbon molecules. This precursor fiber is then subjected to a series of heat treatments analogous to the PAN precursor fiber. The large platelike hydrocarbons become aligned parallel to the fiber axis and develop three-dimensional ordering into a true graphite structure at much lower temperatures than PAN-based fibers.

The Young's modulus of the fiber is highly dependent on the temperature of the graphitization heat treatment. The Young's modulus increases with increasing orientation of the carbon planes and therefore with increasing heat-treatment temperature. Carbon fibers can be produced with a wide range of properties, depending in detail on the process conditions. The higher degree of preferred orientation of the graphite planes parallel to the fiber axis in pitch-based fibers permits pitch-based fibers to develop higher values of Young's modulus at lower values of graphitization heat-treatment temperature.

The tensile strength of the fiber is dependent not only on the degree of orientation of the carbon planes parallel to the fiber axis but also on the number of critical defects present in the fiber volume. Many types of structural defects such as voids, particulate inclusions, misoriented crystallites, and microcracks are present in the fibers as a result of the fiber-manufacturing process. These defects limit the strength of the fiber in much the same way as the weakest link limits the strength of a chain. The tensile strength of the fiber increases, for example, with decreasing fiber diameter as a result, in part, of the reduced number of critical defects present in the smaller fiber volume.

The degree of orientation of the carbon planes parallel to the fiber axis and the concentration of defects present per unit volume can be controlled through variation of the process parameters so that carbon fibers having a variety of properties can be produced. Most carbon fibers fall into one of three different grades:

1. aerospace grade,
2. intermediate modulus, and
3. high modulus.

The Young's modulus and tensile strength of these three grades are given in Table 3.

2.1.3 Polymer Fibers. In carbon fibers, the high degree of preferred orientation of the sp^2-bonded carbon planes parallel to the fiber axis accounts for the extremely large modulus values achieved in these fibers. An analogous situation can be realized using organic polymers, such as paraphenylene terephthalamide (PPT), that can be spun from a nematic liquid-crystalline solution into fibers having a high degree of preferred molecular orientation. In the nematic liquid-crystalline phase, the polymer chains are oriented parallel to one another in local domains. The liquid-crystalline domains are randomly oriented with respect to one another. During spinning, the molecular orientations of the liquid-crystal domains are redirected so that they are parallel to one another, aligning the polymer chains parallel to the fiber axis. The perfection

Table 3. Properties of the three major grades of commercial carbon fibers.

Fiber grade	Modulus range(GPa)[a]	Strain to failure (%)
Aerospace	220–241	1.5–2.0
Intermediate modulus (IM)	275–345	~2.0
High modulus (HM)	379–586	~1.0

[a] Young's modulus.

of the molecular orientations in the fiber can be further improved by a post-spinning heat treatment. The first commercially available fiber based on this process was Kevlar™. The specific strength and modulus of Kevlar 49 fibers are ~5× and ~2× those of steel, respectively. More recently a new grade of aramid fibers has been introduced that has a Young's modulus of 179 GPa and tensile strength of 3.45 GPa at a density of 1.44 g/cm^3 (see Table 4). These fibers have specific properties comparable to those of aerospace-grade carbon fibers. The compressive properties of aramid fibers are somewhat low because of weak intermolecular bonding in the structure that allows it to buckle at low compressive stresses (Diefendorf, 1985). Kevlar-fiber–reinforced composites find use in tensile-dominated loading applications such as rocket motor casings, belts in radial car tires, ropes, and cables. Kevlar-reinforced composites have excellent impact damage resistance and are also used in ballistic protection applications.

Since the discovery of the aramid class of solution-spinnable polymers in the early 1970s, there have been other rigid-rod polymers discovered that also can be solution-spun into highly oriented fibers. These include the aromatic heterocycles such as polyphenylene bisbenzthiazole (PBT) (Helminiak *et al.*, 1975). PBT is a rigid-rod polymer that does not have the kink structure of PPT and therefore produces a fiber that has a substantially larger Young's modulus; see Table 4. Besides solution spinning, other processes have been developed for producing fibers composed of highly oriented rigid-rod molecules such as melt spinning of liquid-crystalline polymers (LCP). This technique has recently been successfully demonstrated on a commercial scale (Vectran™) using thermotropic copolyesters whose properties are comparable to those of the aramid-based fibers (Table 4). The organic fibers offer strength and stiffness intermediate between glass and carbon fibers.

The molecular bonds in linear chain polymers are very strong and when oriented appropriately can produce mechanical properties comparable to those of steel. Calculations of the modulus of fully extended polyethylene, for example, have predicted values ranging from 180 to 285 GPa (Lindenmeyer, 1976). Recently very-high-modulus extended-chain polyethylene fibers have been manufactured using a solution-spinning process. These fibers have a Young's modulus of 172 GPa, tensile strength of 3 GPa, and a density of 0.97 g/cm^3, in good agreement with the early predictions. The key step in the production of this type of fiber was developing a spinning solution that kept the long-chain polyethylene molecule extended, preventing it from folding back on itself. These new fibers are being used in applications such as ropes, cables, ballistic fabrics, and sporting equipment.

2.1.4 Inorganic Fibers. This section describes the major types of ceramic fibers that can be used to reinforce metal, glass, and ceramic composite materials. These fibers are usually intended for use in applications requiring high temperature stability (mechanical and chemical) that cannot be realized using polymeric composites. Many of the ceramic fibers discussed have also found application in polymer-based composites. Although

Table 4. Properties of several high-performance organic fibers.

Fiber type	Modulus[a] (GPa)	Tensile strength (GPa)	Density (g/cm^3)
Kevlar™ 29[b]	58	3.62	1.44
Kevlar 49	124	3.62	1.45

many different types of ceramic fibers have been produced over the years, only the three most commonly used fibers will be discussed. The most frequently used ceramic fibers are boron, silicon carbide, and alumina. The reader is directed to Bracke *et al.* (1984) and Sowman (1988) for a more complete discussion of past work and future trends in ceramic fibers and composites.

2.1.4.1 Boron Fibers. Boron is an attractive candidate material for producing in fiber form as it has an atomic weight less than carbon, a Young's modulus about twice that of steel, and a density of 2.34 g/cm^3. The preparation of fibers from refractory materials such as boron via direct melt spinning as in the case of glass fibers or by pyrolysis of a precursor fiber as in the case of carbon fibers is usually very difficult. Consequently, commercial boron fibers are produced by chemical vapor deposition (CVD) of a thick boron coating onto a continuous core of tungsten wire. The boron fiber is itself a composite consisting of a small-diameter tungsten wire core coated with a thick layer of polycrystalline boron. Boron fibers are produced as a monofilament instead of a tow of many small fibers. The diameter of the tungsten wire core is typically ~20 μm and the final diameter of the boron filament is variable but is usually ~100–140 μm. A schematic diagram of the CVD process for making boron fibers is shown in Fig. 10. Boron is deposited by thermal decomposition of a boron-containing gas such as boron trichloride on the tungsten wire that is resistively heated by passing a current through the wire. The thickness of the boron coating increases as the wire is drawn through the reactor tube. The boron coating is built up to the desired thickness by passing the wire through many reactors placed in series. The boron fibers produced by this method have a Young's modulus of 400 GPa and tensile strength of 3.6 GPa with a density of 2.57

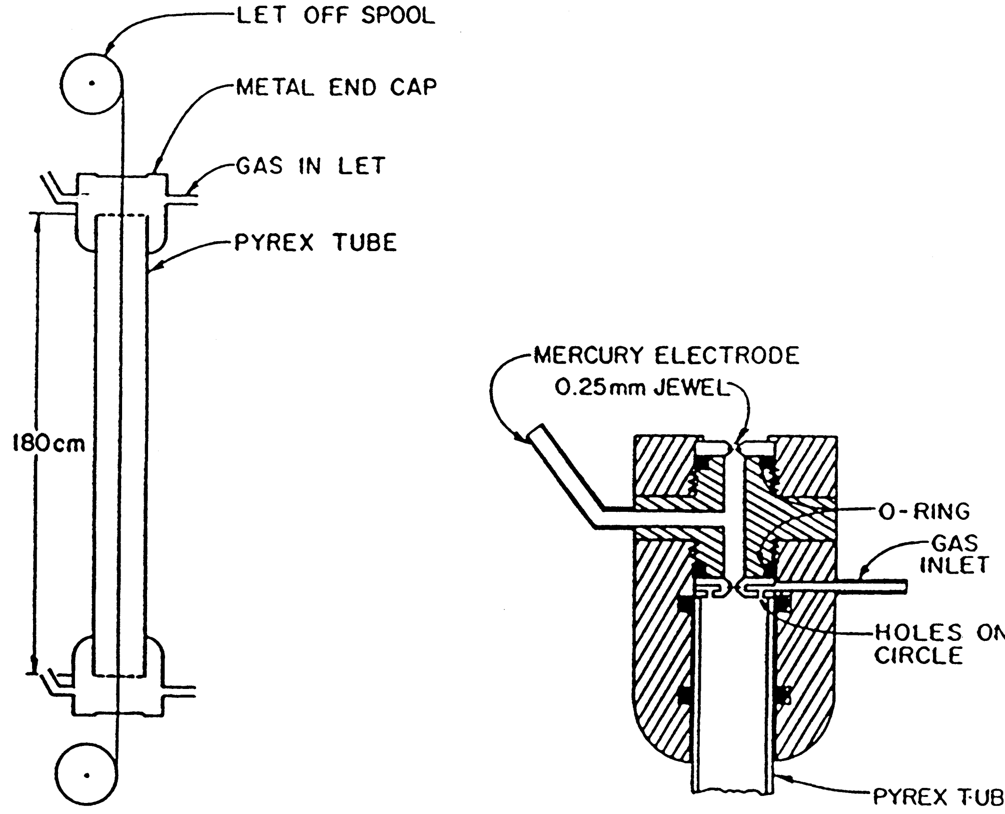

FIG. 10. Apparatus for chemical vapor deposition of a boron fiber onto a tungsten wire. The wire is resistively heated to temperatures high enough to decompose a boron-containing gas such as BCl_3 in hydrogen to deposit elemental boron on the tungsten wire. Reproduced from Diefendorf (1983), with permission.

g/cm^3. One of the largest applications for boron fibers is in reinforcing epoxy matrices for sporting goods such as lightweight racquets and shafts for golf clubs. Boron is also used as a reinforcement in aluminum, magnesium, and titanium metal matrix composites.

2.1.4.2 Silicon Carbide Fibers. Silicon carbide fibers can be produced by CVD on a core carbon monofilament or by pyrolysis of a precursor fiber. Silicon carbide fibers prepared by CVD are most frequently deposited on a carbon monofilament using a process very similar to that for CVD boron fibers. The SiC coating proceeds by reaction of a mixture of chlorinated alkyl silane compounds with hydrogen on the surface of the resistively heated carbon core. The carbon monofilament is $\sim$50 μm in diameter, much larger than the tungsten wire used for boron fibers. The CVD SiC fibers have a Young's modulus of 400 GPa, tensile strength of 3.45 GPa, and a density of 3.3 g/cm^3.

Silicon carbide fibers also can be produced by pyrolysis of Si-containing organometallic polymers such as polycarbosilane. The polymer is first melt-spun into a fiber that undergoes a curing process, which produces a high degree of cross-linking; the cured fiber then is pyrolyzed forming the product SiC fiber. There are many difficulties in the curing process such that easily spinnable high-molecular-weight Si polymers cannot be used because during the curing step they produce structures that result in breakup of the fiber structure. Thus the polymers used contain elements other than Si and C such as nitrogen and oxygen that introduce stable compounds, resulting in a nonstoichiometric silicon carbide fiber. The properties of these fibers are significantly lower than CVD-produced fibers, i.e., Young's modulus $\sim$196 GPa, tensile strength $\sim$2.9 GPa, and density $\sim$2.55 g/cm^3.

2.1.4.3 Alumina Fibers. Fibers of polycrystalline Al_2O_3, Al_2O_3-SiO_2, and Al_2O_3-SiO_2-B_2O_3 mixtures are commercially produced using slurries or sols containing the inorganic phases, various salts, and polymers to control spinnability of the fiber. The solution-spun fibers are given a pyrolysis heat treatment that nucleates the crystallization of the oxide ceramic phase and concurrently removes the polymers or other binders. On further heat treatment, the ceramic particles sinter together, densifying the structure; increased grain growth then follows. The fibers produced in this manner have a very fine grain structure, with fibers produced from sols having the finest microstructures. The properties of fiber FP (Al_2O_3) produced by DuPont, using a slurry-modified sol process, are Young's modulus $\sim$380 GPa, tensile strength $\sim$1.4 GPa, and density 3.9 g/cm^3. Although the tensile strength of these fibers is low, they have excellent compressive properties. The fiber FP also has good stability up to the temperature of 1000 °C and can be processed in aluminum- or magnesium-matrix materials.

2.1.5 Whiskers. It has been known since the early 1950s that materials in whisker form can exhibit superior mechanical properties over bulk forms. Whiskers are small, elongated, single crystals that are almost free of macroscopic defects common to bulk forms of the material. The strength of whiskers increases with decreasing whisker diameter: at diameters less than $\sim$1 μm, whiskers exhibit strengths approaching theoretical estimates; above $\sim$100 μm, whiskers exhibit strengths comparable to bulk forms. The nearly ideal mechanical properties of small whiskers have made them attractive for composite material applications, especially since whiskers of many interesting materials can be grown that have reasonable aspect ratios. Many materials have been grown in whisker form and evaluated in one way or another for composite-material applicability; in this section we will focus on the most promising whisker materials. The reader is directed to Evans (1972) for a review of much of the early work on whiskers.

Primarily for economic reasons, the only commercially available whisker reinforcements are composed of silicon carbide. The SiC whiskers are produced by the controlled pyrolysis of rice hulls that inherently have a high silicon content. SiC whiskers have also been produced by the vapor–liquid–solid (VLS) process in which a solid catalyst particle is placed in a growth reactor and exposed to the reactive gases H_2, CH_4, and SiO. The catalyst particle becomes saturated with Si and C and forms a molten ball that mediates the growth of the whisker through the liquid–solid interface. The crystal grows by precipitation from the supersaturated liquid. The growing crystal is fed from the vapor by the reaction of the constituent molecules at the vapor–liquid interface. β-SiC whiskers having tensile strengths over 8 GPa and a Young's modulus of 581 GPa have been reported (Petrovic *et al.*, 1985). The growth mechanism of the rice-hull–produced SiC whiskers is a variant of the VLS process.

Another whisker material that has recently shown promise as a potentially low-cost reinforcement for polymer-based composites is carbon (Tibbetts *et al.*, 1986). Carbon whiskers can be produced by a vapor growth process that uses a small-diameter iron catalyst particle to grow the whisker. The iron particle is exposed to a mixture of CH_4 in H_2 at elevated temperatures, saturating the iron particle with carbon. The carbon then precipitates from the particle as a hollow graphite tube approximately the diameter of the catalyst particle. The graphite tube produced by this process has the structure of high-quality graphite and is extremely small, ~30 nm in diameter, and difficult to handle. The length of the hollow graphite tube is dependent on the processing conditions, but tubes tens of centimeters in length have been produced. To produce larger-diameter whiskers, a chemical vapor deposition step is carried out that increases the diameter to the desired value, typically ~10 μm. This step represents a departure from the traditional whisker process, and the structures produced are more appropriately called fibers. The properties of the resulting CVD-coated graphite tubes are highly dependent on the final diameter but typically fall in the range of aerospace-grade carbon fibers. The CVD carbon coating is highly imperfect as deposited and accounts for the reduction of the fiber properties from those expected for single-crystal graphite. However, high-temperature heat treatment of the fibers produces properties approaching those of single-crystal graphite. Fibers produced by this method have been shown to have thermal conductivities comparable to single-crystal graphite and should be useful for composite applications requiring this property.

2.1.6 Single-Crystal Fibers. An outstanding deficiency of currently available ceramic fibers is creep at high temperatures. Above ~1000 °C, the structure of polycrystalline Al_2O_3 and SiC fiber changes, causing slippage along grain boundaries, greatly reducing the physical properties of the fiber. Many of the mechanisms responsible for high-temperature creep, such as grain growth and slippage at grain boundaries, can be eliminated through the use of single-crystal fibers. Single-crystal fibers can be produced by many different techniques, such as growth from solutions, melts, and the vapor phases. Production of single-crystal fibers is difficult, and it is likely that only three techniques will be exploited in the future: controlled drawing from the melt, vapor growth, and zone refining.

The most versatile method for producing single-crystal fibers is the recently developed laser-heated pedestal-growth (LHPG) technique (Feigelson, 1988). This is a variation on the float-zone pedestal-growth process. In the LHPG technique, a source rod having the desired composition is heated by a laser focused onto one end of the rod, creating a molten zone from which the fiber is pulled. The process does not employ a crucible. The position of the laser-heated zone is fixed in space while the source rod is translated into the laser beam at a rate necessary to conserve the melt volume. The principal advantage of this process is the ability of the laser to produce extremely sharp temperature gradients (~1000 °C/cm) that account for the high growth rates, from millimeters to tens of millimeters per hour. In addition, the steep temperature gradients, fast growth rates, and high surface-to-volume ratio of the fibers imply that the fibers cool very rapidly. This helps to suppress high-temperature solid-state phase transformations and thus can be important for stabilizing metastable forms of the material for nonstructural applications. Another of the major advantages of this technique is the complete absence of hot furnace elements that can cause contamination of the fiber. The field of single-crystal fiber growth is relatively new and has been primarily focused on fibers for optical applications. There is still need for much more work to be done relating processing conditions to defects in the crystal structure and how these defects influence fiber properties. However, the LHPG technique has demonstrated potential for producing high-quality single-crystal fibers. Czochralski fibers, by comparison, suffer from low pull rates, and therefore, without significant process improvements, it is highly likely that fibers produced by this method will be very expensive.

2.1.7 Metal Wires. Metal wires have also been used to reinforce polymer, metal, and ceramic matrices. Wires are typically made by drawing a rod of the metal through a series of dies of decreasing diameter; typical diameters range from several millimeters to ~10 μm. Wires of steel, tungsten, molybdenum, and niobium and alloy wires such as tungsten-rhenium-hafnium-carbon have been evaluated for the reinforcement of superalloy materials such as iron-, nickel-, and cobalt-based alloys. The reader is guided to Jones (1989) for a review, a compilation of properties, and a comment on the status of wire-reinforced composites.

2.2 Matrix Materials

The purpose of the matrix phase is varied, depending on the intended use of the composite structure. The role of the matrix material in structural composites is to distribute and transfer the applied load to the reinforcement. Even this statement needs to be clarified, as it applies only to those composite systems in which properties of the reinforcement such as tensile strength and modulus are substantially greater than those of the matrix. Examples of such systems are carbon- or glass-fiber–reinforced polymers. Here the strength and modulus of the composite are dominated by the properties of the reinforcement. At the other extreme are systems such as ceramic matrix composites that seek to use the low-density, high-temperature, and environmental stability of bulk ceramic materials while employing a second-phase fiber reinforcement to thwart crack propagation and prevent catastrophic failure modes common to bulk ceramic materials. In both cases, the interfacial reactions between the matrix and the reinforcement are critical to developing the expected properties. Most fibers, for example, are given a special surface treatment to facilitate the interaction of the fiber with the matrix material. In some metal- or ceramic-matrix composites, a thin coating is applied to the fiber to prevent the matrix from aggressively attacking the fiber and degrading its properties. The physical and chemical nature of the fiber surface and how it interacts with the matrix both during the fabrication of the composite and during the actual in-service use determine how effectively the reinforcement is utilized and governs the primary performance of the composite; see Jones (1989), Metcalf (1974), and Kerans *et al.* (1989).

Besides the reinforcement aspects, matrix materials also must provide a whole set of process-oriented properties that permit them to be readily fabricated into a composite. These are properties such as matrix viscosity that permit infiltration of the fiber tows, processing temperatures that are compatible with the thermodynamic stability of the reinforcement, and interaction with and bonding to the reinforcing phase. These comments apply to all four basic classes of matrix materials—polymers, metals, and ceramics including glass and carbon.

2.2.1 Polymers. Polymers represent the most commonly used matrix materials. This is due to their low cost, low density, and acceptable mechanical properties, and the relative ease with which they can be processed. Polymer matrices are readily separated into two types, thermoplastic polymers and thermosetting polymers, depending on their thermorheological behavior.

Thermoplastic polymers have a relatively well-defined melting temperature and exhibit reversible softening or melting behavior. Thermoplastic matrices are processed by traditional polymer processing techniques such as compression molding and extrusion. Examples of traditional thermoplastic polymers are polyethylene, polypropylene, nylon, and polystyrene. These polymers have not been extensively used in structural composite applications, primarily because of creep at elevated temperatures. Thermoplastic matrices are commonly used in noncritical structural applications such as equipment housings and instrument panels in automobiles. Recently, polymers such as polyetherimide, polyphenylene sulfide, and polyetheretherketone have been explored as high-temperature thermoplastic matrices. The excellent temperature resistance and superior impact strength exhibited by these polymers should allow them to be used in higher-temperature structural applications (National Materials Advisory Board, 1987).

Thermosetting polymers do not exhibit the reversible melting behavior of thermoplastics. On initial heating or curing, thermosets develop extensive cross-linking of the polymer chains, and on subsequent heating, the polymer will decompose before melting. The rheological properties of the uncured polymer and the conditions necessary for initiation of the cross-linking reactions can be varied by changing the basic formulation of the thermoset. This is especially important for impregnation of fiber bundles and tows before curing. An interesting property of thermosets that makes them very useful for composite-material fabrication is their ability to be placed in a state of partial cure and held in that condition for long periods of time before being fully cured. This ability to be carried to a stage of partial cure gives the impregnated fiber sheet mechanical properties similar to those of a fabric, facilitating fabrication of complex laminated structures. Typical thermosetting polymers are epoxy, polyester, and phenolic polyimide resins. Thermosetting polymers are widely used in structural composite applications such as military and civilian aircraft, boat hulls, and automotive parts.

2.2.2 Metals. In contrast to polymers, metals offer greater strength and stiffness and higher use-temperature capability. The major purpose for fiber and particulate reinforcement in metals is to improve their high-temperature mechanical properties. The most investigated metals are aluminum, magnesium, titanium, and copper, although there has also been a considerable amount of research on superalloy matrices such as nickel-based, cobalt-based and iron-nickel–based alloys (Islam *et al.*, 1988). These metals, with the exception of copper and the superalloys, are primarily chosen for their low densities. The most commonly used reinforcements are boron, silicon carbide, alumina, and carbon fibers. The fabrication of fiber-reinforced metal requires high temperatures for melting or diffusion bonding of fiber-interleaved metal foils. The interaction of the molten or hot metals with the fiber can significantly degrade fiber properties. Special diffusion-barrier coatings may be required, such as SiC coatings on boron fibers for use in titanium matrices. Similarly, carbon fibers require a protective coating before they can be used in the fabrication of aluminum-matrix composites.

The introduction of a continuous fiber into a metal matrix results in an anisotropic composite whose strength and modulus are greater along the fiber axis than in the transverse direction. Thus continuous-fiber–reinforced metals cannot be readily fabricated using traditional metal-forming machinery. The use of SiC whiskers or particulate reinforcements in aluminum has resulted in metal-matrix composites that are more nearly isotropic. A commercial application of metal-matrix composites is the use of alumina fiber to reinforce and provide superior wear resistance to the upper piston-ring groove region of an aluminum diesel engine piston (U.S. Congress, Office of Technology Assessment, 1988).

2.2.3 Ceramics. Bulk ceramic materials have excellent performance characteristics, such as superior retention of strength and stiffness at high temperature, high hardness, low density, and excellent oxidation resistance. The problems with bulk ceramic materials are their poor tensile strength, poor thermal shock resistance, and poor impact resistance, significantly limiting their scope of applicability. The development of ceramic-matrix composite materials is an attempt to impart toughness to these brittle materials through the use of fibrous and particulate reinforcements to alter the failure mode of the ceramic. The inclusion of fibers and particulates into ceramic matrices can alter the failure mode and toughen the ceramic in one of several ways (Diefendorf, 1985):

1. by increasing the local driving forces necessary to propagate a crack to failure,
2. by increasing locally the amount of mechanical energy per unit area necessary to propagate a crack, and
3. by decreasing the local strain in the matrix by cracking along fiber-matrix interfaces that reduces the stress concentration, preventing catastrophic failure.

In most structural composites, the fibers are needed to provide improved stiffness and strength. In many ceramic matrices, however, the modulus of the matrix is comparable to that of the fiber. This creates a situation in which the strain necessary for transferring the load from the matrix to the fiber is larger than the strain to failure of the matrix; thus addition of reinforcing fibers does not always result in improved properties. The addition of fibers to improve the brittle fracture characteristics of the ceramic may be viewed as the introduction of a homogeneous population of defects that impede crack formation and propagation and may require compromising other properties of the ceramic such as tensile strength. Many ceramic materials have been explored as matrices for composite structures (Schioler and Stiglich, 1986), including glass, silicon carbide, silicon nitride, alumina, mullite, and cements. One system that has demonstrated encouraging results is the use of carbon and silicon carbide fibers to reinforce glass and glass ceramic matrices such as borosilicates and aluminosilicates (Prewo, 1982). The glass and glass ceramic matrices have an important advantage over many other ceramic materials in that their viscosity can be substantially reduced by heating above the softening point so that the matrix can flow and fully impregnate the fiber bundles, producing fully dense composite structures.

2.2.4 Carbon. Almost since the introduction of carbon fibers as reinforcements for composite materials, carbon-fiber–reinforced carbon matrix (carbon/carbon) composites were envisioned (Stoller *et al.*, 1974). Carbon as graphite has excellent high-temperature properties. The high strength and stiffness of graphite are maintained to temperatures well in excess of 2700 °C. Applications such as rocket nozzles and space reentry vehicles, which experience very high service temperatures, have made great use of carbon/carbon composites. A major area of research activity in carbon/carbon composites is environmental protection. Carbon/carbon composites are susceptible to oxidative erosion when heated in oxygen-containing environments and require a protective coating such as silicon carbide.

Carbon/carbon composites are usually fabricated by liquid infiltration of a fiber preform with coal-tar or petroleum pitches. The infiltrated preform is heated to pyrolyze the pitch, leaving behind the carbon matrix. This process must be repeated several times to reduce the porosity in the carbon matrix caused by the release of volatile degradation products during the pyrolysis of the pitch. Other fabrication methods include vapor infiltration in which a carbonaceous gas infiltrates and decomposes on the heated fiber preform. This approach also has problems with porosity due to incomplete filling of the interior of the preform and sealing off the porous interior regions, as the gas phase is most rapidly depleted of the carbon species on the outermost regions of the preform.

Carbon/carbon composites have also received attention for use in biomedical applications such as artificial implant structures for replacing bone. Carbon/carbon composites are attractive for this purpose because of their light weight, excellent mechanical properties, and chemical inertness.

3. COMPOSITE FABRICATION

3.1 Fabrication Processes

There are many methods for fabrication of composite materials. This section describes the more commonly used processes for fiber-reinforced composites in a generic sense and directs the reader who desires a more in-depth description to specific references. The fabrication of a fiber-reinforced composite structure can be broken down into two basic operations:

1. placement and orientation (lay-up) of the various layers of fibers impregnated with resin and
2. consolidation of the laminate to induce bonding between the fibers and the matrix.

The fabrication of laminated structural composites is very hand-labor intensive, although significant progress has been made in automating the hand lay-up procedures.

3.1.1 Molding Processes

3.1.1.1 Contact Molding. The simplest and one of the most widely practiced forms of composite fabrication is contact molding, more commonly referred to as wet lay-up. This molding technique is more suited for fabrication using fibers in the form of fabrics and is not generally used for unidirectional composites because of limitations with selecting fiber orientation. The basic raw materials for this process are a two-part thermosetting resin system and fibers usually in the form of mats or woven fabrics. In this process, the resin is coated onto or into a mold. Fibers in the form of mats or woven fabric sheets are hand placed over the resin-coated mold, and more resin is applied. The resin is worked into the fiber mats, and air bubbles are removed through the use of squeegees or rollers. This process is repeated until the required thickness is achieved. The fiber-and-resin–coated mold is then covered with a release film to provide a smooth surface to the exposed surface. The lay-up is then allowed to cure either at room temperature or by heating.

3.1.1.2 Vacuum-Bag Molding. Vacuum-bag molding is widely used for fabrication of laminates of simple to complex geometries. The technique is an extension of the wet lay-up process, using a simple vacuum technique to remove air bubbles and to apply a modest hydrostatic pressure to the laminate to aid in consolidation and removal of excess resin. The vacuum-bag process is shown schematically in Fig. 11. Fibers in the form of resin-preimpregnated mats, tapes, fabrics, or tows are placed on a mold that has the desired form or shape. The fibers are placed on the mold in the desired orientation, and a laminate having the desired number of layers is built up; a porous release film is then placed over the laminate and covered with a bleeder fabric that takes up excess resin as the laminate structure cures. A nonpermeable bag material such as a polyvinyl alcohol film is placed over the entire structure and sealed around the edges, and a system of vents or passages is provided so that a vacuum can be drawn in the space between the mold and the vacuum bag. The bagged mold is then placed in an oven while the vacuum is maintained to consolidate and cure the laminate. Curing also can be effected by heating the mold. After curing, the vacuum bag, bleeder cloth, and release film are removed, and the laminate can be removed for further processing such as edge trimming, cutting, or further machining. The reader is guided to Schwartz (1984) for a more detailed discussion of the vacuum-bag process.

3.1.1.3 Expansion- and Pressure-Bag Molding. Pressure-bag molding is a variation of the vacuum-bag molding technique in which the fiber lay-up is constructed on a mold in a manner similar to the vacuum-bag technique. The lay-up is covered with a rubber bag that is pressurized to remove voids and excess resin during the curing step. The process is shown schematically in Fig. 12(a). An interesting modification of this process, shown in Fig. 12(b), is the use of silicone rubber inserts in the mold that expand when heated and apply pressure to the lay-up during the curing cycle. The vacuum fitting removes entrapped air and volatiles evolved during curing of the resin. This technique is frequently used in the fabrication of complex structures.

3.1.1.4 Autoclave Molding. The majority of high-performance structural composites for aerospace applications are produced by autoclave molding. Autoclave molding is also very similar to the vacuum-bag process, the difference being that the resin is cured in an autoclave held at elevated temperature and pressure. The vacuum bag allows the removal of air early in the curing cycle while the high pressure permits a higher degree of consolidation than either vacuum- or pressure-bag molding.

3.1.1.5 Injection Molding. Injection molding is widely used for volume production of short-fiber–reinforced articles. The process involves heating a thermoplastic polymer that contains reinforcing materials such as short fibers, flakes, or particulates and injecting the heated charge into a mold. The mold is cooled so that the polymer material rapidly solidifies. The mold is opened and the part is removed. This process is very flexible and has been

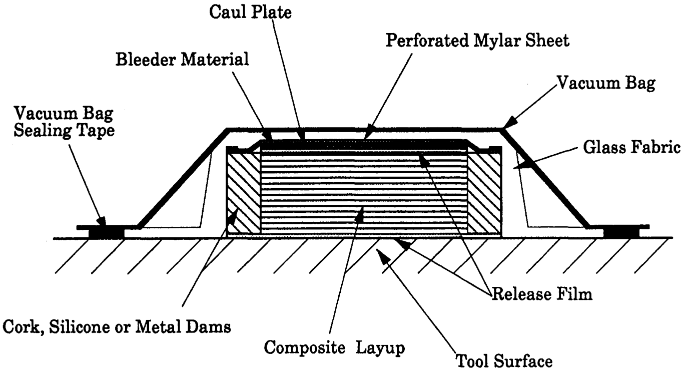

FIG. 11. Schematic diagram of the vacuum-bag molding process. After Schwartz (1984).

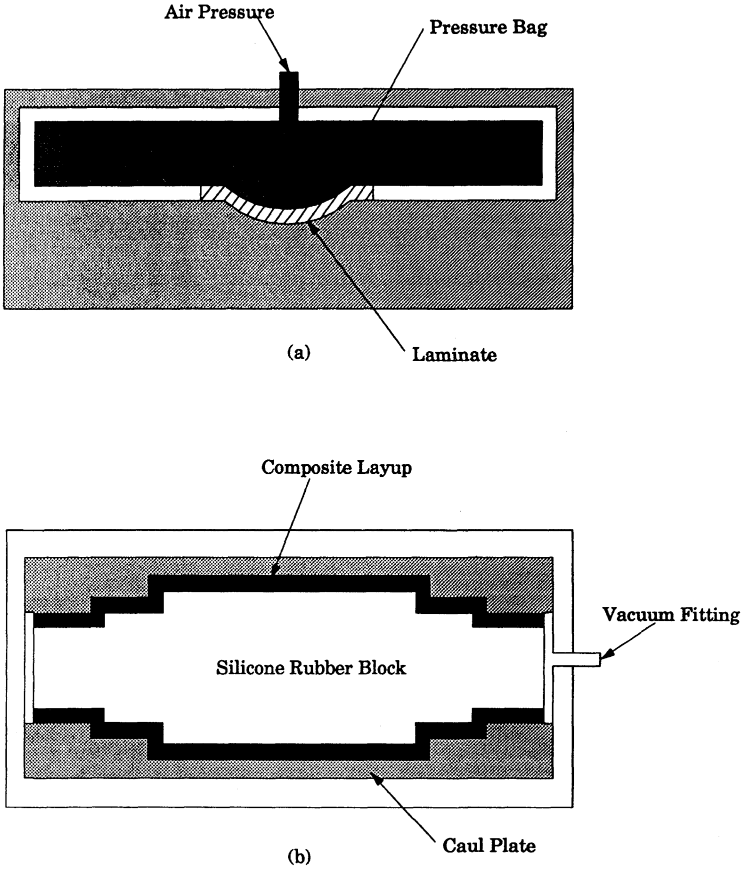

FIG. 12. Schematic diagrams of the (a) pressure-bag and (b) expansion-molding processes. After Schwartz (1984).

adapted to a variety of shapes and sizes. The process cycle time can be very short and therefore attractive for high-volume applications such as glass-fiber–reinforced automotive parts. An interesting modification of the injection-molding process is reaction injection molding, in which a two-component thermosetting polymer such as an epoxy resin is injected into a mold that is prefilled with reinforcing fibers. The two-component resin system is mixed together just before the injection point into the mold. The two components begin to react as they are forced into the mold. On completion of the injection process, the mold is then heated to complete the curing of the resin. This process is very adaptable for complex composite forms that involve the use of several different reinforcements used at selected places in the composite article. The process has been used for limited production of automotive body components and large structures such as boat hulls. The main limitation of the process is the long period necessary to cure the polymer matrix.

3.1.1.6 Compression Molding. This process is primarily used for volume production of fiber-reinforced components such as automotive fascias, fenders, hoods, and trunk lids. The process consists of loading a mold with a charge of a fiber-filled thermosetting resin commonly called sheet molding compound, closing the mold, and forcing the charge to conform to the shape of the mold, followed by heating to effect the cure of the thermoset resin. The cured part is then ejected from the mold and the process is repeated. Typical cycle times are about 30 s to several minutes.

3.1.2 Filament Winding.

The filament-winding fabrication process has received a great amount of attention initially as a method for high-rate production of composite tube structures. The process consists of winding fiber tows or tapes onto a rotating mandrel. Either the winding can be carried out using preimpregnated fibers or the resin can be applied to the fiber by passing it through a resin bath as it is being wound onto the mandrel. In either case, the mandrel is covered with the desired number of plies of fiber and then placed in an oven for curing. The filament winding has been computer-automated to a large extent so that very complex shapes can be produced using multiple-axis filament-winding machines (Schwartz, 1984). The concept of automated filament winding has been generalized to the extent that machines have been produced that can lay down fiber tapes or tow in very complex patterns, removing much of the hand-labor–intensive work and producing composites that have a high degree of accuracy and precision in fiber placement.

3.1.3 Pultrusion. Pultrusion is a technique that was initially developed to produce solid shapes having a constant cross section such as round rod (Schwartz, 1984). In this process, continuous-fiber tows are pulled through a heated die that is the shape of the desired cross section. The resin cures during this heating step and a solid, uniaxially reinforced rod is produced. The major advantage of the pultrusion process is speed.

3.1.4 Infiltration and Diffusion Bonding. These techniques are commonly used for the fabrication of metal-matrix composite structures. In the vacuum infiltration process, molten metal is drawn, through the use of a vacuum, into a mold containing a fiber preform. The fibers are placed in the mold in the desired locations and orientations and the molten metal is allowed to fill the mold. The mold is cooled to solidify the metal after which the composite is removed from the mold. This process is difficult to carry out if selective positioning of the fibers is required so that they are not uniformly distributed in the mold. The process is very dependent on the viscosity of the molten metal and its ability to wet the surface of the fiber to facilitate full impregnation of the fibers to make a fully dense composite.

In the liquid-metal infiltration process the fiber tow is pulled through a crucible containing the molten metal. The infiltrated tow passes through an orifice having the desired diameter, and the metal is cooled quickly on passing through the orifice. The resulting uniaxially reinforced wire is then wound up on a large-diameter spool. The wire can be cut and used at a later time as the raw material in a hot-pressing consolidation process to fabricate a composite structure.

In the diffusion-bonding process, fibers are attached to metal foils by use of an organic binder. The foils are stacked up to form a preform of the laminate having the desired fiber orientations. The preform is placed in a collapsible container and subjected to high temperature and pressure to cause the metal matrix to flow around the fibers and bond the laminae together. The organic binder is pyrolyzed to burn off volatile components during the beginning of the heating cycle. Diffusion-bonding processes have been used to make boron-reinforced aluminum and SiC-reinforced titanium composites.

4. COMPOSITE APPLICATIONS

4.1 Military Aircraft

Historically, military aircraft have provided the driving force behind the research, development, and utilization of composite structures. Composite construction on aircraft is continually increasing from 1% of the structural weight on the F-14 to 26% on the AV-8B (Schwartz, 1984). This trend does not show any sign of changing in the near future, as many of the new military aircraft programs on composite structures are aimed at further mass reduction. For example, the goal of the Air Force Ultra-Lightweight Structures program is to reduce the structural weight of several baseline aircraft by 50%. The extended and successful use of composites in military aircraft is now spilling over to other military applications—for example, the use of ceramic-matrix composites for vehicle armor and of polymer-matrix composites for structural components on ships, submarines, and other weapon systems.

4.2 Aerospace

Carbon-fiber–reinforced polymer and metal-matrix composites have played an important role in providing lightweight, dimensionally stable platforms in space for communications satellites. These applications are primarily performance-driven by the need to reduce the mass of structural components and increase the amount of active payload. The space shuttle orbiter uses many composite components to provide the performance necessary for a reusable reentry vehicle. Programs such as the National Aerospace Plane, a passenger version of the space shuttle for very fast transcontinental flight, are relying on composite materials to provide enabling technologies. The NASA-proposed space station project will require major advances in composite-material fabrication and processing to enable a massive structure to be assembled in orbit.

4.3 Commercial Aircraft

The use of composite materials on commercial aircraft has increased as experience with composites on military aircraft has grown, with both cost and safety mediating the rate of acceptance. Fiberglass-epoxy composite fairings and control-structure applications have increased dramatically and are now being supplanted by more advanced Kevlar-epoxy composites. Graphite-reinforced epoxy composites are also being more extensively used in secondary and primary structural applications such as elevator structures, rudders, and vertical fin structures. The use of carbon/carbon composite brake disks on commercial aircraft has resulted in significant weight savings (~590 kg) and lower wear rates. The use of advanced composites on commercial aircraft is expected to increase, especially as lower-cost materials and processing are developed. The increased penetration of carbon-fiber–reinforced polymer composites into primary load-bearing structures on commercial aircraft depends on the ability to improve the properties of the present composites such as

1. toughness,
2. higher temperature capability,
3. strength and modulus,
4. environmental resistance, and
5. compressive strength.

If these problem areas are solved, the use of carbon-fiber–reinforced polymers will also increase in other applications as well.

4.4 Ground Transportation

One area in which composites potentially could have large impact is automotive applications. At present there is significant use of nonstructural composite materials on automobiles, such as sheet molding compounds reinforced with chopped glass fiber for the front and rear fascias, hoods, trunk lids, and body panels. There have been a few small-volume applications of carbon-fiber–reinforced drive shafts in light-duty vans and trucks. Continuous-filament–wound, glass-fiber–reinforced polyester leaf springs are now used in a variety of passenger cars and light trucks. The composite leaf spring represents a major structural application of composites, having a superior fatigue lifetime over the metal component. Composites have been used in a number of prototype engine parts such as pistons and connecting rods made from both graphite-fiber and silicon-carbide–particulate reinforced aluminum. Prototype engines have been made that are constructed almost entirely from polymer-matrix composites including the engine block. Carbon/carbon composite disk brakes are presently used in racing cars because of their superior performance characteristics and lighter weight. Although many prototype parts have been evaluated, carbon-fiber–reinforced composites have not penetrated the automotive marketplace primarily because of the high costs associated with the raw materials and composite fabrication. The real potential of composites to lower manufacturing and assembly costs through integration of many individual components into a single composite structure has not yet been realized because of the absence of high-rate fabrication processes, and remains a challenge to future scientists and engineers.

4.5 Recreation and Sporting Equipment

In direct contrast to the cost-sensitive automotive applications, sporting and recreational applications of composites are performance-driven. Glass fibers were first used in composite fishing rods to improve performance over bamboo and metal poles. The fiberglass was supplanted by graphite and Kevlar fibers. Tennis racquets that are constructed from graphite-epoxy composite are stiffer than wooden or aluminum racquets and do not dissipate as much energy in deformation of the racquet, allowing more energy to be given to the ball, giving the player a definite performance advantage. Boron-fiber–reinforced epoxy is also experiencing increased interest for tennis racquet applications. Advanced composites are being used in nearly every possible sporting-goods application including fishing rods, snowmobiles, motorcycles, bicycles, skis, track and field equipment, archery bows and arrows, protective helmets, and golf clubs, to mention a few. The application of advanced composites to sports and recreational equipment will continue to grow as new materials are developed, such as the extended-chain polyethylene fibers.

5. FUTURE OUTLOOK FOR COMPOSITE MATERIALS

The use of composite materials is cost- and performance-benefit–driven. Composite materials usually cost more than metals so that direct replacement of metal parts with their composite counterparts is not an effective strategy unless the benefit such as mass reduction, increased lifetime, additional performance, etc., can offset the additional cost of the composite. Substitutional strategies work for performance-driven applications such as aircraft where mass savings have a direct economic impact, such as improved fuel economy or increased payload capability. In cost-driven applications such as passenger automobiles, mass reduction does not result in a sufficient savings to the user in terms of either decreased operating costs or increased payload capability that can offset the increased cost of the composite structure. Thus, the composite must provide an economic benefit in terms of lower overall vehicle construction cost through parts consolidation and lower assembly costs; simple part-substitution strategies do not work, because of the higher cost of the composite part. In order to address high-volume, cost-driven applications, radically new engineering approaches are necessary that depart from traditional engineering practices used for metallic structures. Such new approaches are being explored as high-speed resin-transfer molding of highly integrated structures, high-speed reaction injection molding of large integrated structures, and filament winding of thermoplastic structural components (U.S. Congress, Office of Technology Assessment, 1988).

The development of new low-cost composite fabrication techniques to supplant traditional fabrication practices in cost-driven high-volume applications represents an important goal for domestic industries to achieve in order to remain competitive in the world marketplace.

In addition to the development of new composite-fabrication technology, the development of lower-cost, high-performance constituent materials will also lead to the more widespread utilization of composites. As the use of composite materials has increased, the need for a more basic understanding of the science of composite materials has also increased. Since the early 1980s, our understanding of the complex interactions between the constituents in composites has dramatically improved through the application of more sophisticated analytical techniques. The improved understanding in turn challenges researchers to develop new materials and processes.

GLOSSARY

Anisotropic: Having properties that are different when tested along different directions relative to a coordinate system fixed in the material.

Aspect Ratio: The ratio of the length of a fiber to its diameter.

Autoclave: A pressure vessel that can maintain a prescribed pressure and temperature of a gas for curing polymeric matrix composites.

Carbonaceous: Relating to or composed of carbon.

Cermet: A composite material made by mixing, pressing, and sintering a mixture of metal and ceramic powders.

Die: A tool or mold used to impart shapes to or form impressions on materials such as metals, glasses, polymers, and ceramics. An example is a die used in spinning glass fibers; a molten glass charge is forced through small orifices in the die, which shapes the glass into small continuous cylinders or fibers.

Fabric: Planar sheets of woven or nonwoven materials consisting of intertwined yarns, fibers, or filaments.

Fiber: A term usually used to describe short lengths of a material having very small cross-sectional areas and aspect ratios > 1.

Filament: A fiber having an infinite aspect ratio, such as a continuous fiber.

Laminate: A composite material consisting of multiple layers of a single material or different materials bonded together.

Matrix: The principal phase in which the reinforcing phase is embedded.

Petroleum Pitch: A distillate product from petroleum used in the production of carbon fibers.

Poisson's Ratio: A constant relating the change in sample cross-sectional area to the change in length when a material is elastically deformed.

Polyacrylonitrile (PAN): A polymer of acrylonitrile used in the manufacture of carbon fibers.

Stiffness: A general term used to describe the ratio of the stress applied to a material and the deformation produced. The stiffness of an elastic material subjected to a uniaxial stress is referred to as Young's modulus.

Superalloys: Alloys based on iron, nickel, and cobalt that are an extension of stainless-steel alloys. Superalloys have higher tensile strength than stainless-steel alloys at elevated temperatures and are primarily for use at temperatures above 540 °C.

Tensile Strength: The maximum tensile force per unit area that a sample can sustain.

Thermoplastic: A material that can be repeatedly softened by increasing or hardened by lowering its temperature.

Thermosetting Polymer: A polymeric material that irreversibly converts into an infusible and insoluble solid on curing by heating or chemical means.

Tow: An untwisted loose collection of continuous filaments.

Yarn: Strands of fibers or filaments suitable for weaving.

Young's Modulus of Elasticity: The ratio of the tensile stress to the elastic strain or deformation produced.

INTRODUCTION

Compressible flow is the study of fluid motion with significant induced density changes. Sufficiently strong forces will cause any real material to flow as a compressible fluid. This covers the range from the nonlinear elastic deformation of solids under high explosive loading to the flow of compressed air from an automobile tire. Compressible flows are significant in a wide range of technical devices and natural phenomena. These include high-speed flight, detonations and explosions, gas turbines, rocket engines, nuclear weapons, blast waves and sonic booms, high-velocity impact, power generation, chemical synthesis, laser fusion and high-pressure research, volcanic eruptions, and shock waves within supernovae.

Compressible flows are essentially nonlinear phenomena that arise from the interaction of thermodynamics and fluid dynamics. This article describes the general theory of compressible flow starting from the basic thermodynamic properties of sound speed, the fundamental derivative, the Grüneisen coefficient, and the conservation relations for a compressible fluid. The special case of adiabatic, inviscid flow governed by the Euler equations is given particular attention. Many practical flows can be analyzed in this approximation, since the effects of viscosity and thermal conduction are often confined to thin layers near walls or at slipstreams. Solutions to the Euler equations are observed to consist of smooth regions of isentropic flow joined by discontinuous jumps in properties through shock waves or contact surfaces.

This article begins with basic considerations about thermodynamics and fluid dynamics. The two basic elements of compressible flow, isentropic motion and shock waves, are then introduced. Steady flow within a converging–diverging or de Laval nozzle is discussed with one-dimensional theory. The complexity of real nozzle flows is illustrated with selected experimental results. Shock waves are treated from both the classical Rankine–Hugoniot discontinuity approach and the molecular viewpoint. Detonations are treated as shock waves followed by chemical reaction zones.

One-dimensional unsteady flow is illustrated with a discussion of the problem of shock-wave formation, the theory of shock tubes, and the propagation of blast waves. Steady supersonic flows in two dimensions are characterized by regions of isentropic flow

(uniform motion or expansion waves) interrupted by contact surfaces or shock waves. If the shock waves are curved, a continuous variation of entropy and vortical flow will be produced. Simple flows without vorticity can be analyzed by the method of characteristics in the isentropic regions, supplemented by the shock jump conditions and matching conditions at contact surfaces.

Aerodynamic applications are considered in the context of two-dimensional steady flows over streamlined bodies. Corrections to the lift and drag due to compressibility are derived from linearized equations. Optimal airfoil design for modern aircraft illustrates the issues associated with flow near the sound speed and the interaction between shock waves and boundary layers. Flows at very high velocities are characterized by strong shock waves. Lift and drag on reentry vehicles are determined by the shock configuration and viscous heating at the body surface.

Unsteady compressible flows in two dimensions are illustrated by the problem of Mach reflection. Experimental and numerical results on the interaction of a shock wave with a ramp are discussed. The article ends with some selected results on compressible flow with phase change.

A few comments on the history and origins of compressible flow are appropriate here. Early efforts, starting with Newton, originated in the study of sound generation and propagation. Later the technological problems of steam engines and steam turbines provided motivation for the engineers and scientists of the 1800s. A genuine theory of compressible flow was possible only after the foundations of thermodynamics had been completed in 1850. Ideas from classical fields of mechanics, hydrodynamics, elasticity, and acoustics were ultimately combined with thermodynamic notions to obtain the understanding of today.

The basic foundations of compressible flow were developed in the period 1850–1910. A significant step was the experimental observation of "choking" by Napier (1867) and others and the theoretical explanation using isentropic flow ideas by Reynolds (1885). The problem of nonlinearity and wave steepening was formulated by Riemann in 1860, and the theory of the shock wave as a discontinuity was completed by Rankine (1870) and Hugoniot (1889). Supersonic flow and shock waves were revealed by Mach's experimental observations (1870–1900) and analysis of shock waves produced by high-speed bullets, spark discharges, and gas jets. Berthelot and Vielle discovered (1878–1883) the nature of the detonation process in gases and measured detonation velocities. Chapman (1899) and Jouguet (1904) analyzed the solutions to the shock jump conditions for explosive gases and determined that the minimum-wave-speed solution agreed with the experimental measurements. Vielle (1900) experimentally confirmed Hugoniot's theory for the relation between pressure rise and wave speed for moving shock waves.

Stodola's experiments and analysis of the de Laval nozzle flow (1903) clarified the role of shock waves in steady flows. This was followed by Prandtl's comprehensive experiments and analysis of the nozzle flow problem (1906). Prandtl's analysis (1908) of oblique shock waves and steady expansion waves in two-dimensional flow allowed a complete explanation of the jet phenomena first observed by Mach. These basic ideas were then extensively applied to gas turbines and supersonic flight from 1910 to 1940. Since that time, the technological problems of high-speed aircraft, gas turbines and rockets, and explosives have continued to motivate the further developments of experimental techniques and more sophisticated theory. In the last 20 years, numerical computational methods have played an increasingly important role in both engineering and research.

1. THERMODYNAMICS OF COMPRESSIBILITY

Most relevant to compressible flows is the relation between pressure and volume of a fluid, which can be determined from classical thermodynamics. The relative change in specific volume v for small changes in pressure P and entropy s about an undisturbed state $(\ )_0$ is given by

$$\frac{v-v_0}{v_0} = -K_s(P-P_0) + \Gamma K_s^2(P-P_0)^2 + G\frac{K_sT_0}{v_0}(s-s_0) + \cdots. \qquad (1)$$

The quantity K_s is the *adiabatic compressibility,*

$$K_s = -\frac{1}{v}\left(\frac{\partial v}{\partial P}\right)_s, \tag{2}$$

which is inversely related to the velocity of small-amplitude adiabatic (acoustic) disturbances, the *sound speed* $c=\sqrt{v/K_s}$. Compressibility of low-pressure gases such as ordinary air is on the order of the inverse pressure or about 10^{-5} Pa^{-1} at normal atmospheric pressure. Liquid and solid compressibilities are much smaller, typically 10^{-10} Pa^{-1}.

The *fundamental gasdynamic derivative* Γ is defined (Thompson, 1988) to be

$$\Gamma = \frac{c^4}{2v^3}\left(\frac{\partial^2 v}{\partial P^2}\right)_s, \tag{3}$$

a nondimensional measure of the nonlinear response of the fluid. Values of Γ range from slightly above unity for ordinary gases up to 4–7 for typical organic liquids. Normal fluids have values of $\Gamma > 1$. In some circumstances Γ can be less than 1 and in exceptional cases Γ can be negative. The *Grüneisen coefficient* G is a nondimensional measure of thermal expansion,

$$G = \frac{1}{c_p K_s}\left(\frac{\partial v}{\partial T}\right)_P, \tag{4}$$

which has a value between 0 and 0.67 for gases and around 2 in most solids.

K_s, Γ, and G are thermodynamic properties that are determined by the molecular composition of the fluid and the extent of intermolecular interactions. Representative values of these and related properties are given in Table 1 for selected substances at conditions of $P=1$ bar (10^5 Pa) and $T=20$ °C.

Specific volume may change as a result of either applied pressure or entropy increases that are the consequence of irreversible processes such as external heating or shock waves. Many compressible flow problems of significance to applied physics are adiabatic and consist of smooth regions of *isentropic flow* with zero entropy change interrupted by thin layers or *shocks* in which the entropy irreversibly increases.

It is the variation of the sound speed with thermodynamic state that provides compressible flow with its true nonlinear character. There are two aspects of nonlinearity: the strength of the disturbances, and the degree of nonlinear response of the fluid to these disturbances. Disturbance strength is quantified by the ratio of the amplitude of the pressure variation ΔP to the quantity $1/K_s = \rho c^2$. Material response will be nonlinear when $\Delta P/\rho c^2$ becomes nonnegligible. This will occur for disturbance pressures of >0.2 bar for atmospheric air and pressures of thousands of atmospheres for substances such as water.

Nonlinearity is intimately related to Γ, both as the coefficient of the second term in Eq. (1) and by the relation to the variation (Thompson, 1971) of sound speed with pressure,

$$\left(\frac{\partial c}{\partial P}\right)_s = \frac{v}{c}(\Gamma - 1). \tag{5}$$

Wave propagation in compressible flows is profoundly influenced by nonlinearity. The dependence of propagation velocity on amplitude results in the creation of propagating sharp jumps, *shock waves,* or continually spreading *expansion waves* in the fluid state. The character and degree of nonlinearity are determined by the numerical value of Γ. The sign of Γ determines the curvature of the isentropes in (P,v) coordinates and the type of shock waves that are formed.

Table 1. Properties of some compressible materials.

	ρ (kg/m ^{3})	c (m/s)	K_s (Pa^{-1})	Γ	G
Air	1.205	344	7.01×10^{-6}	1.20	0.40
Water	998.2	1484	4.55×10^{-10}	4.4	0.11
Ethyl Alcohol	790	1159	9.42×10^{-10}	6.4	0.64
Steel (304S)	7896	4569	6.07×10^{-12}	2.98	2.47

2. FLUID DYNAMICS—THE EULER EQUATIONS

Changes in specific volume or mass density $\rho = 1/v$ will produce fluid motion. Conservation of mass applied to a fluid element requires that a local motion inward or outward, indicated by a nonzero divergence in the velocity field $\mathbf{u}$, be produced by any change in mass within that volume:

$$\mathrm{div}\mathbf{u} = -\frac{1}{\rho}\frac{D\rho}{Dt}. \tag{6}$$

The *substantial* or *convective* derivative used in this expression is defined as $D(\cdots)/Dt = \partial(\cdots)/\partial t + \mathbf{u}\cdot\mathrm{grad}(\cdots)$ and represents the time derivative taken in a frame of reference moving with the fluid.

The complete description of the motion is determined by the thermodynamic properties discussed above together with the balance equations for mass, momentum, and energy including the appropriate boundary and initial conditions, and thermodynamic and transport properties (see FLUID DYNAMICS, EQUILIBRIUM). An approximation of wide applicability is that of inviscid, adiabatic flow. Such flows are determined by solutions to the *Euler equations*:

$$\frac{\partial}{\partial t}\rho + \mathrm{div}(\rho\mathbf{u}) = 0, \tag{7}$$

$$\frac{\partial}{\partial t}\rho\mathbf{u} + \mathrm{div}(\rho\mathbf{u}\mathbf{u}) = -\mathrm{grad}P, \tag{8}$$

$$\frac{\partial}{\partial t}\rho\left(e + \frac{|\mathbf{u}|^2}{2}\right) + \mathrm{div}\left[\rho\mathbf{u}\left(e + \frac{P}{\rho} + \frac{|\mathbf{u}|^2}{2}\right)\right] = 0. \tag{9}$$

Pressure plays a special role. As in incompressible flow, the pressure field plays a mechanical role in the balance of momentum as a force field that accompanies material acceleration. An equally important role for pressure in compressible flows is as a thermodynamic variable, which is implicitly coupled to both internal energy $e = e(P,\rho)$ and the mass density through the Euler equations. This dual role of pressure is responsible for many of the special features of compressible flow, including the phenomena of wave propagation and the interconversion of thermal and mechanical energy.

An equation of state for the internal (thermodynamic) energy $e = e(P,\rho)$ must be supplied to complete the Euler-equation model of compressible flow. High-pressure experiments or molecular-dynamics simulations are required for solids and liquids to obtain the necessary thermodynamic information. Ideal models of thermodynamic behavior can often be applied in the case of gases. Most often studied has been the compressible flow of a *perfect gas*, an ideal gas with constant specific heats. Ordinary air and most other gases can be described by this model up to moderate pressures (50 bar) and temperatures (1000 K). Only one parameter is required for this model, the ratio of specific heats $\gamma = c_p/c_v$, which takes on values between 1 and 1.667. The equation of state is

$$e = Pv/(\gamma - 1). \tag{10}$$

Temperature can be determined by the usual ideal-gas law $P = \rho RT$. The various derivatives significant to compressible flow behavior are

$$K_s = 1/\gamma P,$$

$$c = \sqrt{\gamma P v},$$

$$\Gamma = \tfrac{1}{2}(\gamma + 1),$$

$$G = \gamma - 1. \tag{11}$$

Solution of the Euler equations with the perfect-gas equation of state is the subject of classical *gasdynamics*. These equations must be solved numerically except for special cases in which analytic solutions have been obtained for steady flows and self-similar transient flows. Solutions to compressible flow problems have the special feature of the spontaneous generation of discontinuities such as shock waves and contact surfaces.

Fluid composition must be specified in order to analyze chemically reacting flows such as detonations. This requires an equation of state appropriate to a mixture of species and an evolution equation for the composition. Changes in the species concentrations are due to simultaneous material transport and chemical reaction. A reaction-rate model must be developed from molecular considerations of the processes of reactive collisions (combustion chemistry), vibrational–translational energy exchange, and electronic excitation or ionization dynamics. Supersonic and hypersonic vehicle aerodynamics, spacecraft heating during reentry, high-speed flames in gases, and detonation of explosives (gaseous and condensed) (see EXPLOSIVES) offer a rich variety of applications that motivate the study of *compressible reacting flows.*

3. CRITERIA FOR COMPRESSIBILITY

Under what circumstances is a flow considered compressible? Combining our thermodynamic analysis with the Euler equations shows that the nondimensional pressure $\Delta P/\rho c^2$ is of the same magnitude as the *Mach number* $M=u/c$ for steady flows. Therefore, the Mach number must exceed some minimum value for compressibility to be considered an essential feature of a steady flow. A value of $M>0.3$ is often taken as a criterion for ordinary gases. A more important distinction is between *subsonic* flow, $M<1$, and *supersonic* flow, $M>1$, with the case of *sonic* flow, $M=1$, playing a special role.

In the case of unsteady flows, compressibility effects must be considered whenever the acoustic-wave transit time L/c across a characteristic distance L is comparable to or greater than other significant time scales present in the flow. Small-amplitude motion with $M\ll 1$, $\Delta\rho/\rho\ll 1$, and $\Delta P/\rho c^2\ll 1$ can be described by the theory of *acoustics* (see ACOUSTICS, LINEAR). The approximation of acoustics is to neglect the convective derivative terms compared to the unsteady derivatives in the Euler equations and to treat the motion as isentropic. Acoustic flows are described by the linear wave equation, for which a large number of exact solutions can be obtained. Large-amplitude motions are intrinsically nonlinear and require experimental or numerical investigation (see ACOUSTICS, NONLINEAR).

4. SIMPLE FLOWS

Many technical applications of compressible flow require only simple notions about the dynamics of motion in one dimension. Useful information can be obtained by considering only variations in one spatial direction even in the case of apparently multidimensional flow within a nozzle or a tube of variable cross section. Transient flows in ducts of a constant cross section play an important role in the operation of devices such as shock tubes, mufflers, and the phenomenon of water hammer. Shock waves can be analyzed by considering only the one-dimensional structure normal to the wave front, even in cases of curved waves. Detonation waves and transient shock waves (blast waves) resulting from explosions can also be productively examined from a one-dimensional viewpoint.

4.1 Quasi One-Dimensional Flows

A typical application of compressible flow is accelerating fluids from rest to high velocities. This can be accomplished through a de Laval nozzle, first used in steam turbines. It has since been widely applied in the generation of supersonic flow in devices such as wind tunnels and rocket motors. Fluid at high pressure is accelerated through a duct that converges and then diverges as shown in Fig. 1.

Simple explanations of the principal features of these flows are possible by assuming a slowly varying duct cross section and steady-state ($\partial/\partial t=0$), adiabatic flow. This ensures that the flow is almost parallel and that the

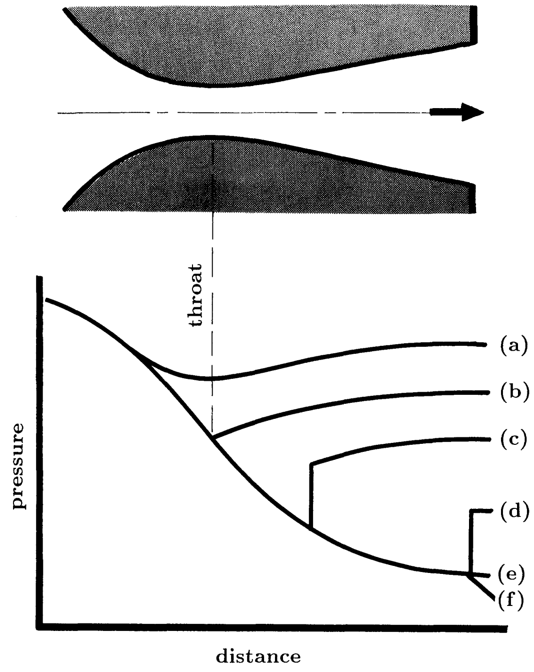

FIG. 1. Flow through a de Laval nozzle and the associated changes in the fluid pressure. Each curve represents a different downstream pressure as discussed in the text.

accelerations perpendicular to the main flow direction are also small. In this *quasi one-dimensional* approximation, the Euler equations can be compactly written as

$$\frac{d}{dz}(\rho uA)=0,$$

$$\frac{dP}{dz}=-\rho u\frac{du}{dz},$$

$$\frac{d}{dz}\left(h+\frac{u^2}{2}\right)=0, \tag{12}$$

where $A(z)$ is the duct cross-sectional area perpendicular to the main flow direction z. In this situation, the total mass flow rate is constant and equal to ρuA. The energy equation is written in terms of the *enthalpy* $h=e+P/\rho$. The combination $h_t=h+u^2/2$ is known as the *total* or *stagnation* enthalpy, which is constant in adiabatic, steady flows.

If the motion is inviscid and no shock waves are present, adiabatic flow can be further simplified as isentropic, and variations in pressure and density can be related by Eq. (1) to obtain the isentropic flow equations

$$\frac{d\rho}{dz}=\frac{1}{c^2}\frac{dP}{dz}, \quad \frac{1}{u}\frac{du}{dz}=\frac{1}{M^2-1}\frac{1}{A}\frac{dA}{dz}. \tag{13}$$

For initially subsonic flow, $M<1$, as in the case of accelerating a fluid from rest, a converging duct $dA/dz<0$ will increase the fluid velocity as the pressure and density decrease. This acceleration is equivalent to the conversion of thermal energy into mechanical energy, as shown by the integrated form of the energy equation $u=\sqrt{2(h_t-h)}$, where the total enthalpy h_t is just the enthalpy of the stationary fluid in the reservoir supplying the duct.

The *stagnation state* is a hypothetical state produced by isentropically bringing a flow to rest (stagnation). If the fluid reservoir supplying the nozzle is large enough, then the pressure P within the reservoir will be equal to the *stagnation pressure* P_t. Stagnation pressure in a steady, isentropic flow is constant. The stagnation pressure in a steady flow can be changed only by external work, energy addition, or dissipative processes such as friction or shock waves.

The Mach number will increase monotonically with the velocity for usual fluids, which have $\Gamma>1$, since

$$\frac{du}{u}=\frac{1}{1+(\Gamma-1)M^2}\frac{dM}{M}. \tag{14}$$

Given sufficient stagnation pressure, continuous contraction in the duct cross section will result in the Mach number approaching 1, a phenomenon known as *choking*. In a constant-area duct, choking can also occur as a result of frictional forces or heat addition.

It is apparent from the differential relation equation (13) for velocity that transition through the *sonic point*, $M=1$, is possible only at an area extremum. This takes the shape of a minimum forming a *throat* in the nozzle for the case of normal fluids, $\Gamma>0$. If the downstream pressure is sufficiently low, as in cases (c)–(f) of Fig. 1, sonic flow will occur at the throat and the flow downstream will be supersonic for some distance. In the supersonic flow downstream of the throat, increasing the duct area results in further velocity and Mach-number increases. Pressure, temperature, and density will decrease with increasing Mach number in a supersonic flow.

For a given nozzle and stagnation pressure, the flow within the nozzle depends crucially on the pressure at the exit of the nozzle. If the flow is subsonic at the nozzle exit, the exit pressure will be approximately equal to the ambient pressure in fluid outside the nozzle. The situation is more complex for sonic or supersonic exit flows and the exit pressure is, in general, not equal to the ambient pressure.

Several possible situations are shown in Fig. 1. First, in case (a), the ambient pressure must be less than the stagnation pressure in order for flow to take place. Second, if the ambient pressure is not too low, then the flow remains subsonic throughout. This is the case for exit pressures above case (b) of Fig. 1. Third, when the ambient pressure is sufficiently low, cases (c)–(f), the flow will be *sonic* at the nozzle throat ($M=1$) and supersonic ($M>1$) for some distance downstream. Sonic flow at the throat will occur when the ratio of stagnation pressure to throat pressure exceeds a critical value. This value is determined by the thermodynamic properties of the fluid and can be estimated to be about 1.9 for air, 5300 for water, 2000 for ethyl alcohol, and 5.21×10^5 for steel. The pressure required at the nozzle exit to first produce this state, case (b), must be determined from the specific nozzle geometry and operating conditions.

Supersonic flow will exist for some distance downstream of the throat for all cases with an exit pressure lower than case (b). For exit pressures between cases (b) and (e), the nozzle flow is termed *overexpanded.* For exit pressures between those of cases (b) and (d), a special situation within the nozzle must exist. A sudden increase in pressure occurs through a nonisentropic *shock wave,* discussed in detail in the next section. The shock wave compresses and decelerates the fluid, resulting in subsonic flow downstream with the pressure increasing with distance up to the exit value. There is a loss of total pressure across the shock wave and an increase of entropy. The shocks are idealized as sharp discontinuities normal to the flow in Fig. 1, but in reality these waves are usually obliquely oriented to the flow (described in Sec. 7.1). An additional feature of real nozzle flow is the interaction between the shock and the boundary layer at the nozzle surface. This interaction can result in separation of the flow from the nozzle surface and the formation of a recirculation or reverse-flow region downstream of the interaction point.

For pressures between cases (d) and (e), shock waves will form in the jet outside the nozzle. The *pressure-matched* situation of case (e) has a smooth acceleration of flow up to nozzle exit where the pressure is exactly equal to ambient. Case (f) is an *underexpanded* flow and the nozzle exit pressure is higher than ambient. Further expansion must take place outside the nozzle. Conservation of energy limits the maximum fluid velocity that can be achieved by expansion to zero pressure to be $u_{\max} = \sqrt{2h_t}$. However, for ordinary fluids, the Mach number will be infinite in this state.

Analytic and tabulated solutions (Brower, 1990) are available for the thermodynamic states and flow variables of quasi one-dimensional isentropic flow of a perfect gas. For other fluids, each case can be treated numerically given sufficient thermodynamic information to compute enthalpies and sound speeds on isentropes. Approximate similarity principles based on Γ are available (Thompson and Sullivan, 1977) as guidelines for liquids and dense gases.

Real fluid flows in nozzles are multidimensional and have complicating factors such as condensation in moist air and a viscous boundary layer on the duct walls. Accurate computations of the flow should include the displacing effect of this layer and the motion transverse to the main (axial) flow direction. Realistic two-dimensional steady-state computations including these effects have been carried out and are in quantitative agreement with experiments. Figure 2 shows a schlieren photograph of the flow (Schnerr, 1989) of moist air through a two-dimensional circular arc (radius 100 mm) nozzle with a throat width of 120 mm. The flow is from left to right. Dark regions in the photograph are expansions; light regions represent compressions.

The fluid in the reservoir was at a pressure of 1 bar and temperature of 295 K, and had a relative humidity of 37.2%. The rapid cooling rate ($> 10^6$ K/s) due to the expansion in the nozzle causes supersaturation and homogeneous nucleation of the water vapor. This occurs downstream of the throat in the supersonic flow region near a Mach number of 1.2 to 1.3, resulting in energy addition to the flow from the heat of condensation. Addition of thermal energy to the supersonic flow causes

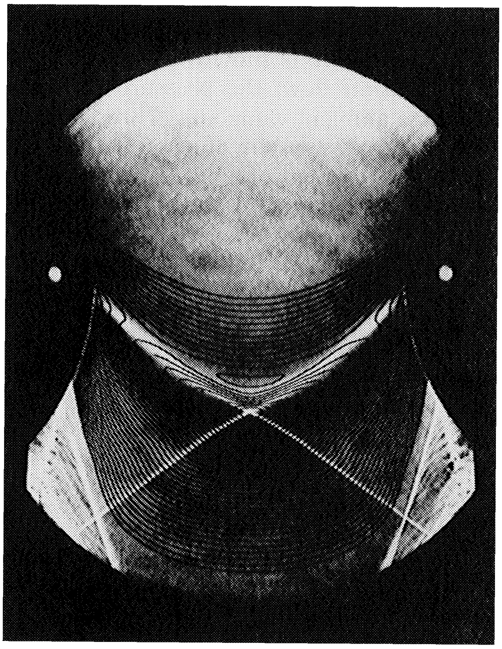

FIG. 2. Experimental visualization of the flow of moist air through a circular arc nozzle with superimposed calculated iso-Mach contours.

the density to increase and oblique shocks to form. These form the bright X-shaped pattern visible in the photograph. Directly downstream of the shocks, a rapid expansion takes place. Unrelated to condensation, but equally important in real nozzles, is the wedge-shaped separated-flow region visible at the downstream edges of the nozzle arcs. Lines of constant Mach number are superimposed on the flow image. These were computed from the numerical solution (Schnerr and Dohrmann, 1990) of the Euler equations supplemented with a condensation model. These contours start with the sonic line, $M=1$, at the left and increase in increments of 0.02 to the right.

The supersonic acceleration process in a nozzle is limited only by the decoupling of translational and internal energy modes that occurs when the density becomes too low for molecular collisions to be effective. When the supersonic expansion occurs in a very low-pressure region (vacuum), the resulting flow is known as an *underexpanded supersonic jet*, illustrated in Fig. 3. This is the multidimensional flow resulting from a converging nozzle with choked flow ($M=1$) at the exit. The sonic exit flow is further accelerated through an expansion fan (discussed subsequently in Sec. 7) after exiting from the nozzle.

The effect of a small but not negligible ambient pressure is shown in Fig. 3. Within the expansion flow, the pressure decreases below the ambient value and is brought back up by a complex system of shock waves. This shock "cell" consists of a barrel-shaped shock surrounding the jet and a nearly planar normal shock, or Mach disk, downstream. The boundary between the jet and ambient fluid is outside of the barrel shock and actually is a region of mixing or a *shear layer*, as indicated by the shaded region. There are large changes of density across this boundary, resulting in the pressure-wave reflections shown in Fig. 3. There are a series of shock cells that can be observed within the jet flow at lower pressure ratios in sonic and supersonic jets, corresponding to cases between (d) and (e) of Fig. 1.

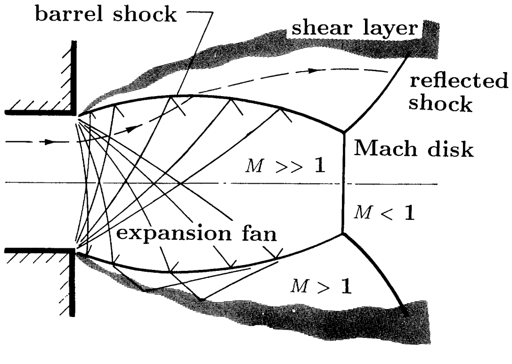

FIG. 3. Features of a free jet expansion from a sonic flow produced by a converging nozzle. The pressure at nozzle exit is much higher than the pressure of the stationary ambient fluid.

Free jet expansions are used to create very low-temperature, supersonic molecular beams essential to modern chemical physics (Levine and Bernstein, 1987). A population inversion can be produced in the molecular vibration–rotation states if the expansion process is sufficiently rapid. This can create the conditions necessary for light amplification, the principle behind the *gasdynamic laser* (Anderson, 1976) (see LASERS, GAS).

4.2 Shock Waves

Steady supersonic flow and transient compressible flows are distinguished by the potential for spontaneous generation of shock waves. Shock waves occur in steady supersonic flows whenever flow deflections are associated with pressure increases. In transient flows, rapid energy addition or boundary motions will produce traveling compressive disturbances that may form shock waves if sufficiently strong. Steady and unsteady shocks are a consequence of the nonlinearity of compressible flow and the underlying *hyperbolic* nature of the Euler equations. In the context of the Euler equations, shock waves appear as jumps or discontinuities in the solutions. Physically, shock waves are found to have a finite thickness, on the order of microns for gases at atmospheric pressure and nanometers for liquids or solids.

All shock waves can be locally analyzed by focusing on a small spatial region (control volume) surrounding the wave and by transforming to a coordinate system moving at the local shock velocity. Conservation of momentum implies that only the component of velocity u normal to the wave experiences change. The tangential component of velocity must be continuous. For simplicity, the tangential component is set equal to zero in this analysis. Including a nonzero tangential velocity leads to the concept of oblique shock waves, discussed in subsequent sections. The analysis carried out here is valid for the normal component of velocity in both cases. Irrespective of the shock orientation or motion, only a single set of equations is required.

Integration of the Euler equations through the thin control volume around the shock yields the *jump conditions*

$$\rho_1 u_1 = \rho_2 u_2, \tag{15}$$

$$P_1 + \rho_1 u_1^2 = P_2 + \rho_2 u_2^2, \tag{16}$$

$$h_1 + \frac{u_1^2}{2} = h_2 + \frac{u_2^2}{2}, \tag{17}$$

in which the subscripts denote states upstream (1) and downstream (2) of the wave and u is the fluid velocity normal to the wave surface in a wave-fixed coordinate system. These equations can be combined into a single expression, the *Rankine–Hugoniot equation*:

$$h_2 - h_1 = (P_2 - P_1)(v_2 + v_1)/2. \tag{18}$$

In the wave-fixed frame, the velocity component normal to the wave is always supersonic, $M_1 = u_1/c_1 > 1$, upstream and subsonic, $M_2 = u_2/c_2 < 1$, downstream. The flow can be supersonic downstream of shock waves oriented obliquely (see Sec. 7.1) to a supersonic flow, since only the normal component of velocity changes across a shock. Flow behind a moving shock wave may also be supersonic relative to a stationary observer. Pressure, density, and temperature always increase across shocks in normal fluids.

Solutions to this equation are known as *shock adiabats* or *Hugoniots*. Shock adiabats can be determined from thermodynamic data $h(P,v)$ by solution of the Rankine–Hugoniot equation. In the case of the perfect-gas model, analytic solutions can be obtained and tabulations are available for many values of the specific-heat ratio γ. The results for $\gamma = \frac{7}{5}$, used for low-temperature air, are shown in Fig. 4. For perfect gases, pressure and temperature increase indefinitely as the shock strength M_1 is increased. However, the density and Mach number reach finite, limiting values ($\rho_2/\rho_1 \rightarrow 6.0$ and $M_2 \rightarrow 0.378$) for large shock strengths. For a general perfect gas,

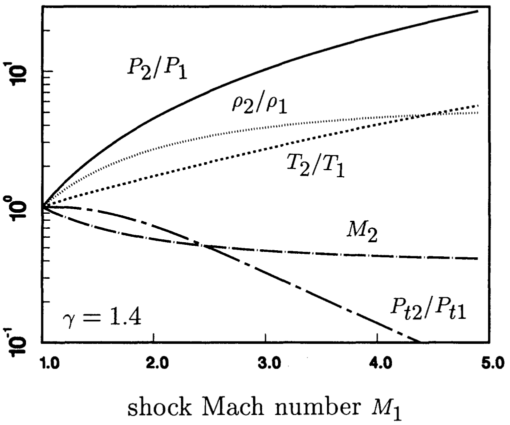

FIG. 4. Solutions to shock jump conditions, perfect-gas model, $\gamma = 1.4$. The Mach numbers M_1 and M_2 are for the velocity component normal to the shock front as measured in a coordinate system attached to the wave.

$$\frac{\rho_2}{\rho_1} \rightarrow \frac{\gamma+1}{\gamma-1} \text{ and } M_2 \rightarrow \sqrt{\frac{\gamma-1}{2\gamma}} \text{ as } M_1 \rightarrow \infty. \tag{19}$$

These limits are consequences of the equipartition of the energy in the incoming flow into internal and kinetic energies in the shocked fluid when the shock strength is large. Stagnation pressure, P_{t2}/P_{t1} in Fig. 4, always decreases across shock waves. This is due to the entropy increase across the shock and represents a source of losses in supersonic flows containing shocks.

For dense fluids and liquids, numerical solutions can be readily obtained using tabulated or empirical equations of state. In the case of solids, the experimental measurements needed for Rankine–Hugoniot computations are often obtained from actual shock-wave propagation measurements. Consider a shock wave propagating with velocity U_s through a material initially at rest. Behind the shock wave, the fluid particles are set in motion with velocity u_p. This moving shock can be considered as equivalent to a stationary wave through a Galilean transformation, yielding the velocities $u_1 = U_s$, $u_2 = U_s - u_p$. Shock data for solids are usually given in form of tabulated (U_s, u_p) pairs. These data (March, 1980) are often found to obey the empirical expression $U_s = c_0 + s u_p$, in which s is an empirical parameter, approximately equal to $\Gamma/2$. Shock data are frequently combined with information about G and K_s to produce an approximate *thermoelastic* or *Mie–Grüneisen* (Zel'dovich and Raizer, 1966) equation of state used for numerical solutions of the Euler equations.

A shock wave is an example of an irreversible natural process and, in addition to the jump conditions, must satisfy the second law of thermodynamics,

$$s_2 > s_1. \tag{20}$$

The amount of entropy generated by the shock depends on the strength of the shock wave. This can be measured by either the shock Mach number U_s/c_1 or any of the nondimensional jumps such as $[P]/\rho_1 c_1^2$ or $[v]/v_1$, where $[P]=P_2-P_1$, $[v]=v_2-v_1$. Shock adiabats are initially close to isentropes, so that weak shock waves can be considered as acoustic disturbances. Shock adiabats progressively deviate from the isentropes as the shock strength is increased. The entropy jump $[s]=s_2-s_1$ is third order in the shock strength,

$$\frac{T_1[s]}{c_1^2}=\frac{\Gamma_1}{6}\left(\frac{[P]}{\rho_1 c_1^2}\right)^3+\cdots, \tag{21}$$

so that the effect of nonlinearity [the second term in Eq. (1)] is more significant than entropy generation in weak shock waves. It is this condition that dictates that shock waves in normal fluids ($\Gamma > 0$) are compressive waves and in unusual fluids ($\Gamma < 0$) are expansive (rarefaction) waves.

A mechanical interpretation of the entropy jump across the shock is possible if we consider the molecular processes involved. Large gradients of temperature and velocity occur within the shock. Molecular transport of energy and momentum across these gradients results in dissipation throughout the shock front region. The dependence of $[s]$ on shock strength given above suggests that the shock layer becomes very thick for weak shocks, $M_1 \rightarrow 1$. Experimental studies of shock structure in gases confirm this, and simple computations demonstrate (Thompson, 1983) that the thickness of strong shocks in gases can even be predicted by continuum estimates of the dissipation rate. The detailed structure of such waves does require the solution of kinetic equations (Bird, 1976) describing the evolution of the distribution function of the molecular velocities. In the case of shocks in complex molecular systems, coupling between vibration–rotational and translation states can result (Vincenti and Kruger, 1986) in unusual wave structures. Low-amplitude waves are *fully dispersed* structures that contain continuous compression waves. Intermediate-amplitude waves are *partially dispersed* structures with both continuous compression and shock jumps. Large-amplitude waves consist of a shock followed by a zone of equilibration ("relaxation") between energy excitation modes.

Compression and entropy generation in strong shock waves will result in a substantial temperature increase across the shock wave. Strong shock waves ($M > 5$) can be produced in gases by use of laboratory shock tubes. The temperature jump across such waves is sufficient (> 1200 K) to initiate molecular dissociation and chemical reactions rapidly (Zel'dovich and Raizer, 1966). Explosion (see EXPLOSIVES) or detonation can occur when strong shock waves are created in combustible mixtures. Ionization and radiative transport of energy are important features of very strong shocks (Zel'dovich and Raizer, 1966), particularly in determining the structure of the shock front.

High explosives or high-velocity impact are used in solids to generate strong shock waves. A variety (Davison and Graham, 1979) of unique electrical, mechanical, and chemical effects can be produced in this fashion. It is possible to simulate conditions (pressures of up to 3.5 Mbar) encountered in geological materials (Jeanloz, 1990) deep within planetary cores. Unique phenomena (Liepmann and Laguna, 1984) occur when superfluid liquid helium II is shocked. The two-fluid nature of helium II gives rise to two shock waves that travel at distinct velocities. One shock wave is a pressure wave with very little temperature rise and the other is a temperature wave at nearly constant pressure.

5. DETONATION WAVES

Detonation waves can be envisioned as shock waves induced and sustained by exothermic chemical reaction, i.e., combustion. The high temperature behind the shock wave initiates the combustion reactions, and the volume expansion resulting from the reaction acts as a piston to drive ahead the shock wave. Gas, liquid, and solid explosives are all capable of detonation and have been extensively studied (Fickett and Davis, 1979; Gibbs and Popalato, 1980). Detonation waves are observed under many conditions to travel with a constant velocity characteristic of the material and the initial conditions. Detonation velocities are 2–3 km/s for gases and up to 8 km/s in solids or liquids. Pressures behind gaseous detonations are 15–30 times the initial pressure. Pressures behind solid or liquid explosives can be as large as 400 kbar.

Detonation velocities can be predicted by supposing that the fluid changes composition within the shock layer and is in chemical equilibrium downstream. Detonation adiabats can be obtained by combining the shock jump conditions with an appropriate multicomponent equation of state and chemical equilibrium relations for the downstream state. The solution for shock velocity is nonunique with the exception of a single distinguished case, the minimum possible wave speed, known as the *Chapman–Jouguet velocity.* The Chapman–Jouguet solution has the special feature that fluid velocity downstream is sonic with respect to the wave and the entropy jump is an extremum. Physically, this can be interpreted as providing a sonic barrier to prevent acoustic disturbances from disrupting the wave from the rear.

Computations of the Chapman–Jouguet (CJ) velocity are readily carried out for gases by numerical methods. Experimental velocities are found to be close (0–5 % below) to the theoretical values computed in this fashion. Detonation products for solid and liquid explosives are in a highly compressed dense-gas state and the thermodynamic computations are less reliable than in gases. Modern statistical mechanical methods based on thermodynamic perturbation theory (Ree, 1984) are moderately successful for detonation velocity prediction in these cases. Of great importance to high explosives is the yielding of the confining container, which can produce a significant influence on the propagation velocity and even result in detonation failure. As the diameter of a cylindrical charge of high explosive is decreased, the detonation velocity decreases until a *critical* or *failure diameter* is reached. Steady detonation is found to be impossible for charges smaller than the failure diameter (Gibbs and Popalato, 1980).

Zel'dovich, von Neumann, and Döring (ZND) independently formulated the theory (Fickett and Davis, 1979) of steady, laminar detonation waves. In this ZND model, the detonation consists of a nonreactive shock wave traveling at the CJ velocity, followed by a reactive boundary layer or reaction zone in which reactants are converted to products. However, both the CJ and ZND models conceal the true unsteady character of detonations. It is observed experimentally and predicted from stability analyses that transverse shock-wave disturbances spontaneously appear on a planar detonation front and that propagating gaseous detonations almost invariably display this instability. The quasiperiodic system of transverse waves forms a cellular pattern with a characteristic wavelength that is indicative of the chemical sensitivity of the mixture. Computations using detailed chemical kinetic models of the combustion process demonstrate (Westbrook and Urtiew, 1982) that the instability wavelength is proportional to the length of the chemical reaction zone computed on the basis of the ZND model. Other types of transient behavior such as initiation and failure are intimately linked (Lee, 1984) to the length scale and dynamics of the reaction zone. The simplest notion is that explosives with larger reaction zones are the least sensitive, have the greatest instability wavelength, and have the largest failure diameters. These ideas are relevant to both gaseous and condensed explosives.

6. ONE-DIMENSIONAL UNSTEADY FLOWS

Analytic solutions to the unsteady Euler equations can be obtained for flows with spatial variation in only one direction. This is particularly true for planar flow since the equations can be written in *characteristic form* and solved exactly for several cases of technical importance. The characteristic form of the Euler equations can be compactly written in the case of nonreactive flow as

$$\frac{du}{dt} \pm \frac{1}{\rho c}\frac{dP}{dt} = \mp \frac{n}{x}\, cu \quad \text{on} \quad \frac{dx}{dt} = u \pm c, \tag{22}$$

$$\frac{ds}{dt} = 0 \quad \text{on} \quad \frac{dx}{dt} = u. \tag{23}$$

The dimension index n takes on a value of 0 for planar flow, 1 for cylindrical flow, and 2 for spherical flows. The time derivatives in Eqs. (22) and (23) are to be interpreted as derivatives obtained by an observer traveling on the lines in space-time defined by the velocities $u \pm c$ and u, known as the *characteristics* $C^{\pm}$ and C^0. Physically, the characteristics associated with velocities $u \pm c$ correspond to the speed of adiabatic disturbances in pressure and velocity *relative to the flow*. Entropy disturbances are associated with fluid motion itself and travel with the particle velocity u. In the present case of adiabatic flow, the entropy of each element remains unchanged with the exception of passage through shock waves. Equation (23) does not apply at the location of the shock, and the jump conditions, Eqs. (15)–(17), must be applied to determine the changes across the shock.

A set of characteristics passes through each point in the flow. The wedge-shaped region determined by characteristics C^+ and C^- coming from the past defines the region of fluid that can influence motion at that point. The projection of the characteristics into the future determines the region that will be influenced by disturbances at that point. For adiabatic, nonreactive flows it is possible to define a quantity F

$$F(P,s_0) = \int_{P_0}^{P} \frac{dP'}{\rho c}, \tag{24}$$

and to simplify further the equations for pressure and velocity to read

$$\frac{d}{dt}(u \pm F) = -\frac{n}{x}cu \quad \text{on} \quad \frac{dx}{dt} = u \pm c. \tag{25}$$

The right-hand side vanishes in planar flows, $n=0$, and the quantities $u \pm F$ are known as the *Riemann invariants*. The Riemann invariants are constant on the corresponding characteristics, except when the characteristics cross shock waves. The value of the invariant must change across the shock in order to be consistent with Eqs. (15)–(17). For the perfect-gas model, the quantity F can be computed in closed form and is equal to $2c/(\gamma-1)$.

As an application of the theory, consider the initial-value problem associated with a discontinuity in pressure separating uniform regions of gas, the so-called *Riemann problem* of compressible flow. This situation occurs in *shock tubes* (Oertel, 1966), used in the laboratory study of shock waves. A closed, gas-filled tube is divided into two sections by a thin diaphragm of metal or plastic. The *driver* section is filled with high-pressure gas. On the other side of the diaphragm is the low-pressure *driven* section. A space-time diagram and the characteristic network associated with this process are shown in Fig. 5.

The diaphragm is ruptured by either overstress or mechanical puncturing. Referring to Fig. 5, a compression wave (shock) propagates into the low-pressure region (1) and an expansion wave, denoted by the "fan" of characteristics C^-, propagates into the high-pressure region (4). A contact surface (dashed line) separates shocked gas (2) from the accelerated driver gas (3). The shock reflects from the end wall to produce a stagnant region (5) in which testing is usually carried out. The reflected-wave interaction (a) with the contact surface produces a secondary shock between regions (5) and (6) that limits the test time to a value τ as shown. The actual test time is significantly influenced by real fluid effects such as the boundary layer behind the shock wave. By varying the pressure and gas composition in driver and driven sections, a wide range of shock strengths can be produced.

For an ideal shock tube, a shock wave is formed immediately on the low-pressure side of the diaphragm. However, if the diaphragm in our example shock tube were to rupture slowly, a shock-free compressive wave could be produced that ultimately would steepen and form a shock wave at some distance from the diaphragm. This process is illustrated in Fig. 6 for a piston (P), analogous to the contact surface in the shock tube, being accelerated into an initially undisturbed region. The particles are accelerated when the first signal arrives along the C^+ characteristic as shown by the trajectory (dashed line) or particle path PP. The slope of the C^+ characteristics decreases as time increases and the piston accelerates. Adjacent characteristics first cross at point (a), producing a shock wave. The point of shock formation can be computed from the piston path and the Riemann invariant on both C^+ and C^-.

The nonlinearity of convection and the thermodynamic dependence of sound speed [Eq. (5)] are both significant to shock formation. Solution of the initial-value problem for

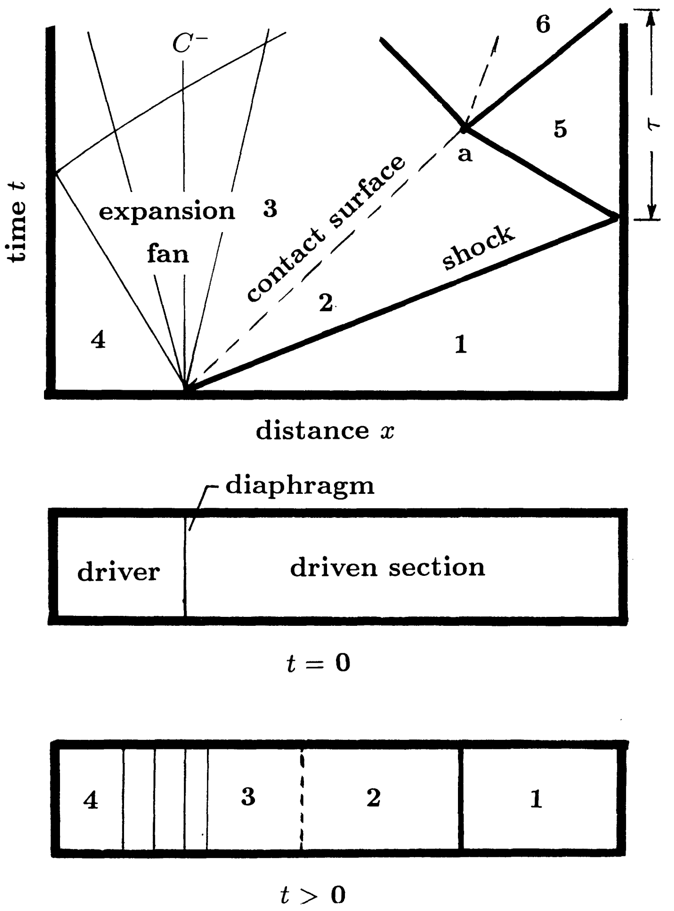

FIG. 5. Space-time (*x-t*) diagram for shock-tube operation.

a simple compressive wave, as shown in Fig. 6, yields the result that the characteristic velocity changes with pressure,

$$\frac{d}{dP}(u+c)=\frac{\Gamma}{\rho c}\,. \tag{26}$$

This leads to the following conclusions about the evolution of pressure disturbances. Compression shocks form when $\Gamma > 0$, shocks never form in the exceptional case $\Gamma = 0$, and expansion shocks form if $\Gamma < 0$.

Another feature of the Riemann problem is the spreading wave or *expansion fan* that propagates into the high-pressure region. This flow is characterized by a self-similar motion dependent only on the coordinate x/c_0t, which results in acceleration of fluid towards the shock wave. The fluid isentropically expands as it accelerates. This unsteady expansion process will result in a maximum particle velocity or *escape speed* of $u_e = 2c_0/(\gamma-1)$ for perfect gases. This is achieved when the low-pressure region is a vacuum. An interface or *contact surface* is created between the fluid originally in the high-pressure region and the shocked fluid. Pressure and velocity are continuous across this interface, but the entropy and composition may change arbitrarily.

In the Riemann (shock-tube) problem, the key elements of many compressible flow problems appear: spontaneous formation of contact surfaces, expansion waves, and shock waves. These features are universal and appear in both one- and higher-dimensional flows. The shock-tube flow is the prototype for many similar technical problems such as *water hammer*, which is simply wave motion in fluid-filled pipes induced by sudden valve operation or other transients. These problems can be analyzed (Moody, 1990) by characteristic methods or other numerical techniques. For small-amplitude waves, a linear analysis suffices and the characteristic relations reduce to $dP = \pm\rho_0c_0du$ for waves moving to the right

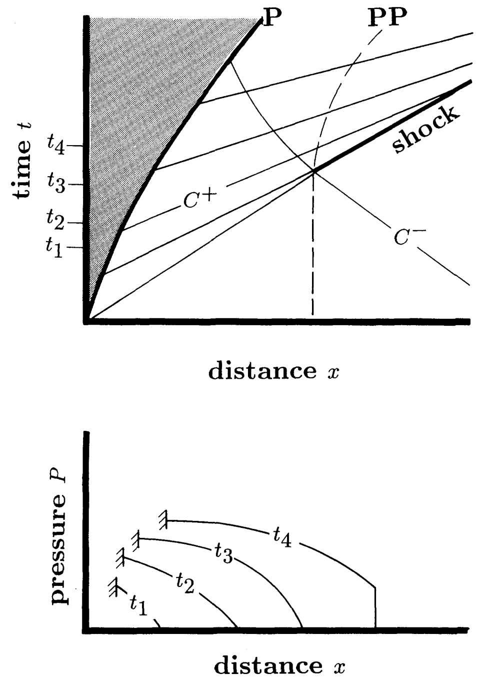

FIG. 6. Compression wave steepening to form a shock, illustrating crossing of characteristics.

$(dx/dt = +c_0)$ and the left $(dx/dt = -c_0)$, respectively. The quantity ρc is referred to as the *acoustic impedance* of the fluid. The ratio of the fluid and solid acoustic impedances determines the pressure produced when a wave interacts with a fluid–solid boundary. At hard boundaries, a large increase in impedance occurs and total reflection results in doubling the pressure. At soft boundaries, a large decrease in impedance occurs and the pressure changes sign. The reflected wave has equal magnitude to the original, i.e., a compressive wave reflects as an expansion and vice versa.

Similarity solutions have played an important role in the development of compressible-flow theory. Perhaps the best-known example is the solution (Taylor, 1950) for the propagation of a decaying spherical shock wave produced by a rapid release of energy within a uniform atmosphere. This solution utilizes the strong shock approximation to the jump conditions, in which the initial pressure in the atmosphere is neglected. If an amount of energy E is suddenly released into the atmosphere of density ρ_0, the radius R_s of the resulting shock wave is proportional to $(E/\rho_0)^{1/5}t^{2/5}$. The pressure P_s immediately behind the shock can be shown to decay inversely with the cube of the distance, $P_s/P_0 \sim EP_0^{-1}R_s^{-3}$. Many variations on this problem can be solved analytically through similarity transformations, including the inverse problem of collapsing or imploding shock waves (Whitham, 1974).

The Taylor solution is an example of the decay of a transient shock or *blast wave* created by an explosion. Blasts from accidental and deliberate explosions have been extensively studied (Kinney and Graham, 1985). Shock pressures from intense explosions follow scaling suggested by the Taylor solution $P_s/P_0 \sim (R_e/R_s)^n$ in which the scaling distance $R_e = (E/P_0)^{1/3}$. In regions close to the energy source, the exponent $n \sim 3$ as given by the Taylor solution. Far from the source, the exponent $n \sim 1$ as given by the acoustic solution. Solutions uniformly valid in the near and far fields can be constructed by the technique of *nonlinearization* (Whitham, 1974). Linear (acoustic) solutions are used for amplitudes but are evaluated on the nonlinear characteristics described by Eq. (25). Shock waves are inserted at the points of characteristic crossing. The shock amplitude is chosen so that the conservation laws, Eqs. (15)–(17), are satisfied.

The dependence of the scaling distance on energy released leads to the concept of *cube-root* scaling for blasts produced by high explosives. Blast pressures from two different charges (mass W) will be equal if the scaled distance $R_sW^{-1/3}$ are the same. Such scaling relations are valuable engineering tools (Kinney and Graham, 1985) for estimating blast waves in air and water. In addition to similarity solution methods, the very useful approximate technique of *shock dynamics* (Whitham, 1974) can be used to solve for shock-wave motion in complex geometries (Schwendeman, 1988).

Because of the importance of one-dimensional compressible flow in technical problems as diverse as plumbing systems and nuclear weapons, numerous methods have been developed for numerical solutions of these flows. A reliable, but cumbersome, method is based directly on the method of characteristics (Ritchmeyer and Morton, 1967) with insertion of shock waves when dictated by characteristic crossing. More flexible but potentially less accurate methods are based on finite-difference approximations to the Euler equations. The accuracy of the technique is determined by the ability to resolve shock waves and contact surfaces. A crude but useful version is to employ *artificial viscosity* to smooth out shock waves. Many more sophisticated techniques such as the methods of random choice (Sod, 1985) and of flux-corrected transport (Oran and Boris, 1987) and the piecewise parabolic method (Collela and Woodward, 1984) have been developed in recent years. Numerical techniques developed for one-dimensional nonreactive flows can be extended to solve reactive, multidimensional flows by the techniques of operator splitting. A solution is built up through a sequence of one-dimensional solutions for each physical process and dimension in space. Very complex problems such as transient supersonic jets, oblique shock reflection, and detonation instability can be treated in this fashion.

7. MULTIDIMENSIONAL FLOWS

Compressible flow in two and three dimensions is of great significance in designing aircraft, space vehicles, propulsion systems, and experimental facilities such as wind tunnels. Realistic design requires including transients, real gas effects, and complex geometrical configurations. Solution of such problems requires a concerted effort with both experimental investigation using scale models and numerical solutions to some approximation such as the Euler equations. However, it is possible to indicate the features of such flows by examining the analytic solutions possible for steady flows of a perfect gas.

7.1 Steady Supersonic Flows

An essential distinction for steady multidimensional flows is the presence or absence of *vorticity*, $\mathbf{\Omega}=\text{curl}\,\mathbf{u}$, in the flow. As in low-speed, incompressible flow, vorticity is a measure of rotational relative motion (rate of strain) within the fluid. Rotational motion can only be created in an initially irrotational fluid by the action of viscous forces at boundaries or by the existence of entropy gradients within the flow. The Euler equations can be used to deduce a transport equation for vorticity, the *Crocco–Vazsonyi equation*:

$$\frac{\partial\mathbf{\Omega}}{\partial t}+\mathbf{\Omega}\times\mathbf{u}=T\,\text{grad}\,s-\text{grad}\left(h+\frac{u^2}{2}\right). \qquad (27)$$

For steady flow, this implies that vorticity exists solely due to gradients in total enthalpy or entropy in the direction transverse to the local flow direction $\mathbf{\Omega}\times\mathbf{u}=T\,\text{grad}\,s-\text{grad}(h+u^2/2)$. Total enthalpy is conserved in steady adiabatic flows (with or without shocks) since the Euler equations directly yield $\text{div}(h+u^2/2)=0$. Therefore any variation in h_t must originate upstream and be a consequence of nonuniform boundary conditions. Transverse entropy variations can spontaneously arise from the presence of shock waves of varying strength. A single curved shock wave or a system of transversely nonuniform waves are the most common origins of such entropy variation. We conclude that general multidimensional flows containing curved shocks must also be rotational flows and cannot be isentropic even if the upstream flow is uniform.

We conclude that steady, adiabatic, supersonic flow can be treated as isentropic in the absence of curved shock waves or viscous effects. Therefore the Euler equations can be written in characteristic form. For simplicity, only two-dimensional flows will be considered here. This is most readily done in the *natural coordinate system* (s,n) in which s is distance measured along the flow direction or *streamline* and n is the distance measured normal to the streamlines; see Fig. 7. Characteristic directions are oriented at angles $\pm\mu$ to the main flow direction (Fig. 7), where μ is the angle that a weak disturbance or *Mach line* will make with a uniform flow,

$$\mu=\sin^{-1}(1/M). \qquad (28)$$

These characteristic directions in space are analogous to the characteristic directions in space-time introduced in the previous discussion on unsteady one-dimensional flow. The similarity of the governing equations results in a very close analogy between one-dimensional unsteady flow and two-dimensional steady flow. Primitive variables for the characteristic equations in natural coordinates are the magnitude of the flow velocity u and its orientation θ with respect to a fixed axis. The equations can be compactly written as

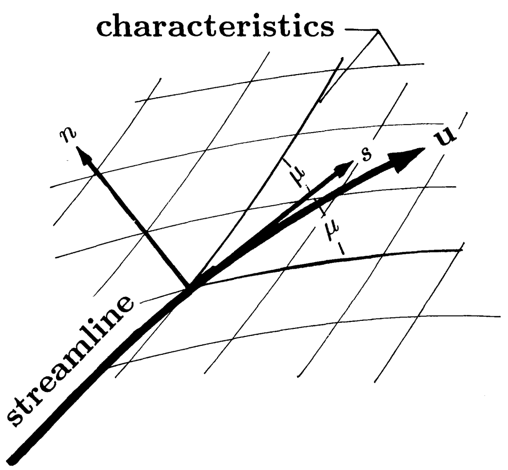

FIG. 7. Natural coordinate system (*s*,*n*) for two-dimensional flow showing Mach lines for supersonic flow.

$$\frac{\partial}{\partial s}(\omega \pm \theta) \mp \tan\mu \frac{\partial}{\partial n}(\omega \pm \theta) = 0, \qquad (29)$$

using the *Prandtl–Meyer function* ω defined by

$$d\omega = \frac{dM}{M}\frac{\sqrt{M^2-1}}{1+(\Gamma-1)M^2}. \qquad (30)$$

The quantities $\omega \pm \theta$ are the Riemann invariants for this theory. The results of quasi one-dimensional flow theory find direct application in steady multidimensional problems. The differential relationships between thermodynamic and flow variables defined in Sec. 4.1 are valid along the *stream tubes* defined by surfaces of constant n. The energy equation (12) can be used to relate the Mach number M to the thermodynamic state in order to evaluate Γ and complete the integration for the Prandtl-Meyer function.

The Mach number appears as a parameter just as in one-dimensional flow. The distinction between subsonic and supersonic flows is of great importance. Characteristic directions and shock waves can exist only when the flow is locally supersonic. Mathematically, this is a result of the *hyperbolic* character of equations in which all characteristics are real. For steady subsonic flows, the equations are *elliptic* and no real characteristics exist.

The characteristic directions, $dn/ds = \pm\tan\mu$, define the cone of influence for a disturbance generated at a point. Only locations inside of this *Mach cone* can be influenced by events at the apex of the cone. These directions also define the characteristics along which the Riemann invariants $\omega \pm \theta$ are constant. The shock jump conditions discussed in Sec. 4.2 imply that the Riemann invariants discontinuously change when the characteristics cross shock waves.

Solutions for simple changes in flow direction can be constructed for initially uniform flows by use of the Riemann invariants originating in the undisturbed flow. Consider a flow moving from left to right in the x direction. Flow deflections $d\theta$ are related to changes in the Prandtl–Meyer function and velocity by

$$d\omega = \frac{du}{u}\sqrt{M^2-1} = \pm d\theta \qquad (31)$$

along the characteristic directions $dy/dx = \pm\tan\mu$. Compressive turns $du<0$ result in velocity decreases associated with stream-tube contraction in supersonic flow. Expansive turns $du>0$ result in velocity increases associated with stream-tube expansion in supersonic flow. For the perfect-gas model, $\omega(M)$ can be computed in closed form. Tabulations are available for many values of γ. A maximum change in ω is associated with the maximum velocity that can be obtained in quasi one-dimensional flow expansion. For a value of $\gamma = 1.4$, $\omega_{\text{max}} = 130.45°$ for acceleration from an initially sonic flow.

A strong compressive turn will result in the crossing of adjacent characteristics of the same family, generating a shock wave just as in the one-dimensional unsteady case. This wave will, in general, be an ***oblique shock***. That is, the wave is not normal to the flow direction. As discussed in Sec. 4.2, only the component of the flow velocity in the direction normal to the shock is changed. An oblique shock at an angle β (Fig. 8) with respect to the incident flow (velocity U_1) is therefore equivalent to a shock at normal incidence to a flow with velocity $u_1 = U_1 \sin\beta$. The flow is deflected through an angle θ which depends on β and u_1.

With this simple geometric transformation, all oblique shocks can be analyzed as equivalent normal waves using the methods described previously. A consequence of the transformation is that the flow deflection is a multivalued function of wave angle and a maximum flow deflection exists at a critical

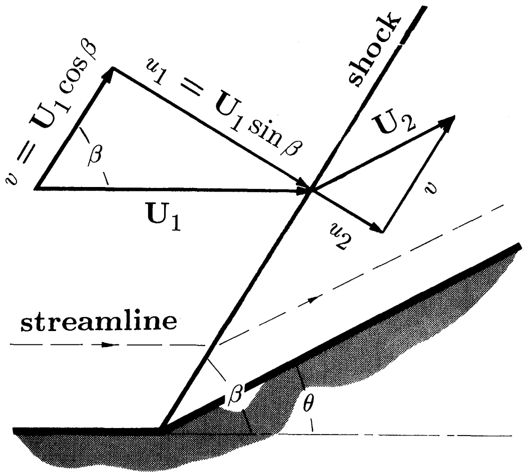

FIG. 8. Oblique-shock velocity diagram, showing wave angle β and resolution into normal and tangential components.

value of the wave angle, which is dependent on the shock strength. For strong oblique shocks in a perfect gas, $\gamma = 1.4$, the maximum flow deflection has the largest value of 45.5° and occurs at $\beta = 68°$. The transition between downstream subsonic and supersonic flow occurs at a critical wave angle β^* that is close to occurrence of maximum deflection. Oblique shock waves with $\pi/2 > \beta > \beta^*$ result in locally subsonic flow downstream of the wave and are known as *strong* waves. Oblique shocks with $\beta^* > \beta > 0$ are locally supersonic downstream and are known as *weak* waves. These properties of oblique shocks play an important role in determining the flow over supersonic projectiles.

7.2 Aerodynamics

Aerodynamics (*q.v.*) is the study of fluid motion over bodies such as wings, fuselages, missiles, and entire airplanes. Flow over streamlined surfaces is characterized by the absence of flow *separation* from the body, and the effects of viscosity are confined to thin *boundary-layer* and wake regions. The flow is usually assumed to consist of two regions. Far from the surfaces and the wake is the *outer* region which is usually treated as inviscid and adiabatic, approximately governed by Euler's equations. Within the wake and near the surfaces is an *inner* region in which the effects of viscosity and heat conduction dominate. Some form of the Navier–Stokes equations must be applied within these regions, and the problem of turbulent flow must usually be addressed.

The outer region is initially computed by supposing that the viscous layer is infinitely thin and that the flow next to the surface must follow the surface contour but *slips* on the surface, i.e., has a nonzero velocity parallel to the surface. The inviscid flow is then used to compute the viscous boundary layer. The displacing effect of the inner boundary layer can then be used to correct the outer flow for viscous effects. In supersonic flow, this procedure is complicated by the presence of shock waves in the outer flow and the interaction of shocks with the boundary layers, which in some cases, can lead to flow separation.

7.2.1 Linearized Flow Theory. Aerodynamic design is a mature subject that uses sophisticated numerical simulations and wind-tunnel testing to develop optimal shapes for lifting surfaces (wings) and entire vehicles. There is also a substantial body of theory on approximate analytical solutions for *thin* or *slender* shapes such as wings and fuselages. One class of theories involves the actual mechanism of lift in subsonic flight, intimately related to the production and maintenance of vorticity in the fluid. Another class of theories attempts to describe the influence of compressibility on the flow, without explicitly considering vorticity.

We are concerned with the second category, which analyzes *irrotational* and isentropic motion. Shock waves can be accommodated by this theory as long as they are weak. Solutions based on potential flow notions are very useful in aeronautics. For wing sections, these theories give very useful estimates of lift, and the drag induced by lift. They also provide the outer boundary conditions necessary for the viscous boundary-layer computations. Linearized analyses usually come to the happy conclusion of an analytical solution that is invaluable in correlating and understanding the experimental data. The irrotational and compressible analyses have particular relevance to near-sonic and supersonic flight. For supersonic and hypersonic flight, the actual mechanism of lift (and drag) is almost exclusively determined by compressibility effects rather than the vorticity mechanism of subsonic flight.

Consider a streamlined body at rest being approached by a flow that is uniform with velocity U_∞ at large distances upstream from the body. If the flow is irrotational, curl$\mathbf{u}=\mathbf{0}$, then we can use a velocity potential Φ to define $\mathbf{u}=\text{grad}\ \Phi$. Linearized flow is the case in which the body has a small aspect ratio (transverse thickness divided by length) and therefore produces only a small perturbation to the incoming flow. Using a velocity potential $\Phi=U_\infty x+\phi$ and linearizing the momentum equation for isentropic flow in a perfect gas, we find that in Cartesian coordinates (x,y,z) the approximate equation for the perturbation potential ϕ can be written

$$(1-M_\infty^2)\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}+\frac{\partial^2\phi}{\partial z^2}=(\gamma+1)M_\infty^2\frac{1}{U_\infty}\frac{\partial\phi}{\partial x}\frac{\partial^2\phi}{\partial x^2} \qquad (32)$$

in which $M_\infty=U_\infty/c_\infty$ is the freestream Mach number. In the case of two-dimensional flows, used in idealized wing theory, the z derivative can be omitted or else the z and y terms can be combined to produce a radial derivative used in the axially symmetric theory for fuselages and missiles. The term on the right-hand side is nonlinear and required only in the *transonic flow* regime, $M_\infty\sim 1$. Solutions for subsonic and supersonic flow are greatly simplified by omitting this term. The main results of the theory, based on solutions to the linearized potential equation, are outlined in the subsequent sections.

7.2.2 Subsonic Flow. Subsonic, compressible flow, $M<1$, is of great technical significance in the design of the modern passenger aircraft, in which $M_\infty\sim 0.78$–0.82 during high-altitude cruise. Acceleration of the flow over the lifting surfaces of the aircraft results in local regions of sonic and supersonic flow, which must be treated as a transonic flow problem, discussed in Sec. 7.2.4. A critical flight Mach number is reached when sonic flow first occurs on the lifting surface. Compressibility effects are manifested before the critical Mach number as an increase or apparent *divergence* in the drag coefficient. This important effect can be understood by simple dimensional analysis of the subsonic potential equation.

The linearized potential equation for subsonic flow can be written as a *Laplace equation*

$$\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y'^2}+\frac{\partial^2\phi}{\partial z'^2}=0, \qquad (33)$$

in which the scaled coordinates are $y'=y\sqrt{1-M_\infty^2}$ and $z'=z\sqrt{1-M_\infty^2}$. The pressure P is conventionally presented in aerodynamic analyses as a nondimensional *pressure coefficient*

$$C_P=\frac{P-P_\infty}{\frac{1}{2}\rho_\infty U_\infty^2}\approx-\frac{2}{U_\infty}\frac{\partial\phi}{\partial x}. \qquad (34)$$

Consider a low-Mach-number ($M_\infty\to 0$) subsonic flow which results in a measured pressure coefficient $C_{P,0}$. If this flow is governed by the subsonic potential equation, the scaling implicit in the spatial transformation used to obtain the Laplace equation implies that for any finite Mach number the pressure coefficient will be given by

$$C_P=C_{P,0}/\sqrt{1-M_\infty^2}. \qquad (35)$$

This is the *Prandtl–Glauert rule* of subsonic flow, clearly indicating the divergence effect as $M_\infty\to 1$. Since lift and drag are simply the net forces, pressure and viscous shear, integrated over the body surface, the drag divergence phenomenon follows. The viscous contribution will also change with Mach number but not directly in a divergent fashion; rather, indirectly through the phenomenon of boundary layer separation. The drag in question is induced drag due to lift since the form or shape drag is known to be zero (d'Alembert's paradox) for potential flows. More sophisticated drag correction rules can be obtained by integrating the correction factor over the surface or using other approximations to the linearized potential equation.

The drag divergence effect described by the linearized potential equation arises purely because of the rise in surface pressures as the local Mach number approaches unity. This is a reliable guide as long as the flow everywhere remains subsonic. For supercritical flows, realistic computations of the compressibility effect must incorporate other significant effects. There is a loss in total pressure if shock waves are formed. The pressure rise on the surface will result in thickening or even separation of the boundary layer due to the adverse pressure gradient. Separation of the boundary layer will result in a large *form* drag associated with the change in the pressure distribution due to the presence of reverse flow region downstream of the flow separation point. It is this effect which is primarily responsible for the severe degradation of performance when airfoils designed for subsonic flight are used near $M=1$.

7.2.3 Supersonic Flow. Supersonic flow, $M>1$, results in a wave equation for the potential function

$$\frac{\partial^2\phi}{\partial y'^2}+\frac{\partial^2\phi}{\partial z'^2}-\frac{\partial^2\phi}{\partial x^2}=0 \tag{36}$$

in which $y'=y\sqrt{M_\infty^2-1}$ and $z'=z\sqrt{M_\infty^2-1}$ are now the scaled coordinates. Solutions to the wave equation are fundamentally different from those of the Laplace equation. However, it is clear from the coordinate transformations in the supersonic case that a divergence in pressure coefficients will also occur as $M_\infty \rightarrow 1$. Consideration of the transonic version of the potential equation is required to resolve this singularity.

Thin wings in supersonic flight can be analyzed via the wave equation, and the results are equivalent to a linearized solution using characteristics. The pressure coefficient of a wing element at a small angle θ to the flow can be computed from Eq. (31),

$$C_P=2\theta/\sqrt{M_\infty^2-1}\,. \tag{37}$$

Airfoils designed for supersonic fight have sharp leading and trailing edges in contrast to the blunt leading edge of subsonic airfoils. A blunt leading edge in supersonic flight is undesirable since it will be proceeded by a detached shock wave with a substantial loss in total pressure. Shock waves emanate from the leading and trailing edge of a thin, sharp-edged airfoil in a supersonic flow. Expansion waves exist between the two shocks, resulting in the *shock-expansion* configuration characteristic of flow field around supersonic bodies. Far from the wing or aircraft, a pressure wave is created that starts and ends with shock waves. The pressure decreases between the shocks, leading to the characteristic *N-wave* pressure profile of a *sonic boom* produced by a supersonic aircraft. The dissipative nature of the shock waves results in an inviscid contribution to the drag.

Flow near the front of a supersonic wedge or cone is of great interest since this is a common configuration, shown in Fig. 9, in vehicles and projectiles. Deflection of the flow by the body results in a shock wave ahead of the body surface. Depending on the angle subtended by the wedge or cone, this shock wave may either be *attached* to the tip of body or *stand off* from it. This behavior is a simple consequence of the maximum turning angle that is possible through an oblique shock, mentioned in the previous discussion. It is possible to obtain similarity solutions for flows over simple wedges and cones when the shock is attached.

The supersonic wedge flow consists of an oblique shock, at a constant angle to the incoming flow, of the appropriate strength to turn the flow parallel to the wedge, and a uniform flow between the shock and the wedge. Supersonic cone flow is similar in that an oblique shock at a constant angle to the incoming flow emanates from the cone tip. However, the flow between the shock and the cone surface is not uniform. The flow does have a similarity character, and the flow field can be obtained from a single differential equation with the similarity variable r/x. This solution reveals that a smooth transition between subsonic and supersonic flow can exist in these conical flows. Such transitions and the associated sonic lines play an important role in the case of a wedge or cone that is blunted or has an included angle that exceeds the maximum turning angle for an oblique shock. In these situations, a subsonic region exists between the shock and body near the tip of the body since the flow behind a normal shock wave is subsonic. Acceleration of the flow over the body can result in a transition to supersonic flow, as shown in Fig. 9. Analysis of such flows is complicated by both the transonic character and the nonlinearity originating in the substantial magnitude of the flow deflections.

7.2.4 Transonic Flow. Transition between subsonic and supersonic flow, the *transonic* flow regime, is of particular significance to modern aerofoil technology. Transonic flow problems are also very challenging to analyze (Cole and Cook, 1986). They are intrinsically nonlinear, i.e., the right-hand side of the po-

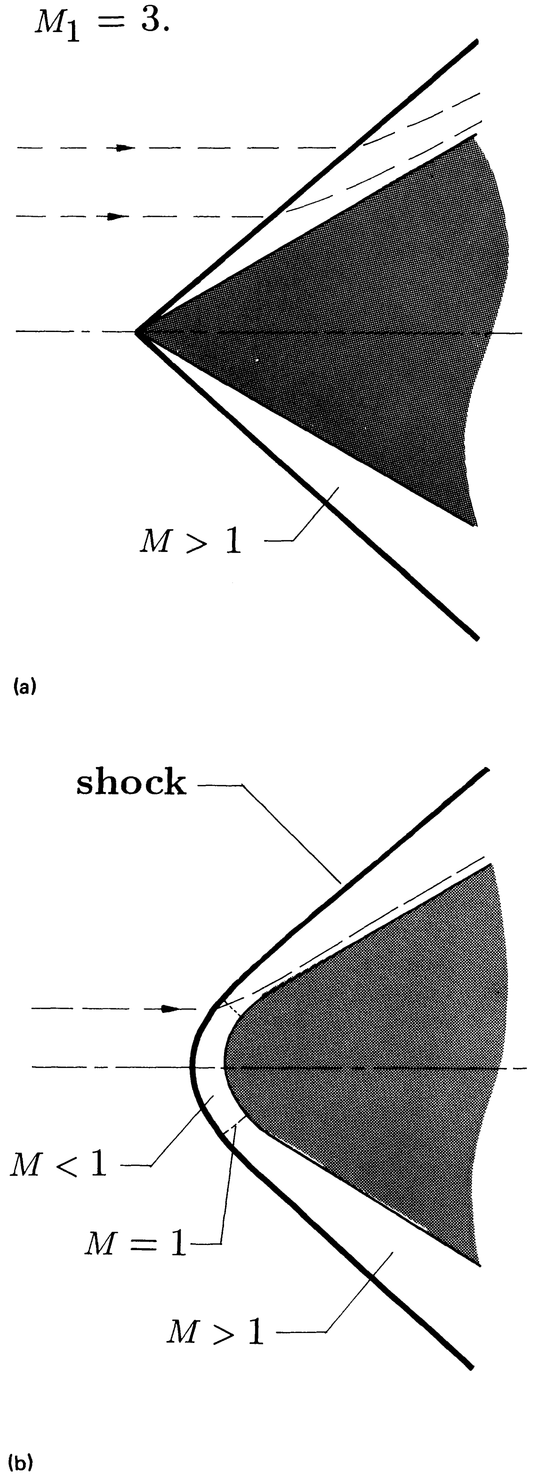

FIG. 9. Flow near the tip of (a) slender and (b) blunt supersonic bodies, illustrating the transition between subsonic and supersonic flow, the distinction between attached and detached shocks, and the streamlines in self-similar flows.

tential equation, Eq. (32), cannot be neglected. The character of the flow and solution methodology changes type, elliptic to hyperbolic, when the sonic line is crossed. Experiments on transonic flows require special care since the cone of influence is quite broad ($\mu \sim 90°$) for near-sonic flow. As a consequence, the configuration of the wind tunnel or testing range is quite significant and substantial corrections for *tunnel interference* are often required.

Supersonic flow will occur over portions of the wings on modern subsonic passenger aircraft. This can result in a shock wave associated with the ultimate deceleration of the supersonic flow. A bubble-shaped region of supersonic flow occurs between the upper surface of the wing, the sonic line, and the shock wave as shown in Fig. 10. By careful choice of the airfoil shape, the critical freestream Mach number at which the shock wave occurs can be increased substantially over conventional designs. With highly optimized surfaces, smooth deceleration from supersonic to subsonic flow, *without a shock wave*, can be obtained. These airfoils, known as *supercritical* designs, can result in substantial drag reduction over more conventional designs and are extensively used on modern aircraft. Design procedures for supercritical airfoils have been developed in some detail (Sobieczky and Seebass, 1984). The design process requires determining an inviscid flow through a solution of the Euler equations, then computing an actual wing profile by correcting for the computed viscous boundary-layer thickness.

7.3 Hypersonic and Hypervelocity Flows

When the Mach number of a vehicle or projectile exceeds a value of $M \sim 5$, the flow is considered to be *hypersonic* (Anderson, 1989), a flow regime encountered in spacecraft launch and reentry. In such flows, the characteristic features are very strong shock waves that dominate the flow field. Lift and drag in hypersonic flows are almost exclusively produced by the high-pressure region generated by the shock on the lower surface of a lifting body. The upper surface is at a very low pressure due to the strong Prandtl–Meyer expansion flow created at the leading edge. Hypersonic flows are relatively simple for vehicles with a sharp nose or leading edge and

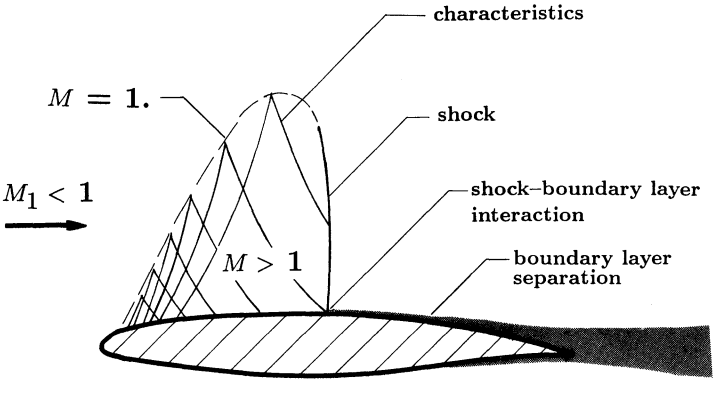

FIG. 10. Principal features of transonic flow over an airfoil.

a small inclination (angle of attack) to the incoming flow. In that case, the region between the shock and vehicle is very narrow since the Mach lines and shock waves are inclined only slightly relative to the flow direction. The region between the shock and the lower surface of the body contains high-enthalpy fluid that has been processed by the oblique shock. Closer to the vehicle can be an *entropy* layer, consisting of fluid processed by the bow shock; and finally, adjacent to the vehicle will be a viscous boundary layer in which friction heating further increases the temperature of fluid. Vehicles with blunt noses (reentry vehicles) will have detached shock and a rather thick associated entropy layer.

Hypersonic flows are distinguished by a large Mach number, although the actual flow velocity may be modest, $u<4$ km/s. This is typical of flows in laboratory shock tunnels with stagnation enthalpies less than 8 MJ/kg. Molecular dissociation and ionization effects are often negligible under these conditions and the gas can be treated as ideal. Hypervelocity flows are distinguished by large velocities, $u \geqslant 8$ km/s, but could have modest Mach numbers. Recall that it is the kinetic energy, $u^2/2$, that is significant in the energy equation, so that these two regimes differ by a factor of 4 in energy. More significant is the strong dependence of chemical reaction rates on temperature. Chemical reaction is much more important in hypervelocity flows, and effects such as dissociation can dominate the observed flow phenomena (Stalker, 1989). In hypersonic flows, the shocks can all be described as strong and the downstream fluid characterized by the limiting density ratio, but hypervelocity flows are better characterized (Stalker, 1989) by a constant-temperature flow downstream of the shocks. It is possible for the two flow regimes to occur simultaneously in the flow over a single body such as a blunt cone.

High-speed flight and atmospheric reentry of space vehicles are the primary applications of hypersonic and hypervelocity research. Atmospheric reentry occurs under both conditions simultaneously, $M=25$ and $u=8$ km/s for a typical near-earth orbit. Behind the shock waves, the temperatures are high enough that dissociation produces atomic nitrogen N and oxygen O, and chemical reaction produces NO. Gas-surface reactions can also be important (Park, 1990) to the survival of reentry vehicles. Scaling methods have been developed so that laboratory hypervelocity experiments (Stalker, 1989) can be used, particularly in problems where near-normal shocks and blunt bodies are important.

A simple means of estimating lift and drag in hypersonic flows is to assume that the fluid molecules inelastically collide with the lower surface of the vehicle and the component of momentum normal to the surface is completely transferred to the vehicle. This is known as the *Newtonian theory* after Newton's early efforts to model low-speed flows. The shock wave and resulting flow next to the body constitute the physical mechanism that produces the inelastic collision effect. If we apply these notions to a surface inclined at an angle θ to the freestream, the local pressure coefficient is found to be

$$C_p=2 \sin^2 \theta. \tag{38}$$

When we apply this concept to a flat plate with velocity U and an angle of attack α in an atmosphere of density ρ_0, the lift L and drag D forces are found to be

$$L=\rho_0 U^2 \sin^2 \alpha \cos \alpha, \tag{39}$$

$$D=\rho_0 U^2 \sin^3 \alpha. \tag{40}$$

These results can be extended to more complex bodies by taking account of the pressure field induced by curved stream lines (centripetal force) and the nonuniformity of the flow between the shock and the body. Another solution technique is indirect and specifies a *waverider* body shape that is a stream surface of a known flow behind a shock wave of specified shape (Anderson, 1989). Yet another solution method is possible for slender bodies, termed *hypersonic small-disturbance theory* (Hayes and Probstein, 1966). Linearizing the equations in the cross-stream direction effectively reduces two-dimensional hypersonic flow problems to an equivalent one-dimensional unsteady flow problem. Numerical and similarity solution methods developed for one-dimensional unsteady flow can then be directly applied to solutions of hypersonic flow.

Hypersonic flows can be created in the laboratory by a variety of steady-flow wind tunnels, shock tubes, and blowdown wind tunnels. All of these systems create in some fashion, either by combustion, shock heating, or electrical heating, a high-enthalpy, high-pressure reservoir of gas. This gas is then expanded through a de Laval nozzle to produce the desired hypersonic flow. Hypervelocity facilities have the highest stagnation enthalpies, up to 30 MJ/kg. These systems are usually transient in operation since the high-enthalpy fluid must be created by a dynamic process such as shock compression. An example of this type of facility is the *free piston compressor* (Stalker, 1990), in which a massive piston is driven by compressed gas into the driver fluid. The compressed driver gas ($P\sim 1$ kbar) then ruptures a diaphragm and drives a shock through the test gas and out the nozzle at the end of the test section, which initiates a quasisteady flow through the nozzle. The model or experiment is conducted in a vacuum tank surrounding the nozzle. Another technique for generating the driver gas is to use a conventional shock-tube arrangement with high-pressure helium or to burn a combustible mixture initially at high pressure. Finally, an alternative method for producing hypersonic flows is the ballistic range. A projectile is accelerated by a gas or powder gun to hypersonic velocities and injected into a test chamber filled with the atmosphere of interest.

7.4 Unsteady Flows

Many flows of interest in applied physics are unsteady flows with significant multidimensional motion. Great advances have been made in understanding these flows through careful experimentation and numerical simulation of the Euler equations. These simulations are based on numerical solution techniques that can either *capture* shock waves as part of the general solution algorithm or attempt to isolate and treat shock waves and contact surfaces separately through special *front tracking* techniques. Common to all methods is the use of the *conservation form* of the equations, generically written as

$$\frac{\partial f}{\partial t}+\operatorname{div}\mathbf{F}=0. \tag{41}$$

The quantities f and $\mathbf{F}$ are the generalized densities and fluxes. For the Euler equations in two-dimensional Cartesian coordinates with velocity components $\mathbf{u}=(u,v)$,

$$f=\begin{pmatrix} \rho \\ \rho u \\ \rho v \\ \rho u\left(e+\frac{u^2}{2}\right) \end{pmatrix},$$

$$\mathbf{F}=\begin{pmatrix} \rho u & \rho v \\ \rho u^2+p & \rho uv \\ \rho vu & \rho v^2+p \\ \rho u\left(h+\frac{u^2+v^2}{2}\right) & \rho v\left(h+\frac{u^2+v^2}{2}\right) \end{pmatrix}. \tag{42}$$

Typical applications are to the problems of unsteady transient jets, blast propagation, and shock diffraction and refraction. As an example, consider the problem of unsteady shock reflection from a wedge. This is a configuration that often occurs when blast waves interact with structures.

Experimental studies (Hornung, 1986) have shown that there are at least two distinct types of reflection, *regular* [Fig. 11(a)] and *Mach* [Fig. 11(b)]. Regular reflection produces a

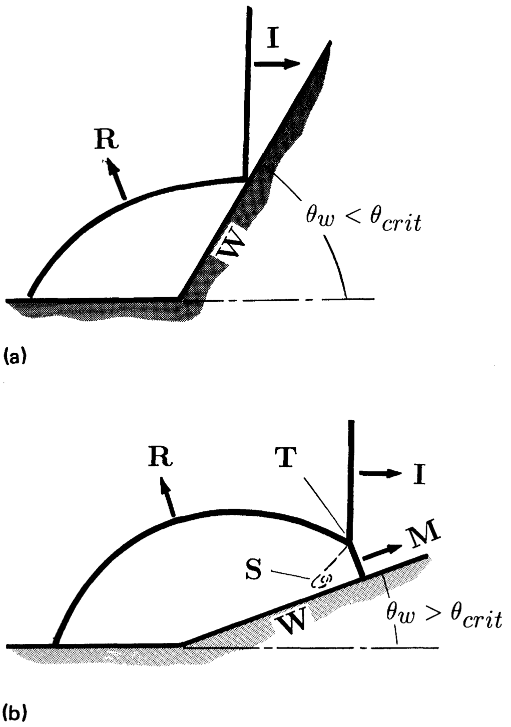

FIG. 11. (a) Regular and (b) Mach reflection of an unsteady shock wave interacting with a wedge.

reflected wave (R) at the point where the incident wave (I) impacts the wedge (W). Mach reflection produces a *Mach stem* (M), a shock wave that is oriented nearly normal to the ramp and intersects the incident (I) and reflected waves (R) in a *triple point* (T), from which a contact surface and associated vorticity [manifested as the shear layer (S)] emerge into the shocked fluid. Mach reflection is observed for wall angle θ_W smaller than a critical value; above that, transition to the regular configuration occurs. The critical wedge angle depends on the shock Mach number. Its determination is apparently complicated (Hornung, 1986) by the displacement effect due to the viscous boundary layer on the ramp surface and the shear layer at the contact surface.

If the viscous effects are ignored, the problem can be viewed as pseudosteady by transforming to a frame attached to the triple point. Oblique shock adiabats (known as *shock polars*) can then be used to construct a simple approximation to the flow field. The critical angle for transition can be determined by applying a causality condition on disturbance originating from the tip of the wedge. Despite the success of the pseudosteady theory and the appealing simplicity of a classification into either Mach or regular reflection, a rich variety of flows are actually observed experimentally. Notable features include secondary and tertiary triple points, vortex structures, and jetlike flows behind the Mach stem. Numerical simulation based on the Euler equations offers insight into the rich variety of these flows. Shown in Fig. 12 is a comparison between observed density contours (isopycnics) in an interferogram image [Fig. 12(a)] and computed isopycnics [Fig. 12(b)] for a Mach 3.51 shock wave in SF_6 incident on a 20° wedge. This is an example of double Mach reflection that clearly shows the "kink" in the reflected wave where the second Mach stem occurs. Other features on the figure include the incidence shock separating undisturbed fluid (0) from shocked fluid (1), a Mach stem between (0) and (3), a reflected wave between regions (2) and (1), and a shear layer between (3) and (2). A vortex is clearly visible behind the curved Mach stem. Letters label the corresponding isopycnics in the experimental and calculated results.

8. FLOWS WITH PHASE CHANGE

A recent development in compressible flows is the exploration of adiabatic phase change induced by rapid compression. While the phenomenon of water condensing from moist air upon isentropic expansion (shown in Fig. 2) is well known, more startling and less widely appreciated is the possibility of liquefying a pure substance by adiabatic compression. Shock-induced liquefaction can occur (Detleff *et al.*, 1979) for fluids with sufficiently large molar heat capacity. Partial and complete liquefaction shocks have been observed in a shock tube when the test (driven) fluid is composed of molecules similar to, or more complex than, perfluoroheptane or octane.

A unique feature of the complete liquefaction shocks is the presence of an extraordinary number of vortex rings in the liquid behind the shock wave. Photographic observations (Thompson *et al.*, 1986) of partial liquefaction shocks demonstrate that the shock wave may be *split* into a precursor shock and a separate condensation wave. These waves

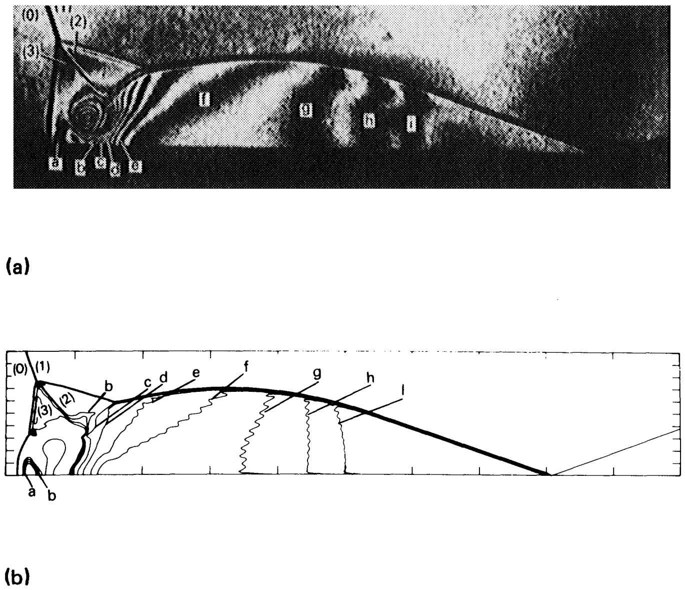

FIG. 12. (a) Experimental and (b) computational results for double Mach reflection of a shock wave in SF_6 (Glaz *et al.*, 1986).

can also be unstable, as manifested by a highly wrinkled wave front. A mild version of this instability is exhibited by the wave shown in Fig. 13. This photograph is an oblique image of a partial liquefaction wave front produced behind a $M=2.63$ shock in isooctane initially at 383 K and 1.1 bar.

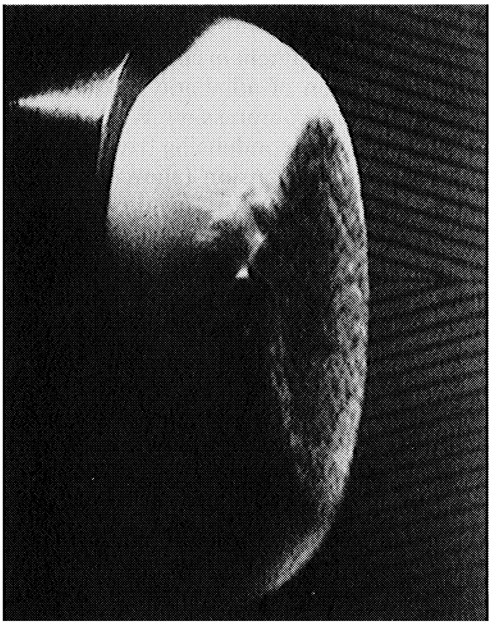

FIG. 13. Diffraction of an unstable liquefaction shock front from a tube (Thompson *et al.*, 1986).

Wave splitting and spontaneous wave-front distortions are two features that may be related to the more general problem (Menikoff and Plohr, 1989) of shock stability. It is known that under certain circumstances, often associated with phase transformations (Duvall and Graham, 1977), shock waves can be unstable to both longitudinal and transverse disturbances. Such instabilities are associated with unstable feedback mechanisms between the mechanics of fluid flow and the thermodynamics of adiabatic compression. Additional instabilities are possible due to the wave structure associated with the finite rate of phase transformation. These instabilities may be similar to those observed in detonations; however, the origin is presently unknown.

Another type of compressible flow with phase change is a two-phase mixture of a liquid with its vapor, typically characterized as a bubbly liquid. Experimental observations (Nakaryakov *et al.*, 1979) of shock waves propagating in such mixtures indicate that many different types of wave structures can exist. The large difference between the vapor and liquid properties combined with the dynamic nature of the phase change results in dispersive waves with complex pressure profiles, including smooth compressions and oscillatory tails, rather than just simple shocks. If the bubbles also contain a combustible mixture, then explosions within the bubbles can result in a self-sustaining wave (Hasegawa and Fujiwara, 1982). Unique wave phenomena (Kutateladze *et al.*, 1987) have also been observed in a pure substance near its thermodynamic critical point. It is possible to obtain very low or even negative values of the fundamental gasdynamic derivative, making possible the demonstration of *rarefaction shock waves*, a possibility hinted at by Eq. (21).

GLOSSARY

Acoustic Impedance: Product of mass density and sound speed ρc, proportionality constant between pressure and velocity changes for acoustic waves.

Adiabatic Compressibility: Proportionality between fractional specific volume changes and pressure changes, $K_s = -(1/v)(\partial v/\partial P)_s$.

Blast Wave: Transient shock wave created by explosion.

Chapman–Jouguet Velocity: Theoretical velocity at which a self-sustaining detonation propagates.

Characteristics: Directions in space-time along which information travels.

Choking: Limitation of mass flow rate due to fluid velocity approaching the sound speed.

Contact Surface: Physical surface in flow separating fluids of different composition, density, or entropy. Pressure and velocity are continuous across contact surfaces.

de Laval Nozzle: Duct containing a converging–diverging section that is used to accelerate the flow to supersonic velocities.

Expansion Wave: Isentropic steady or unsteady flow resulting in a decrease in pressure.

Fundamental Gasdynamic Derivative: Basic measure of the nonlinearity of the fluid, $\Gamma = (c^4/2v^3)(\partial^2 v/\partial P^2)_s$.

Grüneisen Coefficient: Measure of the thermal expansion of a fluid, $G = (1/c_p)K_s(\partial v/\partial T)_P$.

Hugoniot: Relationship between state variables for a shocked fluid, also known as shock adiabat.

Hypersonic Flow: Fluid motion where the velocity greatly exceeds the sound speed, i.e., $M > 5$.

Mach Number: Ratio of fluid velocity to sound speed, $M = u/c$.

Nonlinearization: Process of using nonlinear characteristics together with linear wave equation solutions to obtain approximate solutions to blast wave problems.

Prandtl–Meyer Function: Function used to relate flow deflection angle to velocity changes in steady two-dimensional isentropic flow.

Quasi One-Dimensional: Approximation used to analyze flow in variable-area ducts.

Shock Wave: Adiabatic jump in fluid properties that occurs in a propagating thin layer.

Sonic Flow: Condition in which the Mach number is 1 i.e., the fluid velocity equals the sound speed.

Stagnation State: Thermodynamic state reached when a fluid is isentropically brought to rest.

Substantial Derivative: Derivative following the path of the fluid particles.

Supercritical Airfoil: Airfoil capable of shock-free flight even though the Mach number locally exceeds 1.

Supersonic Flow: Fluid motion with the velocity greater than the sound speed, i.e., $M > 1$.

Thermoelastic Equation: Also known as the Mie–Grüneisen equation, an equation of state used for shock-wave calculations in solid materials.

Transonic Flow: Fluid motion near the speed of sound.

Water Hammer: Shock waves generated by transients in plumbing systems.

Waverider: Shape of vehicle designed by examining streamline solutions for hypersonic flow problems with specified shock profiles.

INTRODUCTION

The application of computers to the design of electronic systems has steadily increased since its introduction in the late 1950s. During the last two decades, the prices of minicomputers and desktop machines (workstations and personal computers) have been steadily decreasing while their overall performance has been continuously improving. This upward trend in computer performance has been accelerated by rapid advances in microprocessors, which have doubled their execution speeds approximately every 18 months, and faster and larger-capacity semiconductor memories. Increased performance has allowed the development of sophisticated new applications whose functionality, in turn, makes possible the efficient design of more powerful machines. This cycle will continue.

To illustrate the increase in workstation computational power, we cite two sets of numbers: The Motorola 68020 family of CISC microprocessors (complex instruction set computer), widely used in these machines a few years ago, had in 1986 an execution speed of approximately 4 MIPS (million instructions per second). Two machine generations later, by mid-1990, Motorola's 68040 microprocessor had achieved a speed of 20 MIPS. In four years, processing power had grown five times. The progress in chips implementing RISC (reduced instruction set computer) architectures has been even more rapid. The first workstation that implemented SUN Microsystems' SPARC architecture appeared in the second half of 1987 and offered 10 MIPS, while in the first half of 1991 Hewlett-Packard's Precision Architecture machines achieved 70 MIPS. That is a sevenfold increase in approximately four years. Hardware prices have decreased to the point where the difference between the low end of the workstation market and the high-end PCs (personal computers) has disappeared.

The progress in the application of computers to the design of computer systems has been equally impressive. New and better computer-aided design (CAD) tools have been one of the key factors making possible the successful design of extremely complex integrated circuits (ICs or chips). To point out the increase in IC complexity, we offer the following illustration. In 1985, the microprocessor designed by Digital Equipment Corporation for use in its MicroVAX II series machines contained about 125 000 transistors. By 1990, Intel's 80486 microprocessor, used in many personal computers, contained around 1 200 000 transistors. Without important ad-

vances in computer-aided design, systems of such complexity would be impossible to design.

The field of computer-aided design includes a wide span of applications. We will cover only aspects related to the design of electronic systems, with emphasis on the design of integrated circuits. Given the many areas of interest, we are forced to mention some of them only briefly. In general, CAD refers to specialized software that allows data entry and verification, simulation of the behavior of pieces of a system, automatic synthesis of increasingly detailed descriptions, and a number of data management facilities. Examples include graphical editors to enter logic schematics and chip layouts, programs to verify that layout design guidelines have been respected, systems to simulate the electrical behavior of a set of interconnected transistors, or programs that automatically generate geometries in order to connect or "route" the desired pins among components placed on a printed-circuit board.

As its name indicates, CAD is an aid to design. So it is not a discipline with its own set of problems, even though many CAD problems have models with great theoretical importance. CAD's effectiveness is measured by what it makes possible. Two areas are emphasized: the ability to design very-large-scale integration (VLSI) chips and systems using them, and the contribution to productivity, such as savings in the size of design teams and overall time-to-market schedules. In consequence, developments and topics of interest have changed through time, tracking the leading-edge technologies used in the design of computers and integrated circuits. Nevertheless, one tendency has been consistent. As systems become more complex, the design process moves toward more and more abstract levels of description. This phenomenon has required a corresponding increase in the development and use of automatic synthesis and simulation tools. While advances will continue in most CAD areas, the most visible increases in design productivity will be achieved through synthesis (at logic and layout levels) and innovative uses of simulation and other verification techniques.

1. HISTORY

CAD, as part of the broader field of design automation, started in the mid-1950s. The use of transistors in computer circuits created new problems, and to solve them, designers took advantage of the wider availability of computers. The first CAD paper probably was by Cray and Kisch in 1956 (see Breuer, 1972), describing a system to check and simulate Boolean equations. Another area of early interest was the entry of data to machines that automatically placed wires to connect components on a board, and programs to verify these data. In these early beginnings we immediately recognize topics that have persisted until today: logic simulation, interconnect estimation, and entry and verification of layout-related data.

In the 1960s, the problems of interest were related to board design. The placement and routing of components on a board were important issues, and we can see early work that is still relevant today (Lee, 1961; Hightower, 1969). Simulation of Boolean descriptions (gate-level simulation in today's terminology) and generation of appropriate input values to exercise the logic (test vectors) became an alternative to the building of increasingly complicated hardware prototypes, often called "bread boards," for system verification. The desire to automate steps in the design process—for example, the automatic generation of logic—also received attention quite early (Friedman and Yang, 1968).

Traditionally, the development of CAD tools was confined to internal efforts in computer and semiconductor companies and research carried out at universities. The CAD development groups were closely tied to the design groups that used their tools, and they were considered truly part of the overall system- or chip-development effort. In the 1970s, the appearance of minicomputers that could be adapted to dedicated tasks in a cost-effective way created new opportunities. Independent commercial companies appeared that offered systems, combining hardware and software, for design entry and for automating some design tasks. The first systems were devoted to the editing and routing of boards and, with the growing importance of the IC, to IC layout entry and geometrical design checking. Schematic entry was the next category of systems that attracted these companies.

Important advances in all areas were achieved in the 1970s. A circuit simulator developed at the University of California, SPICE (Nagel, 1975), while having gone through many enhancements, is still in use today. New ways to do IC layout were proposed (Williams, 1978), and significant attempts to shift the design process toward more abstract levels were reported (Johanssen, 1979). The increased transistor density in ICs allowed by the newest metal oxide semiconductor (MOS) technologies brought the introduction of the term VLSI to describe these new chips that could really be considered a fairly complex computer system. The appearance of the book *Introduction to VLSI Systems* by Mead and Conway (Mead and Conway, 1980) significantly turned the perspective in IC design from a pure "device" to a "system" orientation. Clearly, this approach emphasized the importance of automation. In the United States, the funding provided by the Defense Advanced Research Projects Agency (DARPA) to support research through its VLSI projects had a major impact on CAD development through the mid-1980s. Technology advances, such as the emergence of denser MOS gate arrays, shifted the focus even more towards CAD for ICs.

In the early 1980s, the success of the microprocessor provoked a shift from minicomputers to cheaper workstations. In the commercial CAD world, companies that were not able to port software from their proprietary, minicomputer-based hardware to these new machines ended up disappearing from the market, replaced by new players that competed on the basis only of their software, with UNIX as the dominant operating system. As the entry barriers for developing software are much lower than those for hardware, a large number of companies were formed, most of them offering narrowly focused programs (layout verification, simulation, schematic editors, etc.). But as the decade progressed, two phenomena occurred. Internal CAD groups at computer and semiconductor design houses started to rely increasingly on CAD companies for important pieces of their software, and the CAD companies went through a process of consolidation that continues until today (1992). The survivors of this consolidation process, such as Mentor Graphics (Beaverton, OR) and Cadence (San Jose, CA), are large, publicly traded companies with yearly sales on the order of hundreds of millions of dollars. These companies have concentrated their offerings on fairly wide, integrated systems for design instead of isolated point tools.

Today, CAD is advancing along three different lines. Universities continue to play an important role in new research. The University of California at Berkeley, Stanford University in Palo Alto (both in CA), and Carnegie Mellon University in Pittsburgh, PA, have been leading centers in the United States, while the Universities of Edinburgh in Scotland, Grenoble in France, Louvain in Belgium, and Eindhoven in The Netherlands have been important European contributors. In addition, research centers associated with companies, such as IBM's Thomas J. Watson Research Center at Yorktown Heights, NY, and AT&T's Bell Laboratories in Holmdel, NJ, have played a key role. Commercial CAD companies and internal CAD groups have traditionally functioned using different models. Internal CAD groups have focused more on specialized applications that serve their companies's technologies, particularly in areas that today are leading edge but soon will be more generic, while CAD companies have been generally interested in providing systems with the widest possible appeal. Currently, however, most computer and semiconductor companies use a combination of commercial and in-house tools. The evolution of this mix is not clear at this time, but it will determine much of the CAD development in the coming years.

2. COMPUTER-AIDED DESIGN IN ELECTRONIC SYSTEMS

We will consider only certain aspects in the design of electronic systems, in particular, digital computer systems. We will include CAD tools for the design of a system as a logical unit, including component ICs, for the simulation of the system, and for the design of boards. We will exclude the semiconductor process design and manufacturing, thermal analysis, testing and reliability, cabinet design, specialized software, and other topics that, while significant in the design of a computer system, fall outside our description of a "logical unit."

As already indicated, the focus of CAD has changed through time. While most of the efforts in the 1960s were dedicated to board-level design, the phenomenal increase in the complexity of integrated circuits in the 1980s has shifted its focus. In 1990, a state-of-the-art microprocessor contained between one and two million transistors. It must be noted that, while much more complex than other parts, the microprocessor is only one component in a system. Many CAD tools are equally applicable to boards and IC design, even though the emphasis can be different. Examples are simulation tools, or placement and routing systems that use similar algorithms. Our descriptions will mainly address the IC case, although we will mention differences and applicability to systems.

2.1 Electronic Design of Integrated Circuits

There is a large variety of integrated circuits, using different semiconductor technologies and having equally different kinds of circuit functionality. The first important distinction among the types of ICs is between digital and analog chips. As these names indicate, the main difference is whether the signals can assume a continuous range or are restricted to two discrete values (high and low, or 0 and 1) for basic design purposes. A microprocessor is a mostly digital chip, while a filter can be purely analog. A second distinction is made according to the semiconductor technology used. The most common technologies today are CMOS (for complementary metal oxide semiconductor) and bipolar technologies such as ECL (emitter coupled logic). Lastly, a third distinguishing characteristic is the IC's design style. The most important categories of design styles are custom, semicustom, and gate arrays. Special chips such as memories do not fit any of these types, and traditionally their advances have been made possible through progress in semiconductor-processing technology rather than through CAD. Many developments in IC CAD tools, particularly related to synthesis versus entry and simulation, have been motivated by applications to semicustom and gate-array MOS chips.

The distinctions among these design styles are based on the degrees of freedom we assume. In the case of custom design, maximum flexibility is assumed: Essentially each transistor can be individually tailored. While it achieves the best use of a technology, it levies a large design-effort cost. So it is prevalent in high-speed microprocessors and analog parts. In the case of semicustom design, there is extensive use of a predesigned library of functions, referred to as standard cells, with each usually consisting of a few logic gates. Larger units, called macros, are also employed as single entities. This approach causes a number of inefficiencies, but it allows much more automation. Frequently, custom and semicustom approaches are combined. Finally, in the case of gate arrays, the transistors are laid out in a fixed, regular fashion, and a library of basic gates is constructed, very much as in the case of a semicustom chip but usually with lower performance. A key difference is that in a gate array, we "design" only the interconnection layers, bringing an important economic advantage as only a few layers are customized. Technology advances have increased significantly the capacity of the CMOS sea-of-gates types of arrays, due to the use of more interconnect layers (usually three metal layers), resulting in a higher percentage of utilization of the available gates, and reduced transistor sizes, increasing the density in the chip. Today, the largest gate-array chips contain hundreds of thousands of logic gates and are offered by many semiconductor vendors. Gate arrays constitute the largest component of the market for special-purpose chips (application-specific ICs or ASICs).

2.2 The Design Process

We give now a brief overview of the design process, with the intent of relating design steps to the different CAD tools. The steps involved vary in importance among the types of systems and chips, but they apply quite generically to most computer systems. The design process is a sequence of transformations, each of which produces a description that progressively refines the previous one by adding further detail. This process is usually referred to as "top-down" design.

First, certain technology choices are made and translated into design parameters. For example, a system intended for a certain market will have specific requirements for speed, power consumption, and overall capabilities. A suitable technology is selected to meet these requirements, and the system's basic characteristics are established. In the case of a microprocessor, basic problems include establishing an acceptable clock rate, determining the amount of memory that can go inside the chip, calculating the total power dissipation, and other global factors.

The design proceeds in stages, with each adding more detail in terms of the actual system implementation. Usually, a high-level or "behavior" model is constructed and extensively simulated. From here, logic and circuit design is done to transform the high-level model into Boolean functions and their circuit implementations. In the case of chips, the circuits are laid out, that is, the different mask layers required by manufacturing are drawn. On the other hand, for boards, the positions of the components and the wires connecting them are determined. At each step, extensive verification tasks are performed to establish compliance to technology rules and to establish the equivalence of the different descriptions. Now, we will proceed to describe in greater detail these major steps and the CAD tools employed in the process.

3. HIGH-LEVEL DESIGN

The logic design process can be divided into two major phases. First, a high-level description of the system or IC is usually created using a special language referred to as hardware description language (HDL). Depending on its level of detail, this model is called a behavior or an RTL (register transfer level) model. Second, this high-level or functional model is converted, through manual or automated steps, into a logic description. This description includes the precise components being used at a level of logical units such as Boolean gates, ALUs (arithmetic logic units), etc., and, in the case of boards, components such as ICs that are treated only from the point of view of their input/output behavior.

The functional model indicates what the system does, but does not indicate exactly how it does it. The difference between a pure "behavior" and an "RTL" model is the level of detail, and it is not clear cut. A way to indicate the distinction is through an example: We may want to add two numbers, and we write such a statement in a behavior model, while in the RTL version we indicate exactly which arithmetic unit and registers are actually involved in performing the operation. A functional model resembles a software program. It is written in an HDL that includes a simulation environment so that the system's behavior under specific input patterns can be observed. Architectural decisions and their impact on system performance are usually evaluated by use of a behavior model and extensive simulation.

Many specialized languages, such as DPL or DECSIM BDS (see De Micheli *et al.*, 1987) have been used as HDL. Until the early 1980s, most of the HDLs used by industry were developed by computer or semiconductor companies. In some cases, general software programming languages (such as C) have been used directly, even though only a restricted subset of the language's constructs is allowed. The key tradeoff in the design of an HDL and its simulation environment has been between flexibility and execution speed. Implementations based on interpreters allow excellent observability and user interaction but at a serious cost in simulation speed.

An effort to create an HDL that could be widely used was initiated by the U. S. Department of Defense as part of their VHSIC program (very-high-speed integrated circuits). This resulted in the definition of VHDL (VHSIC HDL), now an IEEE standard (Dewey and Gadient, 1986). VHDL has gained increased acceptance as a natural candidate for standardization. Commercial CAD companies had been offering their own languages and simulators for years, contributing to the creation of a large installed base of models that are exchanged among the system or chip users. Cadence's Verilog HDL, for instance, has played a significant role due to its large market share (Cadence Design Systems, San Jose, CA).

The functional description has taken another increasingly important role as input to the logic synthesis tools now being used in IC design. The logic synthesis process consists of the transformation of a functional description into a structural representation, usually at the gate level, including steps to minimize the logic and to meet timing constraints. This has caused reexamination of the HDL, as the exact interpretation of its statements in terms of Boolean equations has become very important.

4. LOGIC DESIGN

The creation of a representation of the design using only units whose functionality corresponds essentially to Boolean equations and storage elements is called logic design. The most usual description is a set of schematic diagrams involving simple logic gates (such as multiple-input AND, OR, NOT, etc.) and registers. In the case of systems, these functions are divided into components. The representation of a design in these terms is also called a structural description. Many systems, particularly before the advent of VLSI, were designed with schematics, not functional descriptions, as their starting point. Only as complexity increased has the use of functional models become the norm.

Specialized editors to enter gate- and transistor-level descriptions are called schematic editors. Output from the schematic editors are lists of components or cells and their interconnections (netlists), including several levels of detail ranging from large library items (such as an ALU) to transistor-level descriptions, and plots. The netlists are used by simulators to investigate the behavior of the circuits. Special software and computers for schematic editing followed a development path similar to layout editors. This will be described in a later section. Today, software systems for editing on workstations and PCs are offered by many companies, including component libraries for the major gate-array vendors.

4.1 Circuit Design

Circuit design consists of determining the exact implementations of the logic functions and storage elements in terms of the primitive elements of the specific technologies. In the case of ICs, these primitive elements are transistors and other basic elements, including their electrical parameters. Each technology has its own specific circuit techniques. For the case of CMOS the reader can consult Glasser and Dobberpuhl (1986). A design comprises a library of items, each implementing a logic function and parameters such as delays, drive, and power consumption; a method for distributing special signals such as clocks; and general usage rules. In the case of a custom design, there is much more flexibility in the creation of circuits. For example, some tools have been developed to assist the circuit design process, such as CMOS transistor sizers (Hill *et al.* 1989), but it still requires a large amount of trial and detailed simulation.

4.2 Logic and High-Level Synthesis

As already mentioned, the use of logic synthesis has become a part of the design process. Even though work in aspects of logic synthesis started decades ago, it was during the 1980s that the extraordinary progress achieved in this area changed the logic design process. Most of the work has been centered on the generation of the combinational logic (excluding the storage elements that convert the design into a sequential type). The process is divided into two steps: a technology-independent step, where Boolean logic is minimized, followed by a technology-mapping phase where the logic is implemented using a set of predefined gates dependent on specific technology choices.

A Boolean function of N variables can be represented by three subsets of the N-dimensional Boolean cube (the set product of $\{0,1\}$ with itself N times): the points where its value is 1, or ON set, the points where its value is 0, or OFF set, and optionally a "don't care" set, that is, those input value combinations for which the function's output value is unimportant. This case occurs typically when we know that a specific combination of input values will never happen. Minimizing the function is closely related to the problem of "covering" the ON set optimally by subsets of the N-dimensional cube that are themselves lower-dimensional cubes (or "faces") with particular properties. Techniques to obtain a minimal realization of a Boolean function using two levels of logic date back to the 1950s (McCluskey, 1956). One subproblem encountered in this process (finding the collection of optimal special subsets) is "*NP* complete." In loose terms, *NP*-complete problems cannot be solved by any algorithm the number of whose steps is bounded by a polynomial function of the problem variables (Garey and Johnson, 1979), making it necessary from a computational point of view to develop reasonable heuristics. When MOS technology started to predominate in VLSI chips, interest in two-level representations was renewed, as it was possible to produce efficient layouts for a structure called PLA (programmable logic array) to implement two-level logic functions. A detailed description of a widely used program, ESPRESSO-II, and problems found in the logic minimization of PLAs is given in Brayton *et al.* (1984).

Logic synthesis for the general case of a multilevel network, including sequential elements, has been done with a variety of techniques. Systems such as IBM's LSS (Darringer *et al.*, 1984) have combined "local" and "global" transformations to modify the logic until the desired constraints are met. Local transformations examine only a small portion of the circuit, an example being the application of equivalences between AND-NOT and NOT-OR combinations (DeMorgan laws; see Dietmeyer, 1978). Global ones take a larger view, such as following input–output signal flow to identify particular relations among variable values, or collapsing a selected portion of the circuit into two levels to apply special minimization. Several objectives are considered, such as area minimization, timing optimization, and testability. General Electric's SOCRATES (de Geus and Cohen, 1985) employed a rule-based approach to the technology-dependent phase following Boolean minimization. A completely algorithmic approach is followed in MISII (Brayton *et al.*, 1987), applied to strictly combinational circuits. The program executes a user-controlled sequence of optimizations that include tradeoffs between area and time. The technology-mapping phase is based on a technique introduced in DAGON (Keutzer, 1987), where the predefined logic gates and the network are decomposed into tree graphs and matched using local analysis.

A number of new areas closely related to logic synthesis are being actively researched. Because of space constraints, we can only mention them briefly: the relation between the testability of a circuit and its minimal Boolean implementation, the problem of encoding a finite-state machine (see, for example, Dietmeyer, 1978), improved timing optimization algorithms, and the possibility of looking at the full sequential circuit and taking advantage of operations that cross the register boundaries. The interested reader is referred to the CAD conferences cited for further reading.

A different type of logic synthesis is usually referred to as high-level synthesis. The intention is to find a structural implementation for a given behavior and set of constraints, but the basic elements from which we are selecting have a higher level of complexity than logic gates—typically registers, ALUs, multiplexers, and buses. The intended output is a data-path structure and the specification of its control.

Two important problems in high-level synthesis are scheduling and allocation. In scheduling, we determine which operations take place at each control step under a set of restrictions. The restrictions can include, for instance, the number of hardware units available, the total delay that operations can take, or the estimated power consumption. Many algorithms have been investigated, but most fall into two categories. These are exhaustive search combined with some heuristics or standard mathematical techniques such as linear programming (Brayton *et al.*, 1985; Hafer and Parker, 1983), and constructive approaches that proceed by building the operations incrementally (Marwedel, 1986). During allocation, we choose the units in the data path and explicitly assign the operations. Constraints are total area, number of units, and bus interconnects, among others. Techniques used for allocation can be separated into constructive and global ones. In the latter case, graph models have been employed (Hafer and Parker, 1983). Given the generality of the problems, rule-based expert systems have also been applied to high-level synthesis (Thomas *et al.*, 1988).

5. SIMULATION AND VERIFICATION

The need to verify that a system description actually performs as intended under sequences of input values is obvious. Extensive simulations are performed at all levels of system description to ensure two key objectives: that the descriptions match the design intention, and that the different descriptions are actually equivalent. The first of these objectives is usually called the validation problem, even though, unless we are able to do exhaustive analysis, we cannot totally validate a design. The second, or verification, is used in a looser sense to describe approaches that are used to compare different descriptions and obtain a reasonable degree of confidence that the design performs as intended. While detailed electrical simulations—for instance, at the transistor level—would give us a larger degree of assurance that a complex chip will operate properly, the time it would take a computer to perform such a simulation makes this approach completely unfeasible. Thus simulations are performed with models that have very different levels of accuracy in order to cover a large chip or system "adequately."

The most general description available is an HDL program. This representation is usually simulated at the functional or RTL level. The simulation parallels closely the execution of a general software program, and the data that we are observing can be quite general (such as an integer, for instance). The advantages of functional simulation include high execution speed and the ability to perform extensive simulations before the design of the actual circuits has progressed sufficiently to be useful.

A more detailed description is obtained at the logic level. In this case, the description consists of logic gates (ANDs, ORs, etc.) and the values we observe are 0 and 1, plus some "undefined" states, producing what is referred to as gate-level simulation. The concept of time can be now introduced in a much more precise way. Relations are established in discrete units among the different clocks, the behavior of the different register elements is established, and delays through each gate type are indicated. In addition, delays due to interconnects can be modeled. These are usually based on extracted wire lengths or total capacitance including parasitic effects such as couplings. Gate-level simulation has been the most prevalent way to establish a design's correctness, at least from a functional perspective that includes simple timing models, even though in most cases no proof of correctness is achieved. Gate-level descriptions are often combined with RTL sections, creating a "mixed-mode" simulation. An example of such a system, used widely by a large computer company, is found in Insinga (1984). For topics closely related to gate-level simulation, such as test-pattern generation and fault simulation, the interested reader is referred to Abramovici *et al.*(1990).

Many techniques have been used to execute gate-level simulations. We mention the two most basic: compiler and event driven (see Saleh and Newton, 1990). In a compiler-driven simulator, the elements in the circuit are ordered according to the time at which they may execute a transition, usually according to their logic level. Code is then generated to evaluate all gates sequentially. In an event-driven simulation, we try to take advantage of the fact that the ratio between the total number of nodes and the nodes that actually change values is normally below 10% so that it is not necessary to simulate all nodes at each time step. On the basis of the inputs that have changed values, we schedule evaluations only for those nodes that may be affected. As a way to accelerate gate-level simulations, special-purpose hardware accelerators have been built by computer companies for their internal use, and some small companies have offered these machines commercially. Two examples can be found in Denneu (1982) and Agrawal *et al.* (1987). Many attempts to use parallel processing (see PARALLEL COMPUTING) have also been described. The possibility of building systems based on field-programmable gate arrays (FPGA) to do simulation (versus the actual implementation of the chip or system) is being actively researched.

In the case of MOS circuits, the use of switch-level simulators has been quite successful as a way to combine a simulation in terms of obtaining digital information (high and low values at each node) with the inclusion of electrical and timing information. The idea is to model the transistors as fixed-value resistors and capacitors (*RC* model), controlled by a switch (the value on the transistor's gate), and wires as ideal conductors. This simplification allows the use of an efficient approximate model to calculate delays (White and Sangiovanni-Vincentelli, 1987). In addition to high and low values, some electrical notions can be introduced. For instance, based on the transistor's width and length, a concept of "strength" can be introduced to model behavior in a feedback loop. A problem has been the fact that in many common MOS circuits, a transistor can apparently act as a bidirectional device. While this actually may not happen during the circuit operation, to determine automatically the direction of signal propagation is difficult. Efforts to improve the actual processing of the transistor interconnection list and to transform it into a set of Boolean equations has produced important speed improvements in simulation times (Bryant *et al.*, 1987).

In addition to the use of the switch-level model for simulation, it has become common to use it for chip-level timing verification of MOS circuits. The problem here is different: to determine paths that do not meet a timing constraint—for example, whether a signal is arriving at the input of a storage element in time with respect to the clock controlling the element. The analysis now is not based on actual input patterns but on looking at worst-case delays using the *RC* model. In addition to the directionality problem, another concern is the appearance of "false paths," that is, paths that will never actually be logically exercised. An early example of such a system was RSIM (Terman, 1983). The applicability of these techniques to the processing of very large transistor networks has continued to make them extremely attractive (Pan *et al.*, 1991). Many attempts have been made to speed up the analysis of these *RC* networks. Very large networks can be obtained by detailed layout extraction to include the effects of actual interconnect delays. A recent technique called asymptotic wave-form estimation (Pillage and Rohrer, 1990) has been successfully applied to networks with hundreds of thousands of elements.

The most detailed simulations are done at the device level. In this case, very accurate models of transistors, transmission lines, resistors, and other basic circuit elements are used. Analysis of such aspects as transients, steady state, or sensitivity can be performed with great accuracy but involve significantly increased simulation times. In the case of ICs, the number of transistors that can be simulated at this level in a reasonable amount of time rarely exceeds a few thousand. Probably the most widely used circuit simulator is SPICE and its many successive versions from the University of California and commercial CAD companies (Nagel, 1975).

The main components in a circuit simulator are as follows: The complex elements, such as transistors, are broken into simpler components, usually two-terminal linear and nonlinear resistors, capacitors, inductances, and controlled sources, using predefined models (for the case of SPICE MOS devices, see Vladimirescu and Liu, 1980). By use of Kirchhoff's current and voltage laws, systems of differential equations can be written and solved by numerical integration methods. The numerical techniques used account for the large amount of computer resources needed by circuit simulators, the difficulties in solving very large circuits, and problems related to convergence and stability of the solutions. For a more detailed discussion we refer the reader to White and Sangiovanni-Vincentelli (1987) and Saleh and Newton (1990). Also, for a deeper level of analysis of the detailed simulation of devices such as transistors as two- and three-dimensional structures, the interested reader can consult Sze (1984).

A large amount of simulation is done just to ensure that small logic changes have not altered the circuit's behavior. Recently, new techniques have been applied to prove formally the equivalence of two Boolean networks, avoiding multiple iterations through a simulation loop. The general problem of deciding if a Boolean expression is a tautology, that is, is true for all possible input values, is *NP* complete (Garey and Johnson, 1979). But special representations of a function that allow fast comparisons using reasonable amounts of memory for important subsets of functions, particularly those generated by logic synthesis tools, have been introduced (Bryant, 1986; Brace *et al.*, 1990). These functions are given canonical representations as special acyclic graphs called binary decision diagrams. This representation has allowed the verification of equivalence inside logic synthesis programs such as MISII. Combined with the ability to abstract a transistor-level netlist into a Boolean representation, the technique offers new possibilities for the functional verification of MOS circuits.

6. LAYOUT EDITING AND VERIFICATION

An important piece of the design process is the representation of the detailed data describing the exact geometries for the actual masks used to manufacture ICs, or the metal areas and holes for a board. Before the appearance of electronic editors, these large amounts of data were manually transferred (or "digitized") from drawings into computers, so that they could be further processed and used in manufacturing. The basic problem in the design of the first electronic editors was the actual hardware, particularly the graphic display systems. These displays were connected to general-purpose computers or were sold as part of a complete system that included the editing software and a modified minicomputer. Plotting hardware followed a similar path. In the 1970s and early 1980s, several companies offered these very successful systems, running on proprietary hardware closely tied to their specific programs. Then in the 1980s, the appearance of the workstation changed this picture radically. Layout editors could operate on these smaller computers that, in addition, were used for a multiplicity of other tasks. A number of companies, unable to port their software quickly to the new computers, simply disappeared from the marketplace and were replaced by new, software-oriented players.

6.1 Layout Editing

The representation of layout data has two aspects. First, we need standard exchange formats in order to transfer data. Second, each editor needs efficient internal data representations in order to manipulate data in an interactive fashion. Some standard exchange formats, such as CIF (Caltech intermediate form) and GDSII (originally from Calma Company), widely used for IC layout data, Gerber (property of Gerber Scientific Instrument), and the more general EDIF (electronic design interchange format) are described in Rubin's book (Rubin, 1987). As the amount of data increased significantly, dealing with flat polygon representations became difficult. The use of replication and hierarchy became common in IC layout, reducing complexity and memory usage. New data structures, able to include relations among polygons, began to be used. An editor widely used in academia, at least in the United States, is MAGIC (Osterhout *et al.*, 1984), where the concept of links among some neighboring polygons (called "corner stitching") was exploited to perform operations beyond the usual polygon editing such as geometrical design rule checking. Other two-dimensional data organizations, such as dividing the available area into quadrants and storing the data in related trees ("quad-trees"; see Rosenberg, 1985), have been used to allow quick searches.

Entering polygons to represent an integrated circuit is an extremely time-consuming and error-prone task. While reliable data are difficult to obtain, the problem being similar to the question "How many lines of code does a programmer write per day?," the figure is generally a few dozen unique transistors per day. Representing the masks at an abstract level could simplify the process and increase productivity significantly. The concept of symbolic layout (Williams, 1978) was introduced in the context of MOS IC design, even though the idea of representing basic objects as symbols is older. Connections are represented by dimensionless wires along centerlines on the correct process layers, while primitive elements are treated as objects with design parameters. For instance, a MOS transistor would be described in terms of its type, channel width, and length. The editing functions are simplified greatly as the designer does not need to enter the actual polygons and is not concerned with the exact spacings but only with the topology of the layout. A program acts on the symbolic description and expands it into the actual polygons with required spacings based on the technology rules. Unfortunately, the density of the layout obtained after this simple expansion is generally very poor. It has been necessary to alter the relative position of transistors and interconnect in order to reduce the total layout area. This step is called compaction. A compactor program creates a mathematical model to represent the many geometrical constraints (such as spacings, avoiding the intersection of some layers, or keeping some elements fixed) among the large number of basic elements (transistors and connection polygons) and uses an optimization technique to minimize the total layout area subject to the derived constraints. Many algorithms for performing this task continue to be proposed, starting from the first, one-dimensional graph models, to flexible probabilistic ones (Boyer, 1988). In spite of the progress achieved, the use of this technique to design large circuits has not been widespread. The best successes reported have been in the use of symbolic layout to design at the cell level (circuits up to a few dozen transistors), particularly because of the simplicity in transporting the cell layouts across similar semiconductor processes.

Another way of describing layout data is by creating a procedural description that, when executed as a program, generates the actual polygons (Johanssen, 1979; Batali and Hartheimer, 1980). The layout is then represented by text. Typical basic elements, such as a transistor or a contact, could be instantiated by calls of the parametrized procedures. While there is some loss of design freedom as we cannot operate directly on the polygons, the layout representation could take much less memory and storage than the full polygon expansion. Another advantage is the possibility of using more abstract geometrical concepts to express relative positions, such as "to_the_right_of." A useful abstraction introduced in the late 1970s was the simplification of the geometrical design rules so that they could all be described as multiples of a basic unit, resulting in the so-called "lambda style rules" (Mead and Conway, 1980). The use of procedural layout languages and simplified design rules has been especially fruitful in the design of special array-type compilers, such as memory or data-path generators. They form a very important part of today's layout systems, including those offered by commercial CAD companies.

6.2 Layout Verification

The drawings describing the mask layers which form the integrated circuit contain millions of polygons. Whether these are generated by hand or by software programs, errors can be introduced making it necessary to perform exhaustive analysis on the data. One looks for three types of problems: compliance to the geometrical design rules, equivalence with the schematic data, and appearance of electrical effects detrimental to the chip performance.

Each semiconductor process has a set of geometrical design rules describing its layers, the minimum dimensions acceptable for each layer, the minimum separation among polygons, and the interactions between the different layers. These interactions allow, for example, the overlapping of a number of layers to form transistors or the prohibition of intersection of certain layers to prevent connections. A geometrical design rule checking (DRC) program verifies the polygon database measuring polygon sizes, distances, and intersections and indicates the places where a rule has been violated. Usually, the violations are superimposed on the layout in such a way that they can be displayed in the layout editor. Some editors, such as MAGIC (Osterhout *et al.*, 1984), allow running a DRC program interactively as the layout is being done.

The second problem that needs to be resolved is to ensure the equivalence of the devices formed by the masks with the database generated from the schematics (or some other data). Again, the process has rules that describe how electrical elements are formed and how the geometrical dimensions are translated into electrical parameters. A typical case in MOS technologies is how a transistor is formed by intersecting some rectangles in specific layers, and how the resulting rectangle's dimensions relate to the transistor's basic parameters, its channel width and length. So, we are considering two related problems: conversion of the geometrical database into devices and interconnections, and proof that the extracted device database is actually equivalent to another of the same basic type. A CAD program performing the first step is called a layout or node extractor, while the checking one is a wirelist comparator. Unfortunately, another set of circuit elements is created by the layout. For instance, rectangles overlapping in different layers, such as the metal layers used for interconnect, will create a capacitive coupling between the corresponding nets. Each technology has a number of effects introducing unintended circuit elements called parasitics. The parasitics can alter the circuit performance or, worse, the actual function that the circuit was designed to implement. The layout extractors usually extract the parasitics of importance to the design, and these are examined according to design restrictions and passed to simulators.

The approaches to rule checking and extraction have been similar. We can operate on the polygon database through a set of basic operations, such as intersections, unions, differences, and expansion, and express the extraction and spacing rules in terms of these operations. Another approach has been to rasterize the polygon data and "slide" a window recognizing specific patterns, taking advantage of the fact that the rules can be localized. In all cases, use of sorting techniques and special representations has been common. Since many rules are independent and apply on a layer-by-layer basis, the checking process lends itself well to the use of multiprocessors. A much more difficult issue has been the checking of three-dimensional effects, such as conductor couplings, where recognition of particular geometry patterns and scaling are used to avoid solving complex differential equations.

7. AUTOMATIC LAYOUT

Efforts to automate the layout tasks (as opposed to simplifying the entering and checking of data) by use of special algorithms started in the early days of CAD. Traditionally, layout tasks have been divided into placement and routing. Placement consists of finding the exact locations that the basic components or cells (small collections of gates that are treated as a single unit) will occupy on a chip or a board. Routing consists of determining the precise paths, including layers, that nets will follow to connect the basic elements' pins. Since many placement and routing problems fall into the class of *NP*-complete problems, it became necessary to develop heuristic algorithms to obtain solutions in reasonable computer times.

7.1 Placement

A key difficulty in placement problems is the huge search space. If we try to place N elements into N slots, there are $N!$ possible configurations. Today, a block in a chip can easily contain 10 000 cells, making it impossible to do anything remotely close to an exhaustive search. Algorithms to place components on a board started to appear in the 1960s. The basic ideas in the early approaches were first to cluster elements according to some specific criteria, such as having a large number of nets in common, and then to perform element exchanges to improve the configuration on the basis of some measure of its "goodness" or cost. The selection of which components to exchange was based on connectivity considerations. The cost function tried to reflect the congestion of the nets in the areas available for routing and some easily computable approximation to the actual net lengths that would result after routing. The simplest approximation to net length used is the half perimeter of a rectangle circumscribing all pins, followed in complexity by some special trees. The expectations were that routes would be short, and so the same tracks could be used for several nets achieving full routing within the available space. Examples of these approaches are described in Breuer's book (Breuer, 1972). One key deficiency in these initial approaches is that they could only drive the placement into a local minimum of the cost function.

A more elaborate model involved considering a placement as a graph, with the components as vertices and the nets as edges, and application of graph-partitioning techniques. In the early 1970s, the "min-cut" approach was introduced (Kernighan and Lin, 1970). As its name indicates, we try to exchange components so that if we "cut" the graph into two, the number of nets crossing between the two sides is minimized. In the process, many iterations are performed, and we are allowed to go through configurations that are not always better than the previous ones, allowing an escape from local minima. There have been multiple refinements of this basic idea. These include the use of elaborate net-weighting schemes to give preferences to some nets over others, the design of special software data structures to simplify the algorithmic complexity of the procedure (Fidduccia and Mattheyses, 1982), and the introduction of fictitious pins in a recursive approach to divide the available area (Dunlop and Kernighan, 1985).

In the early 1980s, a probabilistic approach to solving combinatorial problems was introduced (Kirkpatrick *et al.*, 1983). The overall process was analogous to the melting of a solid at high temperature and then slowly cooling it to form a crystal (annealing to a state of minimum energy), thus the name simulated annealing. The method had a number of important advantages: the cost function could be quite general, the method allowed escaping from local minima, and the process could be stopped at any desired point. More general schemes following the annealing basic principles were called probabilistic hill-climbing algorithms. The algorithms required determining three basic operations: the generation of new configurations, the modification of the algorithm's control parameters, and the configuration acceptance or rejection criteria. Formal proofs of convergence with probability equal to 1 to a global minimum were given under fairly general assumptions on the specific problem, based on Markov chain theory (Romeo and Sangiovanni-Vincentelli, 1985). In the case of simulated annealing, the control parameter is called temperature. Initially, the temperature was decreased by a constant factor in a geometrical fashion (new_temperature = old_temperature×ratio, where $0 < \text{ratio} < 1$), but a number of adaptive schemes have been introduced. The acceptance criterion is based on the comparison of an exponential function of the cost difference between the current and newly generated configuration, exp(−cost_difference/temperature), with a randomly generated value in the range of 0 to 1. Many problem-specific stopping criteria have been described.

Simulated annealing has been applied with great success to the placement of row-style, standard cell blocks in integrated circuits. A large number of refinements, particularly related to techniques to cut down the computer run times of the algorithm and to more general placement problems, have been introduced. Timberwolf, a system originally developed in the University of California at Berkeley and subsequently at Yale University, deserves particular mention due to its industrial acceptance (Sechen, 1988).

In general, the basic measure used in placement algorithms has been a combination of total area after routing and average interconnect net length. Recently, interest has shifted toward "performance-driven" placement, meaning taking into account the effects of the placement on the overall performance of the circuit in a more direct fashion. For instance, nets can have very different net lengths (roughly proportional to delay) and still meet the timing requirements because of their specific path constraints (Benkoski and Strojwas, 1991). While minimal area and short connections are certainly related to these objectives, the emphasis and resolution have changed. Closer ties to the timing verification systems, and possibly changes in the circuit parameters, may be required to meet all constraints automatically.

7.2 Routing

Routing is the process of determining the actual paths assigned to the interconnections among the pins of the placed components. Each technology allows a certain number of conducting layers to carry nets and of "vias" or "contacts" to switch among the layers. Each layer has its own electrical and geometrical characteristics, such as resistivity per square, fixed or variable widths, and many others. The vias also vary widely; in some cases we can jump directly across several layers, in others only between neighboring ones. To illustrate the ranges, we give two examples. First, until recently, CMOS technologies only allowed the use of up to two metal layers for routing, while boards had dozens of layers available. Second, other typical constraints are that all paths must fit inside a fixed area, that paths must never get closer than a given minimum spacing, or that certain layers are assigned a fixed direction (north–south or east–west). A router is a program that assigns paths to the nets so that paths corresponding to different nets never overlap on the same layers.

A common situation is that only two directions are allowed, so that "wires" can turn 90°, resulting in what is referred to as "Manhattan geometry." If we add to this assumption a fixed width and minimum spacing per layer, then each layer can be modeled as a grid. The first algorithm reported to find paths, still of interest today, is the Moore–Lee algorithm (Lee, 1961), based on graph-theory shortest-path algorithms. The basic idea is to expand a net, starting at its pins, to the neighboring grid points successively until all required connections are achieved. Routers based on this technique are called maze routers. While very flexible, their results depend on the order in which the nets are routed, and their implementation can consume large amounts of memory since we need to store a matrix representing the grid points. A new algorithm was proposed on the basis of a technique called line search (Hightower, 1969). Instead of advancing by a minimum unit, we try to determine in one step a whole line segment containing the "current" point, extending the segment until an obstacle or a target is found. Once a segment is constructed, we explore new segments in the direction orthogonal to the previous one, starting from each of its end points. The search is conducted from the two points we wish to connect, and when the two set of segments intersect, the connection has been achieved. While the algorithm does not guarantee that a path is found, or even that a path exists, it is much faster than a Moore–Lee type algorithm and it takes less memory. Many refinements and combinations of these basic approaches have been used through the years, particularly for board routing. Another problem frequently studied was how to "rip out" a connection already made to allow the completion of others and to "reroute" the previous one.

As integrated circuits moved into the VLSI scale in the late 1970s, routing among their basic cells or blocks required dealing with areas that, properly scaled for the interconnect layer dimensions, were much larger than those found in boards. The routing problem was then split into subproblems, each with a different objective. The available area was divided into routing regions, usually rectangular, with special characteristics so that different algorithms could be applied in each type of area. The overall routing process was divided into phases, each adding increased levels of detail. In the case of ICs, the division of the chip into major functional blocks and routing regions is called floor planning.

The most important division introduced was between global and detailed routing, a concept applicable to IC and board problems. Global or "loose" routing is the process of simply distributing nets among the identified routing areas. Once this assignment is complete, the detailed routing phase determines the exact paths inside each area using any appropriate router. For global routing, there are two key considerations: to minimize an estimated net length and to avoid excessive congestion in any area (the allocation of so many nets into the area that detailed routing becomes physically impossible). One common approach has been to model the routing areas as vertices in a graph whose edges connect only neighboring areas. The model is refined by adding capacity to the edges to represent the number of nets that can be allowed in the region, and a length to indicate an expected average distance that a path will traverse inside the region. Once a model like this is set up, many algorithms can be called to assign the nets to the graph arcs.

Some special areas have become typical in IC layout, generating considerable research to solve their specific problems. The most important has been channel routing. In this case, we have a rectangular region with pins located only at its top and bottom edges; the vertical separation can be changed, and two conducting layers are available, one for each orthogonal direction. The problem is to connect all pins using the minimum possible number of horizontal tracks or, equivalently, vertical spacing (Hashimoto and Stevens, 1971). Many algorithms have been developed to solve this problem (see Lengauer, 1990). Another important region is the switch box, differing from a channel essentially by having pins on all sides and nonrectangular shape.

A related problem is the interaction among the different regions through the routing process. We may be forced to enlarge a channel region, altering the overall structure of the initial division: New regions can easily appear. More integrated approaches to resolve routing without resorting to complex area divisions are starting to receive attention. A key issue is the ability to route these large regions in reasonable computer times. The most recent CMOS gate arrays, offering hundreds of thousands of gates and three metal layers for interconnect, have made the problem particularly interesting for industry.

8. HIGHER-LEVEL DESIGN TOOLS

A number of approaches have been developed to move the design process as much as possible toward higher levels of abstraction. To reach this objective successfully, we need to increase the automation of the "lower-level" design tasks. Systems that automatically produced layouts starting from high-level descriptions were referred to as silicon compilers (Johanssen, 1979, Siskind *et al.*, 1982). The name was based on an analogy with a compiler for a software language, the behavior-level or RTL description playing the role of the language and the mask-level layout the equivalent of the object code. A large amount of research was done on the topic, and the approach generated considerable controversy. Ultimately, these early tools failed in actual applications because of their too broad scope. For a general-purpose microprocessor, many problems needed to be resolved simultaneously at a time when none of them, considered individually, had a fully satisfactory solution. For more recent developments, the reader is referred to De Micheli *et al.* (1987), and Gajski (1988).

Some silicon compilers attempted to map a description into a specialized chip architecture, restricting their applicability but taking advantage of optimizations valid only in their more restrictive domains. The most successful area has been in compilers targeted to digital signal processing algorithms. An early effort, a system developed at Edinburgh called FIRST, targeted filter structures using a bit serial architecture implemented in MOS technology (Denyer and Renshaw, 1985). Other ongoing efforts in this area that can be mentioned are the CATHEDRAL system at the Interuniversity Micro-Electronics Center in Belgium (Note *et al.*, 1991) and LAGER at the University of California at Berkeley (Pope *et al.*, 1987).

Other types of specialized systems in existence today are also called "silicon compilers." In general, these tools generate layouts for special kinds of circuits starting from a schematic like description and using libraries of cell layouts. So most are really special module generators that perform, beyond assembling a layout, specific optimization steps and typically generate appropriate simulation models. Standard examples include PLA and memory structure generators and data-path assemblers. These tools are offered by commercial CAD vendors and have been widely used in industry.

GLOSSARY

Bus: A set of bit signals of related type—for instance, the 32-bit signals commonly used as a word length in computer architectures.

Cell: A set of gates that is treated as a single entity. Cells are usually placed in libraries, with multiple descriptions available such as layout, schematic symbols, and simulation models.

Circuit: A collection of interconnected electrical devices. It consists of electrical devices and connected pins (nets or nodes). See Network.

CMOS: Complementary metal oxide semiconductor, an integrated-circuit technology. See MOS and NMOS.

Contact: Vertical connection from one layout layer to another; also referred to as via.

Data Path: A regular structure used in layout, consisting of functional units and busses connecting them.

Electrical Device: Primitive circuit element, such as resistor, capacitor, inductance, or transistor.

Floor Plan: The physical layout of the chip in terms of its main units, such as data paths, memories, and power and ground busses.

Gate Array: An integrated circuit where transistors are arranged in a two-dimensional array, and the design is done by specifying only the metal interconnect layers.

Grid: Uniformly spaced array of points in a coordinate space. Usually displayed in layout editors to guide the editing process and indicate the minimum geometrical resolution available.

Interconnect: A conductor electrically joining two or more pins.

Layout: The physical description of a design, in terms of polygons attached to technology layers, forming interconnect and electrical devices such as transistors.

Logic Gate: A functional unit of combination Boolean logic, such as an inverter (NOT function) or a NAND-2 (logical AND followed by NOT of two input signals).

Mask: Glass usually covered with chrome etched away in particular areas where specific material will be placed on the wafer during the semiconductor manufacturing process.

MOS: Metal oxide semiconductor, an integrated-circuit technology. NMOS and CMOS are the two most common MOS technologies.

Net: A set of electrically connected pins.

Netlist: A list of all nets in a circuit.

Network: A collection of interconnected electrical devices. It consists of electrical devices and connected pins (nets or nodes). See Circuit.

NMOS: *n*-type metal oxide semiconductor, an integrated-circuit technology.

Pin: A connection point in a device.

Router: A software program used to create the interconnections in a network where the devices have physical locations.

Standard Cell: A cell whose layout conforms to some uniform characteristics (such as given height). Usually, they form libraries, and designs are done with choice restricted to only those elements.

Transistor: An active semiconductor device with three (or more) terminals. It is a basic element in integrated-circuit design.

Via: Vertical connection from one layout layer to another; also referred to as a contact.

VLSI: Very-large-scale integration, a term used to describe ICs containing over 100 000 transistors.

Wire: The physical realization of a connection, indicating a detailed conducting path among pins.

INTRODUCTION

Manufacturing is defined as a function of transforming raw materials into valuable products that meet the public's needs, by means of facilities, information, and labor power. It is also expressed more concretely as a series of interrelated activities and operations involving the design, material selection, planning, production, quality assurance, management, and marketing of the product by the manufacturing industries (CAM-I, Standard Committee, 1978). Automation in manufacturing has made great strides since the invention of electronic computers. Some typical examples of manufacturing technologies developed so far in conjunction with computers are CAD (computer-aided design), CAM (computer-aided manufacturing), CAD/CAM, FA (factory automation), and CIM (computer integrated manufacturing). CAM, which is the subject of this article, is defined as execution of process and operation planning with the proper input data such as product design specification and production order, and control of production processes with the assistance of computers. The interrelationships between CAD, CAM, FA, and CIM are explained in Sec. 2 (see also Fig.1).

1. HISTORY

The history of CAM dates back to the early 1950s when research was initiated for the automation of cutting processes by means of NC (numerical control).

NC is a control method in which motions of machines are controlled according to a number of pulses that are generated by a digital circuit depending on input numeric data. Once a program that represents the numeric data is prepared, the operation of the machine can be controlled automatically. NC can be applied to various machines such as machine tools, industrial robots, plotters, etc. The control equipment for NC is generally called the NC controller.

The developments of numerical control have been made mainly in two areas. One is the development of the NC controller that automates production processes, and another is development in the NC program preparation that leads to automation in the area of information processing for manufacturing.

In the first generation of NC controllers, functions such as arithmetic operations, comparisons, and decisions were carried out by a hard-wired logic circuit. However, complicated circuits became necessary with the expansion of the functions. In the early 1970s, CNC (computer numerical control), which used a computer for performing these functions, was developed to improve functionality, expansibility, operability, and maintainability. Nowadays microprocessors are used. DNC (direct numerical control) was also developed in the late 1960s to control and coordinate a number of numerically controlled machines. The technical developments of NC controllers are summarized in Table 1.

Efforts have also been made to add new control features to the NC controller, such as adaptive control and learning control. An adaptive controller identifies the changes in the states of the manufacturing processes and system components, adjusts the control parameters so as to fulfill the control objectives, and then executes the control. Adaptive controllers have already been put into practical use in certain applications. In the next generation of NC controllers, the development of a learning controller is also desired. In addition to the adaptive control function, a learning

Table 1. Development of NC Controller.

Year Item	1976–1979	1980–1985		1986–1991	
		Microprocessor			
Processor	Bit slice	8 bit	16 bit	32 bit	CISC/RISC

Servo system	DC analog servo		AC analog servo	AC digital servo	

controller has the function of accumulating and making use of the data obtained in the preceding operations to improve the control performance.

The automation of information processing for manufacturing originates in the development of a general-purpose NC programming language called APT (automatically programmed tools). It was developed at MIT for automatic tool path generation. Later on, IITRI (Illinois Institute of Technology Research Institute) took over the responsibility of the development program and improved the system. The project resulted in APTIII and APTIV, which have greatly contributed to the automation of NC data generation.

Tens of general-purpose NC programming languages have been developed in the world since then. At the same time, a large number of special-purpose programming languages that can be applied to specific machine tools or products have been developed by many companies. The success of the APT system has stimulated the development of programming languages for many other manufacturing processes, such as those for plastic forming, assembling, and inspection.

The APT system can only generate tool paths of cutting processes. However, there has been a demand for the extension of the programming system functions to cover the automatic selection of tools and the determination of operating conditions. EXAPT (extended subset of APT), developed in the mid-1960s, is the first general-purpose system that was provided with such functions. Many special-purpose NC programming systems with these functions have been also developed.

The next step in the development of CAM information systems was to realize a system that could execute all necessary information processing from obtaining CAD data to generating data for production processes, such as NC data and process instructions. This kind of system is called the CAD/CAM system. The main problem of the system was that of developing CAPP (computer-aided process planning). Three approaches have been proposed for CAPP so far; they are a variant type, a generative type, and an expert type. The studies of these three types of approaches were started in the late 1960s, the mid-1970s, and the early 1980s, respectively.

In the early 1980s, people became interested in producing a variety of products; therefore, the integration of CAPP and production scheduling in addition to the integration of CAD and CAPP were proposed (e.g., Chryssolouris and Chan, 1985; Iwata and Fukuda, 1989).

In 1988, the concept of concurrent engineering or simultaneous engineering was proposed suggesting parallel processing of design and manufacturing information with constant interactions with each other rather than serial processing (Pennell and Winner, 1989).

FA came into practical use in the early 1980s, and from the mid-1980s, CIM (computer integrated manufacturing) has been put into practice. (The first book about CIM is Harrington, 1973.) With the advance of FA and CIM, CAM is regarded as the integrating component of the total manufacturing system.

2. BASIC CONCEPT AND MAJOR COMPONENTS OF CAM

CAM covers the functions of process planning, operation planning, production control, and production process systems as shown in Fig. 1. FA, on the other hand, includes design and production management (production planning, scheduling, and dispatching) in addition to the activities involved in CAM. Further expansion of the concept of FA leads to CIM, which includes R&D (research and development), marketing, and sales. Therefore, CAM can be understood as a subset of FA and CIM.

The information processing relevant to design, process planning, and operation planning is generally called technological information processing. Thus CAM plays a main role in technological information processing.

Process planning is the planning of production processes of parts or products based on the information and drawings generated in the design stage. Production processes include operations (machining, assembling, painting, packaging, etc.) and interprocess operations (transportation, storage, etc.). The results of the process planning are used as input information for operation planning and scheduling/dispatching.

In operation planning, operations comprising the process are identified and various items required for the executions of operations are determined, such as machining conditions and tool paths.

Production control is processing of control and management information for achieving efficient and reliable execution of various operations and interprocess operations. The production process is a series of operations to transform material into valuable products. CNC and DNC are the important elements of systems that execute the production processes.

It should be noted that in some countries the term CAM is used with a wider or narrower meaning than the definition given here. It may include the functions of production planning, scheduling, and dispatching in addition to the functions defined here, or on the contrary, it may exclude production process systems. The term process planning may also be used in a different way. It may involve functions of both the process planning and operation planning.

3. PROCESS PLANNING

3.1 Processing Flow of Process Planning in Machining for Machine Parts

As defined in the previous section, process planning is the process of generating the production process information such as information about production processes, production machines, jigs, fixtures, and so on, based on the data obtained from design information and drawings (geometry, dimension, tolerance, working conditions, etc.). The results of process planning are usually described in the form of a process chart. Figure 2 shows the information processing flow in the process planning of machine part production. Although the figure shows a straightforward process, there could be a number of feedback loops in the process. This processing flow can be applied to process planning for the production of other types of products such as semiconductors, printed circuit boards, apparel, food, etc., though there are specific features and particular considerations in the details of processing according to the type of product.

3.1.1 Understanding Design Information and Drawings, and Recognition of Production Features. The first step of process planning is to understand the information represented in assembly drawings, part drawings, and part lists, which are prepared in the design stage usually using CAD systems. The information is then checked to see whether it provides all the necessary and error-free information for the subsequent steps. At the same time, the features of products or parts are identified from the aspect of production; these are generally called production features. For example, typical forms or surfaces to be machined are recognized to prepare for the subsequent steps.

3.1.2 Determination of Production Processes and Their Sequence. In this process, possible production processes are selected on the basis of design information, drawings,

and manufacturing features. There can be many possible combinations of various production processes such as deformation processing (casting, forging), removal processing (machining, grinding), joining (welding, adhesion), and treatment (surface treatment, heat treatment) for producing the same part with the same geometry. The optimum combination of production processes is determined on the basis of various evaluations in terms of quality, lot size, economic efficiency, and resource savings.

In the case of machining, for example, possible machining processes (such as turning, drilling, end milling, cylindrical grinding, etc.) are selected for each form or surface to be machined in the part. Another example is the selection of a welding method. There can be arc welding, resistance welding, electroslag welding, electron beam welding, laser welding, etc., depending on material and geometries of parts.

If there are multiple possibilities, the optimum processes and their sequences are selected in terms of available facilities, technological level and experience, economic efficiency, production time, etc.

3.1.3 Determination of Production Machines. The production machines (machine tools, forming machines, assembling machines, etc.) are determined corresponding to the production processes selected in the previous step. Since the forms and surfaces of the part are generated by the relative motion of the tool and the part, the possible tool geometry can be identified in this step.

It should be noted that one production machine may be able to perform multiple production processes. Therefore, there could be a number of possible combinations of machines. The optimum combination should be selected considering production time, the number of machines, load balance of the machines, economic efficiency, etc.

3.1.4 Selection and Design of Jigs and Fixtures. Fixtures for fixing workpieces on the pallets or tables of the production machines, and jigs for positioning and clamping the workpieces and for guiding the tools, are selected in this step. This is called auxiliary equipment and is used for improving accuracy, simplifying operations, and shortening the working time.

There are various technological and technical factors to be considered in designing and selecting the auxiliary equipment. These factors are classified into mainly three categories. They are the factors about the production machine such as the position and orientation of the spindle; the factors about the workpiece such as the gravity center and the reference planes for clamping, machining, and assembling; and the factors about the production operations such as vibration and thermal deformation.

3.1.5 Estimation of Operation Time. The operation time is estimated on the basis of the results of the steps described in Secs. 3.1.1–3.1.4. If there are multiple options in the process plan, the shortest operation time is adopted as the estimated time. The estimated time in this step is, however, a rough estimation based on standard times. The precise estimation is carried out after the operation planning.

3.2 Process Planning for Assembly of Printed Circuit Boards

Assembling methods, sequences, and machines are determined in assembly process planning. Few general-purpose process planning systems have been developed for assembling operations that differ from those for machining operations. Process planning systems developed so far are specific to the assembling operations by particular machines. In the following, the process planning for assembly of printed circuit boards, which are widely used in modern industries, is explained.

Figure 3 shows the processing flow of process planning for mounting electronic parts (resistors, condensers, ICs, etc.) on printed circuit boards. Obtaining the data from the CAD system, assembling processes are assigned first. Then collisions between insertion heads of inserters and parts are examined. This process, which is generally called collision check, is important, because the proper insertion sequence should be selected so as to avoid these collisions. Next the assembling processes are determined. Finally, the optimum operation sequence is determined, if there are multiple possibilities in determining insertion sequences. The total mounting time is usually adopted as a criterion for optimization (Japan Society for Precision Engineering, 1991).

3.3 Computer-Aided Process Planning System in Machining

Automation of process planning has been studied mainly for machining. The efforts in developing the CAPP system have contributed to the standardization of manufacturing processes and facilities, and for the rationalization of organizations. However, technologies have not matured to the point that current CAPP systems provide sufficient capabilities for CAD/CAM integration. Thus, the improvement of CAPP systems is an important subject for future factories.

The CAPP systems developed so far are categorized into the following three types:

1. variant type,
2. generative type, and
3. expert type.

3.3.1 Variant-Type CAPP System. The variant-type system uses a decision table for planning the production processes as shown in Fig. 4. The decision table represents the logic of the process planning that has been acquired from past experience. Many systems utilize the concept of GT (group technology) in which parts are grouped into families based on similarities in their production. The code representing the parts family is called the GT code. G2030 and H1819 in Fig. 4 are examples of GT codes. The decision table can be formed so as to represent the sequences of production processes corresponding to the specific GT codes. The systems of this type were the first of the three types to be developed. AUTOPROS (Nissen, 1969), MIPLAN (TNO, 1981), CAPP (CAM-I, 1976), and AUTAP (Eversheim and Fuchs, 1980) are some well-known systems of this type.

3.3.2 Generative-Type CAPP System. In the generative-type CAPP system, the process planning is performed on the basis of the logic that is obtained from the analysis of the part

and the machine tool, in terms of part geometry, required accuracy, form-generating functions of the machine tool, and other related manufacturing technologies. Figure 5 illustrates the basic concept of the generative-type system. Although systems of this type have been studied for many years, further studies are required to develop practical systems, because the logical relations between the production features of the part and the production processes are not clarified.

Some typical research works about systems of this type are CAPSY (Spur *et al.*, 1978), CIMS/PRO (Iwata *et al.*, 1977), and CPPP (Mann, 1977).

3.3.3 Expert-Type CAPP System. In recent years, as it became clear that the knowledge and know-how of the process planner played an important role in the practice of the process planning, many expert systems were developed. These systems consist of the inference engine, the knowledge base (containing the know-how and knowledge of the experts), the database (containing general data), the system that acquires the knowledge from the experts, and the interface between the CAD system and the users, as shown in Fig. 6. Many systems of this type have been developed, such as GARI (Descotte and Latombe, 1985), TOM (Matsushima *et al.*, 1982), CIMS/PRO (Iwata and Sugimura, 1984), XPLAN (Van't Erve and Kals, 1986), and KAPPS (Iwata and Fukuda, 1987). Current research work is mainly focusing on a feature-based approach. Process planning is associated with production features identified in the geometric models of parts that are generated in the design stage using CAD systems.

Until 1980, research and development work about CAPP was carried out in the field of removal processing, especially for machining. In the 1980s, however, research was extended to cover assembling and deformation processing (casting, forging, sheet-metal forming). Since 1990, it has been recognized that research on automation of process planning for all manufacturing processes is needed.

4. OPERATION PLANNING

4.1 Processing Flow in Operation Planning

The task of operation planning is to determine the detailed information necessary for the execution of production processes (such as machining and assembling), on the basis of the output of the process planning. The information processing flow for the operation planning of machine parts includes

1. determination of the operation sequence and operators within a process,
2. selection of tools,
3. determination of conditions of the operations,
4. determination of the tool path, and
5. postprocessing.

Operation planning of products or parts with simple geometries does not require much experience. However, for products with complicated geometries even the determination of

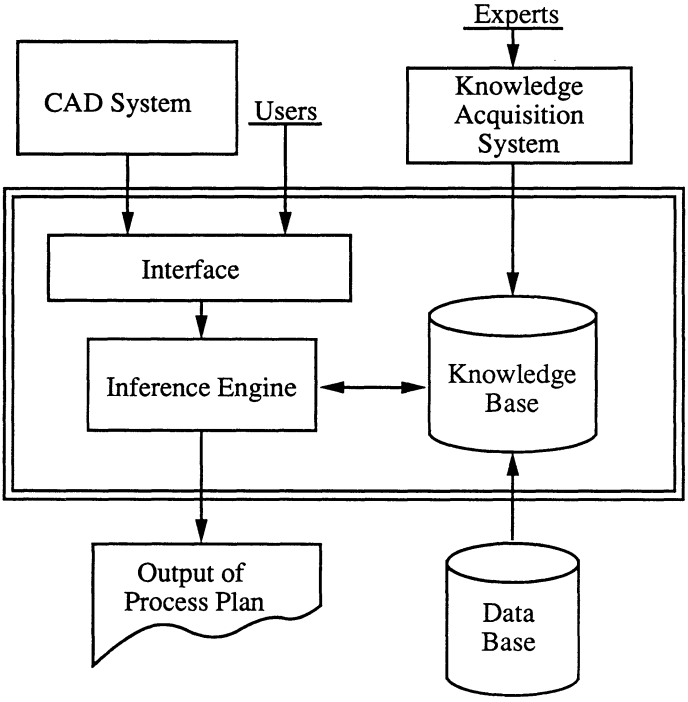

FIG. 6. Basic structure of expert-type process planning system

the tool path is a difficult task and requires a lot of work, time, and cost. A lot of effort has, therefore, been made on the automation of operation planning.

4.1.1 Determination of the Operation Sequence and Operators within a Process. Each production process determined by process planning is analyzed to identify what operations should be executed in which sequence and what actions of the operators are required within the process. Let us consider the operation of external cutting in turning, for example. The required operations are chucking the workpiece, clamping by the tail stock, air cutting, cutting (a number of times, if necessary), measuring, detaching the workpiece, cleaning the machine, disposing of chips, etc. In operation planning, such operations must be properly selected and their sequence must be determined. The series of operations for one production process is usually called the work cycle.

4.1.2 Selection of Tools. In this step, proper tools in terms of material, geometries, and dimensions are selected on the basis of the selected machines (type, size, rigidity, power, structural configuration, etc.), workpieces (material, hardness, rigidity dimension, and accuracy before and after machining, etc.), and types of operations.

4.1.3 Determination of Conditions of Operation. The proper conditions of the operations are determined in this step on the basis of the selected machine, tools, fixtures, and the role of the operators if operators are necessary. The conditions have to be determined so as to produce a product or part that meets the specifications and also to achieve efficient, economic, reliable, and safe operations.

Many studies have been carried out about the optimization of the condition of operations. Note that there are multiple operations to be considered in optimization, and different companies have different objective functions and constraints.

4.1.4 Tool Path Generation. In this step, proper tool path is generated according to the geometry of the part, the movement of the machine tool or assembling machine, and the geometry of the tools. The path must be determined to avoid collision between the tool and tool holder, on the one hand, and the workpiece and the jigs, on the other, and also to achieve minimum operation time.

In the past, the problem of tool path generation was dealt with independently whether the part geometry was $2\frac{1}{2}$ dimensional or 3 dimensional. However, efforts have been made to unify these problems in recent years. The term $2\frac{1}{2}$-dimensional is a special term in the field of manufacturing. It is defined as the dimensionality that is composed of a contouring motion in a 2-dimensional plane and a linear motion along the line perpendicular to the plane. Examples of $2\frac{1}{2}$-dimensional machining are drilling operations, face milling operations, and turning operations.

4.1.5 Postprocessing. In the previous steps, the tool path data were obtained in the form of cutter location data (CL data), which has a general format independent of the configuration of the machine tool. Postprocessing is a process to convert CL data into NC data adapted for the specific machine tool. The postprocessor should be designed so that NC data generated by it should not contain waste motions, should be adjusted to the timing of the mechanisms such as an automatic tool changer, and should be accompanied by proper documents that can be used for various checks by the operator.

The results of operation planning as described above are available through various media such as paper, tapes, and floppy disks. Nowadays they are often transmitted directly from the computer to the machine.

4.2 Computer-Aided Operation Planning Systems

Most computer-aided operation planning systems have been developed as special-purpose systems in companies; thus very few general-purpose systems have been developed.

The most famous general-purpose systems are APT (automatically programmed tools) and its subsets that were developed for the automation of tool path generation. EXAPT (extended subset of APT) is also well known as a general-purpose system that covers the determination of operation sequence, the selection of tools, and the determination of conditions of operations in addition to the tool path generation (e.g., Budde and Weisswellar, 1973).

The EXAPT processor reads a part program written in EXAPT language, executes technological calculations, and outputs the tool path data in the form of CL data, which are then processed by the post processor and converted to the NC data adapted to the specific machine. It can also issue work lists and work orders to the operator.

In the APT and EXAPT systems, NC language is used to input part programs into the system. Other types of input methods have also been developed such as a menu-driven interactive system and a direct interfacing to CAD system.

5. PRODUCTION CONTROL

As described previously, the objective of production control is to realize effective and safe operations of production processes such as machining, assembling, and inspection, and interprocess operations such as transportation and storage. As seen in Fig. 1, the data utilized for production control are classified into the following categories:

1. technological data generated by process planning and operation planning and management data prepared by production planning and scheduling, and
2. the data gathered in the production process (shop floor).

Figure 7 shows the software organization of the production control system which generates the control information using various relevant data. The system has five major functions: data management, operation control, operation monitoring, performance tracking, and status display.

The basic subfunctions and typical application-oriented subfunctions of each function are represented in the figure. The extent of the functions that are covered by a system is dependent on the level and organization of the system. Taking for example FMS (flexible manufacturing system: computer-controlled automated manufacturing system for mid-volume, mid-variety parts production, in which NC machine tools or NC manufacturing cells are combined organically by automatic transportation equipment), the operation control function is, so far, limited to the control of machining operations. There are very few systems that have the functions of assembling control and washing control. Recent systems, however, tend to be equipped with all these functions.

The operation monitoring function is an important function in order to realize automated operation of the production processes.

FIG. 7. Software organization for production control.

This function includes monitoring of machining and assembling operations, monitoring of work cycles and monitoring for failure diagnosis, and recovery actions.

It is also very important to pay attention to the human interface that provides the means of communication between the system component and personnel, especially when the system advances in automation.

6. COMPUTER NUMERICAL CONTROL AND DIRECT NUMERICAL CONTROL

Machines and equipment that comprise the production process system are commanded by production control. Computer numerical control (CNC) and direct numerical control (DNC) play a major role in controlling these machines and equipment.

6.1 CNC

The typical architecture of a CNC system is shown in Fig. 8. In a CNC system, most of the NC functions such as input/output, arithmetic and control, and servo control are performed by microprocessors instead of hardwired circuits. As seen in Fig. 8, various processing units are contained, such as a communication control processor, a graphic processor, a peripheral equipment control processor for robot and sequence control, and a servo processor. It also has a PTR/FD interface and main spindle drive interface.

Input devices are dependent on the input method of information. Industrial robots, for example, often use a teaching pendant instead of a paper-tape reader by which an operator can instruct the controller in motions of robots. It was a common practice to use paper tapes or floppy disks containing NC programs for inputting the control information to the CNC controller, but recently, an interactive programming function has become available on CNC controllers. With this function, an operator inputs necessary data under the guidance of messages and menus displayed on a CRT in an operational panel. The CNC controller then generates NC programs automatically.

6.2 DNC

DNC systems have been developed for the purpose of controlling and coordinating a number of machine tools and robots on a shop floor by a central DNC computer. The DNC computer manages part programs and distributes them to the machines. The management functions of the part programs include the functions of input/output, storage, editing, copy, deletion, modification, renewal, retrieval, etc. While the DNC computer transmits the part programs to the machines, it monitors the operating status of the machines and coordinates their operations. At the same time, it can perform other functions such as production management and part programming. A DNC system is effective in improving the availability of machines because of the timely distribution of NC data. It is also effective in improving the reliability of distributing part programs, because it can transmit them directly to the machine without use of NC tapes that have been commonly used with NC machine tools.

To make the most of the DNC system advantage, it is important to use effective DNC computer software for production management, such as software for scheduling, controlling machine loading and material supply, and report generation (percentage of machine utilization, production performance, etc.).

7. DEVELOPMENT OF CIM

The application of computers in the manufacturing field has made rapid progress since the 1960s. Until the mid-1980s the systems were developed separately in each area of manufacturing such as design, production planning, production management, and shop floor control. In the late 1980s, however, there appeared a strong movement to the integration of the systems of different areas, which is called CIM (computer integrated manufacturing). The trend from CAD and CAM to CIM is illustrated in Fig. 9.

The several levels of CIM can be considered in the course of development as seen in Fig. 9. In the early 1990s, most CIM systems correspond to level 3, which integrates the activities from the acceptance of customer's

needs and orders to shipping and distribution of products. The system aims to achieve the integrated processing of manufacturing tasks by realizing a coherent flow of information and material. As the number of companies and researchers engaged in CIM increases, however, the concept of CIM tends to diversify and to become ambiguous. The organization of level-3 CIM is represented in Fig. 1.

The base technologies that support CIM are

Besides CIM,

1. concurrent engineering or simultaneous engineering in which CAD and CAM are integrated and
2. integration of CAM and scheduling

are the noteworthy topics in relation to the CAM integration.

8. SUMMARY

CAM involves two aspects of computer application in manufacturing. One is the computer control of machines to automate the production processes, which originated in the development of NC machines. The other is the computer processing of production data, which involves computer-aided process planning, computer-aided operation planning, and production control.

Nowadays CAM is widely realized in most areas of manufacturing, and the level of automation is becoming more and more sophisticated. Along with this tendency, expert systems that can accumulate and utilize human knowledge and experiences relevant to CAM were recognized as a practical approach and have been rapidly developed in recent years. Automated operation of the factory has also made progress resulting in the automated operation of the 66 h from Friday evening to Monday morning. In addition to the development of each CAM technology, the integration of various manufacturing activities such as design, management, marketing, etc., has attracted strong attention. The trend is now moving from FA to CIM. CIM is, and will be, a key technology of manufacturing in the 1990s and will develop further, moving toward "intelligent CIM."

GLOSSARY

CAD: Computer-aided design.

CAM: Computer-aided manufacturing.

CAPM: Computer-aided production management.

CAPP: Computer-aided process planning.

CIM: Computer integrated manufacturing.

CNC: Computer numerical control.

DNC: Direct numerical control.

FA: Factory automation.

FMS: Flexible manufacturing system.

GT: Group technology.

IC: Integrated circuit.

Manufacturing: A series of interrelated activities and operations involving the design, materials selection, planning, production, quality assurance, management, and marketing of parts or products.

NC: Numerical control.

Operation: A defined action, i.e., the act of obtaining a result from one or more elements.

Operation Planning: Planning of operations based on the plan prepared by the process planning.

Process: A systematic sequence of operations to produce a specified result.

Process Planning: Planning of processes for the production of a part or product on the basis of the information and drawings generated in the design stage.

Production: Fabrication and assembly of a part or product.

Production Control: The function of directing or regulating the ordinary movement of parts or products through the entire production process from the requisitioning of raw materials to the delivery of the finished products.

INTRODUCTION

Data of every kind (citations, facts or numeric data) have been collected and handled since the beginning of the scientific era. Until a few decades ago, this handling was carried out by pencil, by ink, or in printed form, but all on paper. Thus we can speak of the paper age in science. In physics, data were published in journal articles, in monographs, in textbooks, and in data compilations. In addition, citations were already regularly compiled and published in abstract journals in order to facilitate the access of physicists to literature. Good examples were *Physikalische Berichte,* founded as *Fortschritte der Physik* in 1845, and *Physics Abstracts,* founded as *Science Abstracts* in 1898.

As far as numerical data are concerned, major efforts have been made to compile and evaluate these in handbooks. One of the best examples is Landolt–Börnstein, *Numerical Data and Functional Relationships,* of which the first volume was published in 1883. However, even in this paper age the physics community was confronted (as also holds true for other science communities) with an exponential growth of the literature and data, a fact that was, however, not realized by the community because the absolute numbers were not so large as they are today.

After the second World War, at the end of the 1940s and the beginning of the 1950s, the development of computers began (see COMPUTERS). In the middle of the 1950s we had the first mainframes, in the middle of the 1960s the first minicomputers, and in the middle of the 1970s the first microcomputers. In parallel, new supercomputers became available from the middle of the 1970s onwards. This computer development had two effects. On the one hand, it speeded up the increase in the amount of data and information generated, by some kind of feedback effect (e.g., because of the automatization of the measurement process), and, on the other hand, the capacity to handle and store numeric as well as alphanumeric information also increased. For the first time large amounts of data and information could be handed easily and inexpen-

sively. Thus the electronic revolution offered the possibility to overcome at least partly the problems connected with the data and information explosion.

In the electronic age we now have data in electronic form or, as it is normally said, in machine-readable form. Usually a collection of electronically stored items is called a database. These electronically stored items can be citations, facts, numerical data, or even the full text of an article. Accordingly, one distinguishes between ***bibliographic, factual, numerical***, and *full-text* databases. The bibliographic databases contain only references (titles, authors, abstracts, sources, etc.) together with other items for the corresponding subject analysis (classification, descriptors, etc.) The factual databases contain other structured but mainly non-numeric data. The numerical databases are defined by the fact that their content is dominated by structured numeric data. The full-text databases contain complete and unshortened texts from articles or other written papers. Next-generation databases will be bigger and more complex, containing a mixture of the above types of data, and will be used extensively for decision support purposes (Silberschatz *et al.*, 1990).

Let us now come back to the computers themselves: What are their advantages? They are ideal for handling data insofar as they are able to store, manipulate, display, and retrieve large amounts of data quickly. Even printed versions can be produced with very little human intervention, so that the transfer of data from the electronic form into the old-fashioned paper form is greatly facilitated. Another advantage of the computer technology development is that the costs of storage and access are constantly decreasing, that we can more easily replace old data by new data, i.e., it becomes easier to update our data collections, and that we can search more specifically for data in a database than was possible in the printed works via the indexes.

As was to be expected, the introduction of computers has also led to unwanted and less favorable developments. In the paper age each scientist and engineer interacted directly with each data item. He had to select the data and make all the necessary manipulations himself. Therefore the contact of each scientist and engineer with his data was very close. The introduction of computers had the consequence of a certain decoupling between humans and the data, which in some instances has led to inconsistencies, ambiguities and a loss of overall quality. On the other hand, whenever computational cross-checks can be made, typical human errors have been all but eliminated.

1. DATA MODELS AND FILE DESIGN

1.1 Data Storage

A computer is an excellent instrument for storing information. Even the simple $5\frac{1}{4}$-in. magnetic floppy disks, which have been around for many years, manage to store a respectable 360 kB (B=byte) of data. This represents about 140 typewritten pages. The $3\frac{1}{2}$-in. high-density disks popular with IBM-compatible personal computers store 1.46 MB, or as many as 580 pages. Hard disks with storage capacities of up to 300 MB are readily available for microcomputers. Optical disks or CD-ROMs (compact-disks read-only memory) have typical capacities of 550 MB.

With the advent of such cheap mass storage devices, storage of data is no longer a problem. Also, the user does not have to worry about the low-level physical organization of the data on disk, since this is taken care of by the operating systems. Care has to be taken, however, to preserve any relationships between the data items. A telephone directory is not created on a computer by storing at random names and telephone numbers. At the very least, one has to know which number "belongs" to which person. In addition, of what use is any data collection if the data needed cannot be retrieved? It is this aspect of computer-based data collections or databases that has become of increasing importance with the advent of the CD-ROM, needing special retrieval and indexing techniques in order to guarantee acceptable retrieval times.

Small data collections can easily be handled by modern text editors or word-processing systems. Most of these software packages are extremely flexible, they provide for rapid searching of text passages, they provide a nicely formatted output, and they have many other useful features. Managing, for example, a collection of 50 or so cooking recipes does not warrant the expense of a database management system. Any relationships among the data items can be recognized by just "looking" at the data, i.e., reading the recipe.

1.2 Data Models

More extensive data collections have to be structured in some way and cannot be retrieved by just "browsing" through them. The starting point in designing a database is an informal model of the real world, the *entity–relationship* (ER) model. This starts off by listing all relevant "objects" or *entities* and the *relationships* among them. An entity is a thing that exists and is distinguishable, such as a PERSON or an AUTOMOBILE. An entity has *attributes*, e.g., a PERSON has a name, age, address, etc., each of which in turn has a certain value from a *domain* of values for that attribute in the whole set of entities. The domain of the attribute AGE belonging to the entity PERSON is the set of integer numbers in the range 0 to 120—assuming that no person is older than 120 years. An attribute or a set of attributes that uniquely defines each entity in a set of entities is called a *key* for that entity set. A relationship among entity sets is simply an ordered list of entity sets. The list may consist of only two members, e.g., PERSONS and AUTOMOBILES with the relationship "has a" or "belongs to."

Entities and their relationships are best shown in the form of a diagram, the ER diagram (Fig. 1). Entity sets are represented by rectangles, their attributes by circles, and the relationships by diamond-shaped diagrams. Note that relationships may be of the kind one to one (1:1), many to one (*n*:1) or many to many (*m*:*n*). In our case we have a *n*:1 relationship between AUTOMOBILES and PERSONS when we assume that a person may own more than one car. The *n*:1 relationship is shown by the arrow in the diagram. More precisely, the arrow stands for "determines uniquely." A *m*:*n* relationship would exist if an AUTOMOBILE could in addition have more than one owner. More details on ER diagrams may be found in Ullman (1982).

Closely connected to the ER model are "data models," three of which, viz., the *relational*, *hierarchical*, and *network* models, have been used in practically all commercially available database systems (DBSs). These data models can be transcribed more directly into the physical structures and organization needed to make a DBS work on a computer.

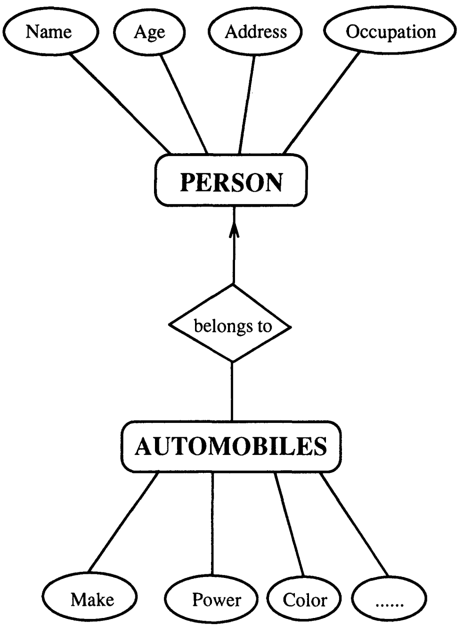

FIG. 1. Entity–relationship model of PERSONS and AUTOMOBILES. Objects (rectangles) together with their attributes (ellipses) are linked via undirected graphs (lines). The diamond-shaped relationship "belongs to" between AUTOMOBILES and PERSONS is of the "many-one" kind (*n*:1). This is expressed by the arrow into PERSON.

1.2.1 Relational Model.

A relation is any subset of the Cartesian product $D_1 \times D_2 \times \cdots \times D_k$ of a list of domains $D_1, D_2, \cdots, D_k$. The members $(v_1, v_2, \cdots, v_k)$ of a relation, where v_i is a value from domain D_i, are called *tuples*. An example illustrates this more clearly. Let us assume that the entity PERSONS has the attributes NAME, AGE, and TELEPHONE. Let us assume that NAME consists of only two values, Smith and Jones, i.e., the domain $D_1 =$ (Smith, Jones). Simplifying in a similar way, the domains for AGE and TELEPHONE might be $D_2 = (10,24,60)$ and $D_3 = (456\,789,\ 234\,567)$. The Cartesian product of the domains D_1 to D_3 or $D_1 \times D_2 \times D_3$ is given by the twelve 3-tuples (v_1, v_2, v_3):

(Smith, 10, 456 789), (Jones, 10, 456 789),
(Smith, 10, 234 567), (Jones, 10, 234 567),
(Smith, 24, 456 789), (Jones, 24, 456 789),
(Smith, 24, 234 567), (Jones, 24, 234 567),
(Smith, 60, 456 789), (Jones, 60, 456 789),
(Smith, 60, 234 567), (Jones, 60, 234 567).

Any subset of this set of 3-tuples including the set that might correspond to the real world,

(Smith, 24, 456 789),
(Jones, 60, 234 567)

is a relation of degree or arity 3. The relation scheme is written PERSONS (NAME, AGE, TELEPHONE). It helps to view relations simply as tables of values of given attributes, where the order of the attributes is unimportant.

The relational model may be used to construct a DBS for the entities PERSONS and AUTOMOBILES as follows. A relation scheme describing AUTOMOBILES might by written as AUTOMOBILES (AKEY, TYPE, COLOR, SERIAL__NO). Here AKEY serves to uniquely identify an automobile. It might consist of the letter *A* followed by a running number, e.g., A001, A002, ..., A376. Such a quantity plays the role of a "key" for accessing any particular automobile. To the PERSONS relation scheme we would add a unique person key PKEY consisting of, say, P001, P002, etc. Then the relationship between PERSONS and AUTOMOBILES is described by HAS__A__CAR (PKEY, AKEY), i.e., by tuples of the kind (P001, A002), (P001, A009), (P002, A001), etc., where we have assumed that person P001 owns two cars, A002 and A009. The three relations PERSONS(···), HAS__A__CAR(···), and AUTOMOBILES(···) suffice to describe the ER diagram in Fig. 1.

Note that by introducing a relation HAS__A__CAR(···) to describe the relationship between PERSONS and AUTOMOBILES, we can in effect handle *m*:*n* combinations: A person need not have a single car, nor is it necessary for a car to have one owner only. Restricting ourselves to *n*:1 relationships between automobiles and owners makes the relation HAS__A__CAR unnecessary: Augmenting the scheme AUTOMOBILES(···) with PKEY clearly defines the ownership of a car.

Relational database systems (RDBSs) have many advantages, and for this reason commercial systems for microcomputers are almost exclusively of this type. Data can be easily changed or updated. Deleting a car from the DBS would involve deleting a record from AUTOMOBILES without affecting the PERSONS file. Furthermore, the theory of RDBSs is well advanced and other data models can be reduced to the relational model at the cost of data storage (see below).

1.2.2 Network Data Model. This is the most general form in which data and their relationships can occur. Many real-life situations are of the network type. In order to avoid confusion with the relational model, it is best to talk here about logical records instead of tuples and logical record formats containing fields instead of relational schemes (Ullman, 1982). Instead of *n*:1 relationships one uses links connecting different record types. Figure 2 shows network data at the record level. The corresponding ER diagram (not shown) consists simply of the entities PARENTS, CHILDREN, and TOYS joined by undirected links. Parent records (P1,P2,...), children records (C1,C2,C3), and toy records are linked by pointers (not shown in the figure). Toy T4 is shared between children C2 and C3, whereas T5 is also owned by parent P4. Data are found by navigating along the links and not by performing relational algebra. In order to simplify implementation of networks on a computer, *m*:*n* relations are replaced by *m*:1 and 1:*n* relations by introducing intermediate record types containing the respective link information.

1.2.3 Hierarchical Model. The hierarchical model can be considered to be a special case of a network. Bidirectional links are replaced by parent-children 1:*n* links. The data structure looks like an inverted tree (Fig. 3), where the lower nodes and leaves can be reached only via the root. A linear physical record representing the hierarchical structure might look as shown in Fig. 4. The child and toy data are contained in a repeating group of fields called a periodic group (PG). In this case three such groups occur, i.e., the periodic

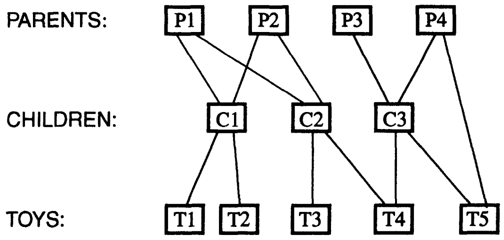

FIG. 2. Parent–child–toy diagram as an example of a network. The record types PARENTS, CHILDREN, and TOYS are linked by pointers. Note that toy T5 is owned by parent P4 and child C3. Complex relationships can be represented in a network diagram.

group multiplier Pm is 3, since there is one instance of the group for each child. PG1 consists of data belonging to child C1 together with its toys T1 and T2. The toy multiplier Tm is needed to tell the computer the number of toy names that follow. Note that updating a record of this type is much more complex than in the relational case. Deletion of a node in Fig. 3 (say C1) eliminates the access paths (physical links) to the lower levels of the tree. Removing a child node from the tree also eliminates its toys. This can be considered to be an advantage or disadvantage depending on whether or not one argues that a toy is an entity even when not linked to its child owner.

Both the network and hierarchical data models can be transformed to the relational case. Linkages are replaced by relations. The hierarchical data in Fig. 4 can be represented by the relational schemes MOTHER(MKEY, ...), CHILDREN(CKEY, MKEY, ...), and TOYS(CKEY, ...). Here the three levels of hierarchy are linked by the unique keys CKEY and MKEY, identifying tuples in the CHILDREN and MOTHER relations, respectively.

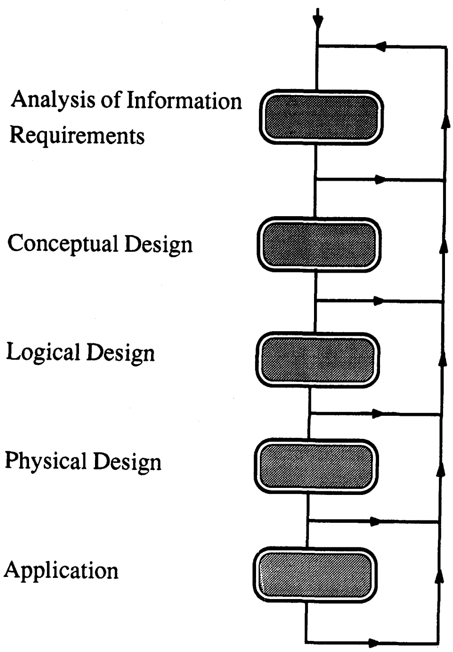
1.3 File Design

Designing a database is an iterative process consisting of a number of steps shown in Fig. 5 (see Lockemann and Schmidt, 1987). The first step involves an analysis of information requirements in the broadest sense. What data are to be stored, who has access, and what information has to be provided by the DBS are some of the topics that have to be clarified. The *conceptual design* involves specification of objects and their relationships as in the entity–relationship model. At the *logical design* level, the data model most suited for the problem at hand is chosen, and the record and field formats for each of the files comprising the database are specified. The type and length of fields needed and the questions that have to be answered will determine to a large degree the database management system (DBMS) that can be used. The nature of a DBMS is explained in Sec. 2.2.



Analysis of Information Requirements
Conceptual Design
Logical Design
Physical Design
Application

FIG. 5. Steps in designing a database.

The *physical design* is taken care of by the manufacturer of the DBMS—unless the whole system is to be developed from scratch, something that was only done for the older physics databases, where dedicated systems written in FORTRAN or PL/1 were used. Usually the data are organized sequentially in a direct access file with pointers to the organizational units of the data file (documents, fields) stored in one or more index files. Access to the data is usually by one or more keys constructed by concatenating the contents of some data fields. Lookup of these keys in the index files may be by use of a hashing algorithm, by an index sequential access method (ISAM) or by use of Bayer trees (BTREE/ISAM techniques) (see Bayer and McCreight, 1972); these terms are defined in the Glossary. Physical data organization is described in detail in the book by Ullman (1982).

The *applications* are the real test for the DBS. At this stage the gap between planning and reality becomes evident, and, depending on how well the database has been modeled to fulfill the overall requirements, some modifications will be necessary at the higher design stages of Fig. 5.

2. DATABASE MANAGEMENT SYSTEMS AND THEIR COMPONENTS

2.1 Dedicated Databases

Even today, most DBSs in use in physics are dedicated systems developed for some specific purpose and are usually written in a high-level language such as FORTRAN or PL/1 (see COMPUTER PROGRAMMING LANGUAGES). Many databases originated at a time when commercial DBMSs were either nonexistent or too expensive, and it is only natural that physicists used the programming language that they knew best and that they had been using for their numerical computations, FORTRAN. Systems written in PL/1 having more sophisticated input/output (I/O) routines and indexed access to the data emerged in the 1970s. Modern programming languages such as C are little used up to now in the physics community.

Dedicated DBSs can be very efficient as regards performance and the need for data storage. Their main drawback is their inability to adapt to changing user requirements. A new file design means major changes to the software. Updates are commonly done by generating the files anew. Developing a dedicated database or retrieval system is worthwhile only in very few isolated instances (Tepel and Müller, 1990).

2.2 Structure of Database Management Systems

A database management system (DBMS) is simply a database system (DBS) with additional management facilities. Some of these features are listed below (see Ross, 1978).

1. *Database security.* Provision has to be made to control user access to the data. This is achieved by introducing different external or user views of the data (in effect a filter allowing users to see only certain data fields), by disallowing certain commands that modify the data, by password protection, and by encoding of the data.
2. *Database integrity.* Routines have to be provided to allow backups to be made of the DBS. Larger DBMSs have transaction logging, checkpointing, and capabilities for restart after system failures.
3. *Data definition language (DDL).* The DDL provides a means of describing the data structures and maps them onto the storage media. As an example, Fig. 6 shows the ADABAS™ DDL module for Fig. 4. Low-

```
01,NA,20,A,DE          **Person's Name
01,AG,2,U,DE           **Age
01,AD,60,A             **Address
01,TL,12,U             **Telephone No
01,CH,PE               **Periodic Group
      02,CN,20,A,DE    **Child's Name
      02,CA,2,U        **Age
      02,TY,30,A,MU,DE **Toys
```

A = Alphanumeric Field DE = Descriptor Field
U = Numeric Field MU = Multiple Values

FIG. 6. ADABAS™ data definition module for the data of Figs. 3 and 4. Each entry consists of a level identifier (01 or 02), the field name, field length and type, and additional information such as whether the field is to be indexed (DE) or not.

level routines for disk access and file management are usually taken from the operating system.

4. *Data dictionary.* The data dictionary or database system catalog provides the user or database administrator with an overview of the DBS. It lists the files and data structures (tables and attributes) present in the system. Data definition modules appear in the data dictionary, where they are kept for future reference and modifications.
5. *Data acquisition.* Data input routines in batch mode and via masks depending on the data structures as described by the DDL are usually provided.
6. *Data manipulation language (DML).* The DML is the command language of the DBS and allows operations on the database such as the creation or deletion of whole files or groups of files and the start and termination of user sessions as well as manipulations on the data itself, such as deletion, insertion, and updating of individual logical fields or records. The query language used for retrieving data is often considered to be a subset of the DML. Database producers often call their DMLs programming languages of the fourth generation, since they provide direct database support with commands such as FIND, ADD, and DELETE. In addition, most commercial DBMSs have interfaces to high-level programming languages such as PL/1 or C, and to Assembler. Well-known query languages are SQL, which is a de facto standard for relational database systems, and NATURAL™, which is used together with the DBMS ADABAS™ on mainframes.
7. *Report generator.* Most DBMSs include a report-generating facility that presents retrieved data as properly formatted reports. Personal computer (PC) systems often provide advanced features such as graphics capabilities and support for a variety of printers including systems using PostScript™.
8. *Support for multiple access.* An important feature of a DBS is the centralized storage of data. In addition to reducing data redundancy, this consolidates updating procedures, since only the master copy of the file has to be maintained. It is preferable to use a single database under a single control rather than having scattered collections of computer files maintained by individual groups or users. Multiple and simultaneous access to such a centralized system is important, and the DBMS software has to preserve the integrity of the data and prevent deadlock situations.

2.3 DBMSs for Personal Computers

The three types of DBMSs for use on PCs are the flat-file, relational, and network or hierarchical types. Of these, the relational database management systems (RDBMSs) are by far the most common.

Flat-file systems consist of linear arrays of data and permit no logical file couplings. Each database consists of a single file only. Records are usually subdivided into fields of fixed length, a certain number of which may be indexed.

Data acquisition and report generation are supported. These systems are inexpensive, are often available as public-domain or user-supported software, and are ideal for keeping simple lists of data. Through their menu-driven user interfaces they are very user-friendly.

A few professional network-type DBMSs exist for special applications on personal computers. An overview may be found in Seymour (1988).

Relational DBMSs for PCs are very common. Very widespread is dBASE™ by Ashton–Tate. Although more a DBS than a DBMS, it has a powerful programming language and is supported by a large number of software firms. Procedures can be rapidly developed and tested, since dBASE runs as an interpreter. These procedures can then be compiled with dBASE compilers, such as CLIPPER™, which produce executable files. dBASE relies heavily on the PC operating systems for file management.

An example of a full relational DBMS for PCs is ORACLE™. ORACLE was originally developed for minicomputers, but nowadays the whole spectrum of computer hardware is supported, from microcomputer and workstations to large mainframes. It uses SQL as query language (Date, 1987) and has interfaces to several high-level programming languages, in particular to C. Data management is reminiscent of mainframe systems, with password protection, clustering of files in definite partitions (areas on the hard disk), rollback and commit statements (*rollback* makes the changes to data at the end of a session undone, *commit* confirms the changes), and provision for a systems supervisor—the DBA or database administrator.

2.4 DBMSs for Mainframes

Most of the older types of DBMSs for mainframes are of the network or hierarchical type, e.g., Information Management System (IMS) of IBM. In recent years, relational DBSs have become more important. The advantages of such RDBMSs are easier maintenance of individual files and flexibility with respect to user queries. The data structure and linkages in a hierarchical system determine what type of questions can or cannot be answered, whereas the linear file design of relational systems allows future applications, which were not foreseen at the time of the file design. Possible drawbacks of RDBMSs, viz., the need to compute joins between many different relations with a corresponding loss in performance and the need to construct displays from relations stored on different physical regions of the hard storage devices, are partly offset in commercial systems such as ADABAS by allowing some types of repeating fields (multiple fields) and repeating groups (periodic groups) in each record of a file. In this way, retrieving a record for display purposes usually places all data at one's disposal, while still allowing indexing on individual values of multiple fields, such as author names in a bibliographic document.

The DBS used in the Messenger retrieval system of STN-International, FIDO, is a hierarchical system allowing linkage of terms on several different levels (word, sentence, paragraph, and linkage proximity). However, the requirements of a DBS for information retrieval systems used mainly for bibliographic and full-text databases (see below) are somewhat different from those of other DBSs.

2.5 Choosing a DBMS

Choosing a DBMS for a proposed application is not an easy task and needs a good understanding of the underlying principles of electronic data processing and data modeling. Unfortunately, often a choice has to be made before the scope of the application or the abilities of the DBMS software are known completely. Changing subsequently from one DBMS system to another can be very costly.

There is probably no single system that satisfies all the user requirements. A DBMS that works well with some type of data, e.g., records of fixed length subdivided into fields, performs very poorly or is unable to handle data of varying length. A number of criteria are helpful in determining which system is best suited for the particular purpose:

1. Structure of the data—free text, free text with some structure (e.g., a book), documents from on-line retrieval sessions, data in fixed format.
2. Data types—text, numeric, graphics, or a combination of these.
3. Lifetime of data—static or changing data (frequent updates).
4. Size of the database.
5. Searchability of the data—free text search, full text search, search by means of indexed fields or inverted lists.
6. Data relationships (1:1, n:1, n:m) and models.
7. User interfaces—what provision is made in the software package for user interaction with the data.

3. INFORMATION RETRIEVAL AND HYPERTEXT

3.1 Information Retrieval Systems (IRS)

Systems in use with bibliographic databases fall into the category IRS rather than DBMS. Of primary importance are the user interface and the retrieval possibilities for the documents. Less emphasis is placed on the DBM part of IRSs. The data are more static than with classical DBS, and much effort is spent in building index files for efficient data retrieval. The index parts of such files are normally larger than the actual data. Updates to older data are rarely done; files change because new documents are added at regular intervals. In addition, IRSs usually support structured thesauri containing hierarchical and associative relationships between terms (keywords), which makes document retrieval very effective. These terms are usually called descriptors and are classified into superordinate or broader terms, subordinate or narrower terms, and associative or related terms.

3.2 Hypertext

A comparatively recent development, hypertext combines the virtues of full-text DBSs with user-defined access paths to the data (Marchionini and Shneiderman, 1988; Franklin, 1989). In hypertext the underlying DB structure permits the user to traverse complex networks of information quickly. The user can select his own topics of interest, link these with related concepts, and navigate on-screen through the full text by choosing at each stage among a set of alternatives. The ability to browse through the text using a filter of selected topics is characteristic of hypertext systems.

3.3 Information Retrieval Models

In order to retrieve documents from an IRS the user formulates a query in the query language of the particular system. The goal of such a query is to maximize the *recall* of documents, defined as the ratio (number of relevant items retrieved)/(number of relevant items in the DB), while keeping the *precision*, defined as (number of relevant items retrieved)/(total number of retrieved items), as large as possible. Broad query formulations tend to have a high recall but a low precision, whereas narrow formulations have high precision but low recall figures.

IRSs used by large on-line hosts employ the so-called Boolean retrieval model. A search query is formulated and all documents are retrieved that exactly match this query. The query may contain terms connected by the Boolean operators AND, OR, and NOT, as in the following example from the database PHYS (comments have been added within the delimiters /*....*/):

```
/* user entries are expected at the system prompt ⇒  */

⇒ s database                          /* search for the term database  */
L1      527  DATABASE                 /* found 527 documents  */
     /* query results are labeled consecutively by L1,L2,...  */
⇒s information retrieval              /* find information retrieval  */
     37241  INFORMATION
      1039  RETRIEVAL
L2      387  INFORMATION RETRIEVAL    /* 387 documents found  */
/* search for documents which contain both the terms DATABASE and
   INFORMATION RETRIEVAL */
⇒s      L1 AND L2
L3      31 L1 AND L2
⇒ s  L3 NOT optical                   /* of the 31 documents found
                                         previously show only
                                         those that do not contain
                                         the word OPTICAL  */
   125284 OPTICAL                     /* 125284 occurrences
                                         of OPTICAL in DB  */
L4      29 L3 NOT OPTICAL             /* final result of combined
                                         queries  */
```

Here documents are retrieved that contain the word "database" and "information retrieval," but not the term "optical." One of the documents found is displayed in Fig. 7.

Apart from the Boolean model, where an exact match between terms in the query and in the documents is required, other retrieval models such as the probabilistic model and the vector-space model relax this condition (see Salton, 1989). Here a measure of similarity is introduced between the terms in the query formulation and in the documents. Documents may be ranked according to the degree of overlap with the query. Recall is improved by these methods, and users can decide by themselves at which point in the

ranked list they want to place their cutoff of useful documents. Little practical experience is available with these more advanced retrieval models.

4. BIBLIOGRAPHIC DATABASES

The databases, producers, and hosts mentioned in Secs. 4–7 are listed and described in the Cuadra directory of databases (Cuadra, 1990), which is updated regularly. For this reason, we have omitted the administrative details, such as addresses, from our overview.

As already mentioned in the Introduction, bibliographic databases are defined by the fact that they only contain references (titles, authors, sources, etc.) to published literature. Of course, there exist a very large number of small, mostly private files of this type. It is, however, not the intention to describe these in more detail, but to restrict ourselves to the large bibliographic databases covering whole fields of science, such as physics, chemistry, materials science, etc. They are produced professionally by large producers like the Institution of Electrical Engineers, Fachinformationszentrum Karlsruhe, Chemical Abstracts Service, etc., and are offered on line via so-called hosts.

Retrieving simply bibliographic citations is not enough for an on-line researcher. More is involved. Thus, in order to provide the prospective user with the details of the content of an original document and in order to make a specific and selective retrieval possible, each bibliographic item (documentation unit) also contains terms derived by what is known as subject analysis (see Fig. 8). This subject analysis, often also called indexing, is usually carried out manually by the document analysts. In some, very few, modern systems, parts of this analysis process (the indexing and adding other information) are nowadays also handled automatically (or semiautomatically) by application of suitable computer systems (automatic indexing and retrieval).

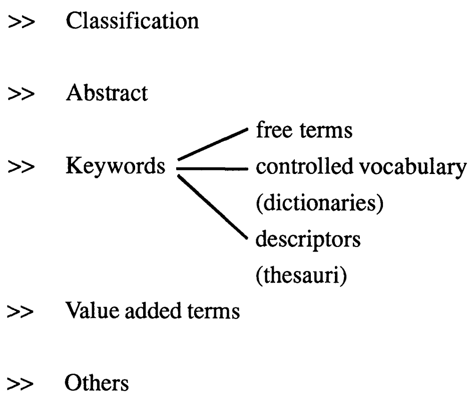

FIG. 8. The subject analysis of a document consists of adding the terms shown.

A normal documentation unit, which is the smallest unit of a bibliographic database and which contains all necessary information about an original document, consists of two parts, the technical bibliographical or subject cataloging part and the subject analysis part.

Documentation unit:
Technical bibliographical part

Field	Prefix
Accession number	AN
Authors, editors	AU
Title	TI
Source	SO
Journal title	JT
Corporate source or affiliation	CS
Publication year	PY
Publication date	PD
Meeting date	MD
Number of report	NR
Country of publication	CY
Language	LA
Document type	DT

Patent number	PN
Update code	UP

Documentation unit: Subject analysis part

Field	Prefix
Abstract	AB
Classification code	CC
Controlled terms (descriptors)	CT
Treatment code	TC
Value-added (e.g., element) terms	ET

A typical documentation unit making use of this scheme and taken from the database PHYS is shown in Fig. 7. Other information items, so-called value-added terms assigned in the process of subject analysis, are data flagging, chemical indexing with or without chemical structures, numerical indexing, astronomical objects, etc.

In physics, normally classifications are applied that are strongly related to the international ICSTI (International Council of Scientific and Technical Information) classification. It consists of a hierarchical scheme four levels deep of which the first two levels consist of 10 and 67 classes, respectively (see ICSTI, 1991).

For indexing free terms, controlled terms and descriptors from a thesaurus might be used. A thesaurus contains controlled terms only with additional hierarchical relationships in the form of so-called broader or narrower terms (see, e.g., Salton, 1983) and with so-called forbidden (synonyms) and other related terms. Typical examples in physics are the thesauri of the database INSPEC and of the database PHYS, which are described below.

Of the discipline-oriented bibliographic databases, those of major importance for the field of physics are the databases PHYS and INSPEC. Both have a long tradition because they already existed before the computer age in printed form as abstract journals.

PHYS originates from the *Physikalische Berichte*, which was founded in 1845 in Berlin under the title *Fortschritte der Physik.* In 1920 this abstract journal was renamed *Physikalische Berichte*; today its title is *Physics Briefs/Physikalische Berichte.*

In 1979 the abstract journal was computerized so that a database called PHYS today exists in parallel to the printed version with citations back to the publication year 1979. The producer since that time is the Fachinformationszentrum Karlsruhe or, briefly, FIZ Karlsruhe in Germany. Actualization takes place biweekly. In addition to the normal bibliographic terms such as title, authors with affiliations, sources, etc., this database contains document analysis terms such as abstracts, international physics classification codes, and descriptors from a thesaurus. For the field of astronomy the names of the astronomical objects are added as searchable key words. Searching for special substance designations is supported by a mixture of manual and automatic adding of substance names. The database PHYS covers the whole of physics, which includes elementary particles and fields, nuclear physics, atomic and molecular physics, classical areas of phenomenology, fluids, plasmas, discharges, condensed matter, cross-disciplinary physics, geophysics, astronomy, and astrophysics. As of September 1990, it contained about 1.4 million citations with an increase per year of about 125 000 entries.

INSPEC goes back to the abstract journal *Science Abstracts*, which was founded in 1898 in England. Very soon this abstract journal was divided into two parts, one for physics and one for electrical engineering, the physics part being named *Physics Abstracts*. At the end of the 1960s the production process for this abstract journal and other abstract journals was mechanized by the producer, the Institution of Electrical Engineers, with the consequence that a database was created in parallel to the printed version.

In the case of INSPEC, subject analysis is done by assigning classification codes (the classification used is similar to the ICSTI international classification) by indexing with a free and controlled vocabulary, and by chemical (for the designation of substances) and numerical indexing. The database covers the fields of electronics, computers, computing, electrical engineering, physics, and information technology. The physics part corresponds to the printed version *Physics Abstracts*. The total number of citations as of September 1990 was about 3.7 million (50%–60% physics). The updating is carried out biweekly, which results in an increase per year of about 270 000 citations.

In addition to those physics-specific databases that cover the field of physics completely, there are others that either are of a multidisciplinary character or focus on other fields like energy, chemistry, materials science, etc. A database of the first type is PASCAL, which covers fields such as chemistry, biology, engineering sciences, geoscience, medicine, and also physics (about 13.5%, without nuclear and elementary physics). The citations stored go back to the publication year 1973. PASCAL contains presently about 8 million citations with an increase per year of about 450 000. It is produced by l'Institut de l'Information Scientifique et Technique du Centre National de la Recherche Scientifique in Nancy, France. Titles are bilingual, French and original language; the abstracts are in French; and the descriptors are trilingual, French, English, and Spanish.

Other multidisciplinary databases are ENERGY [produced by an International Energy Agency (IEA) international cooperation], which covers energy research and technology, but contains also a large part of physics-relevant citations, and NTIS, which is devoted to reports on research and development sponsored by U.S. and non-U.S. governments. In this same context, the Science Citation Index (SCI or SCISEARCH), which contains references from approximately 3800 journals to worldwide literature across many disciplines, should also be mentioned. Discipline-oriented databases focusing on fields other than physics, but containing partly also physics-relevant citations, are CA (chemistry) produced by Chemical Abstracts Service in the U.S., INIS (nuclear research and technology) produced by an International Atomic Energy Agency (IAEA) international cooperation, METADEX (metallurgy and material sciences) produced by the Institute of Metals in London and by the American Society for Metals (ASM) in the U.S., MATH (mathematics) produced by FIZ Karlsruhe in Germany, and MathSci (mathematics) produced by the American Mathematical Society (for corresponding addresses see Cuadra, 1990).

What are significant quality criteria for bibliographic databases? First, the degree of in-depth subject cataloging and subject analysis, which varies from bibliographic database to bibliographic database, should be mentioned. Then, currency, completeness, and consistency are very important. The last points are self-evident since for researchers, for instance, timeliness is of major relevance because otherwise they will lose citations to the most recent publications. The same is true for completeness, because researchers must be sure not to miss citations to important papers in a well-defined area.

5. FACTUAL DATABASES

By definition, factual databases contain other structured but mainly non-numeric data. The factual databases are sometimes also alluded to as referral and textual-numeric databases. Conversely, factual and numeric databases together are sometimes called factual databases. The majority of their data consists of text data. This type of database refers to organizations, projects, experts, patents, products, conferences, etc. Typical examples are research databases, product databases, and conference databases.

Research databases contain information on research institutes and research projects (research in progress). The usual content of the file segment INSTITUTE is

- Institute (company) name and address
- Telecommunication numbers
- Classification code
- Director of the institution
- Staff (names)
- Description of the main research activities
- Facilities of the institute
- Accession numbers of projects carried out at the institute
- Update code

and of the file segment PROJECTS is

- Title of project
- Classification code
- Description of the project
- Performing organization
- Cooperating organizations
- Name of project leader
- Staff (names)
- Supporting organization
- Duration begin, date
- Duration end, date
- Number of contract
- Funding
- Update code

Typical examples relevant for physics are in Germany the databases VADEMECUM (information on institutes), INFOR (information on institutes and projects), and FORKAT (projects funded by the German Federal Ministry for Research and Technology); in Britain the database Current Research in Britain (descriptions of projects conducted at British universities); and in France the database Telelab (information on governmental and university laboratories).

Another prototypical example consists of the conference databases that refer to future meetings and conferences. The components of the record are the following:

- Accession number
- Meeting title
- Meeting organizer
- Meeting location
- Meeting date
- Meeting secretariat
- Classification code
- Status date

A representative example is the database CONF produced by the FIZ Karlsruhe in Germany. A record of this database is shown in Fig. 9. Perhaps it should be mentioned that many of the factual databases are based on questionnaire actions for the acquisition of the necessary information needed for the input. The examples shown before show this very clearly. It is here our intention not to give a complete collection of the existing factual databases (such a complete survey can be found in Cuadra, 1990), but only to present some representative examples and to explain typical features.

6. NUMERIC DATABASES

A database is called numeric when it consists mainly of structured numeric data. Before considering the databases in more detail let us look at the kind of data stored in such a database. In physics we are dealing with numeric values of observables. The data we have to consider usually has the following structure:

1. Measured value
2. Uncertainty
3. Units (SI)
4. Data type
5. Range of validity
6. Method of measurement
7. Combination with other quantities
8. Bibliographic citations

Generally speaking a *datum* can also be any parameter deduced with the help of a model or a theory. It should, however, be noted, that very often some of the fields listed above are empty.

The automatic techniques that are nowadays employed in experiments either in laboratories or outside, for instance in satellite experiments, often generate large amounts of data, sometimes more than can be handled afterwards. These raw or primary data are recorded continually or at specific intervals.

FIG. 9. Retrieval example from CONF.

Later on they are analyzed and interpreted according to the physical quantity involved. Very often this methodology leads to databases containing large volumes of raw data. We shall, however, not consider these in the following because their usage is mostly restricted to the very few specialists carrying out the particular experiments. We shall also not discuss further how to build private numeric files and databases (this has been sketched in the sections before) or go into further details concerning the numerous small home-built data files in physics. As before, we shall only elucidate the publicly available larger databases that are produced in a professional and organized manner.

In physics we are mostly dealing with time- and location-independent data. Therefore, in the following we shall restrict ourselves to the handling and storage of this type of data. In certain subject areas, including astronomy, astrophysics, and geophysics, time series are important. However, that would be a topic of its own.

More often than not we have more than a single experimental result available for a physical quantity. Sometimes these measurements even contradict one another. It is therefore very important to know what must be done in order to store these data in machine-readable form. It is now customary to distinguish between the following forms of data handling and presentation:

- *Tabular lists.* These are simple systematic lists of numerical information.
- *Data compilations.* These are systematic collections of numerical data with some

reorganization for an optimal presentation.

- *Evaluations.* These are collections of numerical data, but with just one recommended best value for one measured quantity. This recommended best value is derived by a critical consideration of available information.

It is obvious that the last form, "evaluations," is of major importance when we are considering storage of data in machine-readable form in a field where we have very often more than one value for one physical quantity.

The structure of numerical databases under consideration can be described in four parts as follows:

1. Bibliographic part—title, authors, bibliographic citation.
2. Information part—for example, substance name, molecular formula, material description, experimental conditions.
3. Data part—for example, melting points, lists of spectrum peaks.
4. Computational part—For example, general program packages, including statistical packages, interpolation routines; specialized program packages, including calculation of thermodynamic properties, spectrum estimation.

This outline shows that a numerical database in physics will contain, aside from the dominant numerical information, also other alphanumeric information (for example, the source where the data came from in the bibliographic part). Very important, sometimes even essential, are also the specialized computer packages integrated in a numerical database. Their purpose is normally to offer a possibility for calculating data not stored on the basis of basic data or of some kind of knowledge base.

The structure of the numeric part is described by matrices (data tables) with m rows and n columns (m and n have any numerical value) where the elements A_{mn} of these matrices contain the numerical information (sometimes also alphanumeric comments). Further details are best illustrated by examples. For this we have selected three: one from the field of crystallography, one from the field of nuclear physics, and one from the field of spectroscopy.

The first database we would like to consider is the Inorganic Crystal Structure Database (ICSD). It contains crystallographic data (crystal structure data) from inorganic compounds:

- reference (authors, journal, year of publication, volume and page)
- chemical name (and phase designation)
- mineral name (and origin)
- chemical formula
- Chemical Abstracts registry number (if available)
- density
- unit-cell dimensions
- space group
- atomic coordinates, site occupation, oxidation state, and temperature factors for each element of the structure
- reliability index (R value)
- remarks concerning conditions of measurement or specialties of the structure not described by the above parameters

ICSD is produced by FIZ Karlsruhe and Gmelin-Institut in cooperation with the University of Bonn (for more details see IUCR, 1987). A typical record is shown in Fig. 10. ICSD contains about 30 000 structures that have been compiled from the open literature. Before the data were entered into ICSD, they were carefully checked both manually and automatically by application of suitable test programs. There are also two specialized program packages integrated into ICSD, one for the calculation of the different angles between the various atoms in the crystal and one for the calculation of distances between specified atoms. Both components can be accessed with the retrieval software without any problems.

As stated above, our next database example has been taken from the field of nuclear physics. In this area the database ENSDF (Evaluated Nuclear Structure Data File), where the printed version is the *Nuclear Data Sheets,* plays a major role. It contains the nuclear structure and radioactive decay characteristics of all isotopes known so far, i.e., the existing energies of the energy levels, the spins, the parities, and the half-lives and all decay energies of the related α, β, and γ transitions. It consists of a data part and bibliographic part, with the data part containing only evaluated data. ENSDF is produced and kept up to date by an international coop-

FIG. 10. Data set from ICSD.

eration coordinated by the IAEA. In detail its contents can be characterized by the following figures.

1. Bibliographic part: contains about 120 000 bibliographic citations (from 1910 to 1991).
2. Data part: contains about 920 000 card image-based records. Data sets number about 10 700 of which 24% are adopted levels data sets, 27% are radioactivity data sets, and 49% are nuclear reaction data sets.

The structure of the database is shown in Figs. 11 and 12. An example of a typical data set is presented in Fig. 13.

The next database we would like to consider in this context is the spectroscopic C13 NMR/IR (carbon-13 nuclear magnetic resonance/infrared) database, which is produced jointly by Chemical Concepts and BASF (a large chemical company in Ludwigshafen, Germany) (the on-line version is offered by STN International).

A sample for a ^{13}C NMR record is presented in Fig. 14 (see also Luksch, 1990). It should be noted that the database also has a graphical component that allows graphic representation of chemical structures and corresponding spectra. The database contains 102 000 ^{13}C NMR spectra (85 000 chemical structures) and 16 000 IR (15 000 structures). The data are taken from journal articles, spectral catalogs, and unpublished sources. In addition, specialized software packages are connected with the database. These are packages for spectrum estimation, spectrum interpretation, and similarity search. Of these, the most important and interesting one is that for spectrum estimation. It allows the calculation of unknown ^{13}C NMR spectra (chemical shifts) from a known chemical structure. This is based on the correlation between spectral features and the environment of an individual atom in a molecule described by the HOSE and HORD codes (hierarchically ordered spherical description of environment, hierarchically ordered ring description; see Bremser, 1978). A special library with spectral information linked to these HOSE and HORD codes is then built up which allows the derivation of spectra from topological matrices (see Bremser, 1978 and

FIG. 13. Example of an ENSDF data set.

1987; Zupan, 1986). Why is this so important? As we said before, 102 000 spectra are in the database. We have, however, many more compounds existing in nature (about 12 million). Thus in case a spectrum must be interpreted that is not in the database, the corresponding chemical shifts for a postulated chemical structure can be estimated. In a retrieval session it is also very easy to manipulate the structures of the chemical compounds under investigation in order to achieve the greatest possible correspondence between calculated and measured spectra.

Since each of the spectroscopic methods [^{13}C NMR, IR, mass spectroscopy (MS)] has its own specific analysis potential for an unknown chemical structure, it is of great advantage to apply several spectroscopic techniques in parallel (multidimensional spectroscopy) to one unknown compound. The future of spectroscopic databases is therefore devoted to multidimensional spectroscopic databases in which the different sublibraries of specific spectroscopic data such as ^{13}C NMR data, IR data, etc., are linked to one central structure library with connections to the CAS, Beilstein, and Gmelin databases via corresponding registry numbers (see Fig. 15). A typical example is the SpecInfo database originally developed by BASF in Germany and now offered by Chemical Concepts.

These multidimensional databases can be combined with suitable intelligent software to build a multidimensional interpretation system, which is shown schematically in Fig. 16. The flow of information can be described in the following way. The MS, NMR, and IR spectra for the unknown substance are transferred to the system. On the basis of the MS, NMR, and IR subdatabases, chemical structure sets are found by applying similarity searches and statistical analysis of the resulting "hit" list. A structure generator then assembles the substructures and derives structures. MS, NMR, and IR spectra can afterwards be predicted and then fed back with suitable ranking into the interpretative system. Finally, the solution space of the structure gen-

FIG. 16. Organization of a multidimensional spectral database system.

Contrary to the situation we have for the bibliographic databases, the coverage of the whole field of physics by existing numeric databases is very uneven. For example, the fields of crystallography (see Table 1), of nuclear physics (Table 2), of thermophysics and thermodynamics, and of spectroscopy are well covered. In the wide field of solid-state physics, on the other hand, there are hardly any databases. Those that exist contain mostly materials data and strictly speaking do not belong directly to the field of solid-state physics.

Concerning quality criteria there are specific differences between bibliographic and numeric databases. Reliability of data is most important in numeric databases, whereas this point is not so critical in bibliographic databases. In addition, it is important to store data and metadata (information necessary to define data), to refer to the sources of the data, to give information about type of apparatus, experimental conditions etc., and to make available special comments whenever necessary. In many cases the storage of the uncertainties belonging to the data is also of importance. In addition, continuous data maintenance and updating are often essential.

7. ON-LINE SERVICES

Usually, the producers of databases do not make their databases available to the public themselves, but pass these on to database vendors or on-line service centers, the so-

1. Nuclear structure and decay data databases:
   ENSDF (Evaluated Nuclear Structure Data File)
2. Nuclear reactions (non-neutron) databases:
   None
3. Neutron reaction databases:
   a. Experimental data:
      EXFOR (EXchange FORmat database for experimental nuclear reaction data)
   b. Evaluated data:
      BROND 90 (USSR Evaluated Neutron Data Library)
      ENDF/B-VI (Evaluated Nuclear Data File, Brookhaven, USA)
      ENDL-84 (Evaluated Nuclear Data Library, Lawrence Livermore Labs.)
      IRDF 90 (International Reactor Dosimetry File, IAEA)
      JEF-2 (Joint Evaluated File, Nuclear Energy Agency, NEA)
      JENDL-23 (Japanese Evaluated Nuclear Data Library)

called *hosts*. These hosts have suitable mainframes at their disposal where the databases are loaded. By offering also a more or less refined retrieval software they make the databases available to the public. The on-line access for the normal user will be via the usual telecommunication networks. As the word "on-line" implies, this search technique is an interactive process, where user and computer are conversing in real time. For the user the following type of equipment is required (see COMPUTER HARDWARE). First, a terminal or, even better, a microcomputer with ASCII standard and with some suitable communication software is needed. To link the PC (or the terminal), which should have an RS232 port and an asynchronous communication card, to the phone, a *modem*, which stands for modulator/demodulator, is also needed. The modem is a device that converts the digital signals coming out of the PC into the analog language of the telephone system, and vice versa. An important point in this context, however, is the number of characters to be transmitted per second over the line. Usually, the modem speed is measured in baud (bits per second). A 300-baud modem can handle 30 characters per second (approximately five average-length words) and a 2400-baud modem, 240 characters per second (approximately 40 words). Thus it is advantageous to have at least 2400-baud facilities, but today even faster lines and modems are available.

In the first part of the communication link, the connection between the user's PC and the host is made via the ordinary telephone line. Because of cost considerations, the second and major part of the path makes use of special telecommunication networks. These are accessed by making a telephone call to the nearest node; from this the call is automatically switched through the telecommunication networks (packet-switching systems) to the host. At present, one sometimes finds more complicated schemes, viz., a mainframe at the center with telecommunication links to both the host and the user. Of course, the customer has to sign an agreement with the host in order to receive a password that permits access to the databases.

Today we have about 5000 databases publicly offered on line and about 600 hosts (Cuadra, 1990). Such a host may offer from very few to hundreds of databases for all fields of science. For physics the most important public hosts are STN International, DIALOG, BRS, ESA-IRS, Questel, and Data-Star (addresses and more detailed description can be found in Cuadra, 1990). Each of these hosts uses its own retrieval software. This has the consequence that the corresponding search languages are different. In case of STN International, for instance, the name of this language is Messenger. In many cases, however, the necessary commands are similar to a large degree. It is clear that the difference between the various command languages complicates the human–host interaction since a user must learn the language peculiar to each service. In the interaction process that takes place between a human user and the host, there are also other frustrating although often trivial problems. One of these is the log-in procedure to a host computer, which is a trivial but very often cumbersome procedure. It could require typing in a certain number of consecutive digits with restrictions for timing. One typing error normally has the consequence of an invalid call and of the obligation to repeat it. Therefore a large number of on-line searching aid software packages are nowadays available. When installed on the PC they can, for instance, be used for retrieval. Their purpose is to improve the user-friendliness of the host access. These on-line searching aid systems can be classified as (Efthimiadis, 1990)

- gateway systems,
- front ends, or
- intermediary systems.

Gateway software allows auto-log-on (automatic dialing, automatic selection of a communication network, automatic connection to the host computer, automatic transmission of the user's log-in password) and possibly uploading and downloading. Front-end software includes the above features, but goes beyond by simplifying steps of the searching process itself (presearch formulation, editing, uploading of search formulation, downloading, and post-processing). Intermediary systems are often real expert systems and have the aim of replacing human intermediary searchers in some way (query reformulation, query expansion, natural language interface). For more details, see, e.g., Efthimiadis (1990).

From the above it follows that on-line searching aids also simplify the problem of accessing more than one host. In addition, file transfers such as downloading (capturing of data sent by the host computers) and uploading (sending data from the user's computer to the on-line host) are easily performed by making use of online searching aids. This is important because the users very often want to manipulate (post-process) the data they retrieved, which can be done after downloading by application of various packages. Examples for gateway systems are PC Net/Link and iNet; for front-end systems ProSearch, Sci-Mate, STN-Express, STN Personal File System, Molkick, etc.; and for intermediary systems CONIT, NDA, etc.

8. OTHER DATA DISTRIBUTION CHANNELS

An on-line connection between user and host computer is but one of many data distribution channels. Nowadays, quite a few alternative methods of storing and transferring data from one location to another are being used. The possibilities include tape drives, Bernoulli cartridge systems, removable hard disks, write-once optical disks (WORMs), erasable optical disks, floppy disks, and even VHS video tapes.

Tape drives are by far the most popular medium. Data are transferred between mainframes on nine-track, half-inch, open-reel tapes with capacities between 100 and 300 MB depending on reel size and recording density (e.g., 6250 bits per inch). Capacities for systems for use with mini- and microcomputers range from 40 MB to 5 GB. These include cartridges of various makes, such as TK50 and TK70 (VAX computers), DC 6000 QIC, DC 2000 minicartridges, Teac's D/CAS cassettes, and 4-mm digital audio tape (DAT). An overview of the different systems available can be found in Stone (1990).

Because of the predominance of MS-DOS™ and its offspring in the world of personal computers, exchange of smaller amounts of data on standard $5\frac{1}{4}$- or $3\frac{1}{2}$-in. floppy disks is very common. The use of optical disks with their larger storage capacities is increasing (CD-ROMs). WORMs and erasable optical disks are still quite expensive at present, and lack of standardization hampers their use for data exchange.

GLOSSARY

Bibliographic Database (also called Reference Database): A computer-readable file containing literature citations or references to published articles and documents.

Bit: A single linear digit having one of two states, 0 or 1.

BTREE (or Bayer Tree): A way of organizing structured data in a computer in order to minimize the time needed to access it.

Byte: Group of eight bits, used as the smallest computer storage and processing unit. In addition, it is the basis of our character representations.

CAS: Chemical Abstracts Service, P.O. Box 3012, Columbus, Ohio 43210.

CD-ROM: Compact-disk read-only memory. Read-only optical disk for the storage of digitized data.

DBMS or Database Management System: A software system with management and administrative capabilities for maintaining and controlling access to large amounts of structured data on a computer. A DBMS is a DBS with management facilities.

DBS or Database System: A software system supporting structured data on a computer, usually arranged in one or more files.

DDL: Data definition language, used to describe the logical file structures in DBS.

DDM: Data definition module, containing the data definitions for a file in a DBS in original text or compiled form.

Descriptor: A keyword contained in a thesaurus.

Direct Access File: A collection of data in a computer file to which access can be gained directly, i.e., without scanning the data from the start of the file.

DML: Data manipulation language. Command language of a DBMS. Sometimes there is no clear distinction between DDLs and DMLs.

Documentation Unit: The smallest unit of a bibliographic database containing all the data of a literature citation together with the terms of the subject analysis.

ER or Entity–Relationship Model: Conceptual model of the real world used in a DBS containing objects (entities) and their relationships.

Entity: Any object that exists on its own and is distinguishable (e.g., a person, an automobile).

Factual Database: A database containing factual information, mainly of non-numerical nature.

Field: The smallest subdivision of a record and usually contains numeric or alphanumeric information for a single topic.

File: A named organized collection of related data elements stored in a computer system.

File Design: Conceptual and logical design of a DBS.

Front-End Software: Software that is loaded on the user PC in order to improve the user-friendliness of the host access by allowing automatic log-on, prepared search formulations, editing, etc.

Full-Text Database: A database containing the entire text of a document.

Gateway Software: PC software allowing automatic log-in to a host computer.

Hardware: Any piece of physical equipment associated with computer processing or communication networks.

Hashing Algorithm: A function that computes, from a character string serving as key for a file, an integer in the range 0 to some maximum value. This "hash value" is used for directly gaining access to the required data in the file.

Hierarchical Model: Data model structured like an inverted tree. Each item may have one or more descendants, but only one parent.

HORD Codes: Hierarchically ordered ring descriptions. They describe rings and their environments in chemical molecules.

HOSE Codes: Hierarchically ordered spherical description of environments of atoms in chemical molecules.

IMS: IBM's Information Management System.

Index: An ordered list of the contents of one or more fields or parts thereof, each element or key pointing to or identifying the location of the corresponding record.

Indexing (of Documents): The assignment of keywords (descriptors) to bibliographic documents. The term is sometimes also used as a synonym for subject analysis.

Information or Data Retrieval: Transfer of selected information from long-term storage to computer memory for subsequent processing, e.g., for display on a terminal or printer, or downloading to some other device.

Inverted File: A file that contains the addresses or locations or records in which the values for given keys exist. It is arranged for each key in order of record number.

ISAM: Index sequential access method. A method for gaining access to data in a file containing records sorted by key values. A dictionary and a telephone book are everyday examples of index sequential lists. Access to these is by first locating the correct page, i.e., by looking at the entries on the top left or right corners or each page, and then sequentially reading the individual entries on the page.

Link: Connection between two data items or records. A link may be physical, i.e., one item may contain a pointer (or address) to the other, or logical, where two items are connected by fields having identical contents.

Modem: An acronym for modulator/demodulator, the name for a hardware device that interfaces between a telephone line (analog signals) and a terminal or PC (digital pulses).

Network Model: Data model in which the elements have complex (*m*:*n*) relationships. Each item may be connected to a number of parents and descendents.

Numerical Database: A database that predominantly contains structured numerical data such as physical properties of substances.

On-Line: Interactive process where the user and the host computer are conversing in real time by a constant connection via a computer terminal or a PC.

On-Line Searching Aids: Software systems providing support for on-line searching.

Packet-Switching Network: A communication network which, in order to transmit a message from one location to another, breaks the message into small units called packets containing the destination address. Through multiple use of a single transmission line the costs are shared and are much lower than with normal telephone lines.

Pointer: A data element containing the address of the object being pointed to. In the programming language C, pointers are 2- or 4-byte quantities that may be used in simple arithmetic operations (addition, subtraction).

Record: A linear logical unit containing data associated with one entity or object of a database.

Relational Model: Data model in which the elements can be ordered linearly like the rows of a table.

RS232: A specification defined by the Electronic Industries Association (EIA) detailing the physical configuration of the serial interface connector between data terminal equipment and data communication equipment.

Subject Analysis: The assignment of terms such as classification codes, keywords (descriptors), and other "value-added" codes to bibliographic citations.

Thesaurus: A controlled vocabulary of keywords to be used for indexing of documents. Entries are ordered hierarchically in narrower (NT) and broader (BT) terms. An entry may be classified as forbidden or point to related (RT) or preferred terms.

WORM: Write once, read many times optical disk for storing digitized information.

INTRODUCTION

Computer graphics is the subfield of the computing sciences concerned with the computational creation of visuals, that is, of visually perceived and interpreted information with a predominantly spatial character. This is in contrast to the display of language-based information using symbols (e.g., letters). Visuals may take the form of something as simple as a graph plot of empirically acquired data, in which the geometric setting is used to convey nongeometric information, or it may be as complex as synthesizing realistic images that are not easily distinguishable from photographs, in which the visual component is the essence.

Regardless of the objective, computer graphics uses analytic geometry embedded in various data structures, such as arrays, lists, and graphs, as the basis for representing the basic geometry. This geometry is augmented by a variety of attributes, most notably color, which are appropriate for the intended use. Collectively this forms the *geometric model.* Operations on this model, such as creating a picture of it, are provided by a variety of algorithms.

Since visual perception is a dominant component for much of human experience, and is the sense that receives information at the greatest rate, computer graphics has many application domains. To date, these include visualization of data in business, science, medicine, engineering, architecture, mathematics, and the visual arts, and the simulation and control of processes in manufacturing. Its reliance upon computational representations of geometry, a subject addressed by the subfield of geometric modeling, is shared with other computational fields such as robotics, computer vision, image processing, and computational geometry, as well as with various forms of scientific geometric computation.

Computer graphics began in the early 1960s, most notably with a system called Sketch Pad developed by Ivan Sutherland (1989 Turing Award). Sketch Pad was an interactive design program for electronic circuits that used for its display a variant of an oscilloscope: a CRT in which the electron beam draws the image in a manner analogous to a person drawing with pen and paper. Such a device has been called variously a stroke or vector or random-scan display, and has with rare exceptions been monochromatic.

A flowering of basic research occurred in the field at the University of Utah's Computer Science Department, headed by Ivan Sutherland, during the very late 1960s and throughout much of the 1970s. This work focused on synthesizing more realistic images using TV-based CRTs, called raster-scan displays, that could easily paint a full-color image on the entire screen. Similar work was taking place

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

in industry with the creation of flight simulators: mock cockpits used to train aircraft pilots in which the images in the cockpit windows were generated by computer graphics, thus creating a "virtual reality." Raster-scan-based graphics has since become the dominant display method, made possible by greatly reduced costs of memory and much greater processor performance. It is now available on almost all computer systems, including personal computers. Accompanying this technological advance has been a flowering of the field in research, academic, and commercial arenas.

1. GEOMETRIC MODELING

Creating visuals is primarily a spatial activity, and so one must have a computational representation of space. This space is usually taken to be a Euclidean space, and it is almost always two dimensional (2D) or three dimensional (3D). Euclidean space is modeled algebraically either as an affine space, in which parallel lines never meet, or as a projective space, which adds to an affine space the "points at infinity" at which parallel lines meet (and so has the elliptic parallel property). Real affine spaces use the standard Cartesian coordinates to denote points: (x,y) if in 2D, or (x,y,z) if in 3D, where the coordinates are real numbers. Projective spaces add one more coordinate so that the affine point (x,y) corresponds to the projective points (xw,yw,w) for all $w \neq 0$. If $w=0$, then it is a point at infinity in the (x,y) direction. Points are typically represented computationally as one-dimensional (1D) arrays of reals, and a real number is usually represented by "floating point," where a number is represented in a manner comparable to scientific notation.

Geometric objects, such as lines, circles, or polygons, are interpreted as sets of points. These points are usually defined as those satisfying some equations and inequalities. Thus, for instance, a line in 2D is the set of points satisfying the equation $Ax+By+C=0$. A line segment is the subset of a line between two points on the line, say (x_1,y_1) and (x_2,y_2), which determine a set of inequalities, viz., $x_1<x<x_2$ and $y_1<y<y_2$. These expressions can then be used to test if an arbitrary point lies on the line segment by seeing if it satisfies the line equation and the inequalities. It is also possible to generate any number of points known to be on the line segment using these expressions. The data structure for a line segment can be just its two end-points, since they determine the line and bound the segment as well. Analogously, a circle can be represented by its center and radius.

1.1 Affine Transformations

A fundamental class of operations on sets of points consists of those that map each point onto another point to form a one-to-one correspondence between points, while preserving the neighborhoods of the points; that is, the relative closeness of points is preserved. As a consequence, they preserve the topology or "connectedness" of the set, and such transformations are called *homeomorphisms*. The simplest and most important member of this class are the *affine transformations*. These include translation, scaling, and rotation. If one excludes translation from this class, one is left with the class of *linear transformations*, also called linear operators, which has been studied thoroughly in the context of linear algebra on vector spaces. One can represent a 2D point (x,y) as a 2D vector $[x\ y]$ of a 2D vector space, and coordinate axes can be represented by the basis vectors of that space: the x axis by [1 0] and the y axis by [0 1]. Similarly for any dimensionality. Linear transformations are equivalent to a change of the vector basis: each basis vector is mapped to any arbitrary vector. The length of each new basis vector provides scaling along each axis. A rotation is achieved if the new basis vectors remain mutually orthogonal; otherwise, shearing is introduced. Any linear transformation on a d-dimensional space can be represented by a $d \times d$ matrix, whose computational representation is usually a 2D array of reals.

However, a change of vector basis cannot provide translation. While vector addition can do so, the use of only linear transformations can be retained if instead one uses projective space, so that a 2D Euclidean point will be represented by a 3D projective point (xw, yw,w). Most often $w=1$, so that one can think of the original 2D space as simply the $w=1$ plane in the 3D projective space (see Fig. 1). This solves the translation problem by mapping the 2D origin/zero-vector [0 0] to the new w basis vector [0 0 1]. A translation of $[Tx\ Ty]$

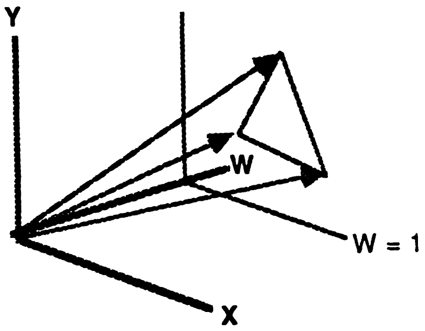

FIG. 1. Homogeneous coordinates.

is achieved by mapping the w basis vector to [Tx Ty 1], while the standard 2D linear transformations affect only the x and y basis vectors. In general, then, affine transformations of a d-space are represented by a restricted class of linear transformations of a $(d+1)$-space.

Projective space is also useful for central projections, e.g., the perspective projection in 3D, as well as for representation of surfaces as rational functions, and is generally preferable to affine space. The coordinates of a projective space are called *homogeneous coordinates*, because a point in d-space is mapped to a line through the origin in $(d+1)$-space. Similarly, lines are mapped to planes that contain the origin; that is, a line $Ax+By+C=0$ is represented by a vector [A B C], which can be interpreted as the normal of a plane containing the origin. As a result, the zero vector is a solution to the new equation representing each original point or line: thus, the term "homogeneous."

This mapping of a point or line to a set of one greater dimension applies to spaces of any dimension. The dimension-independent versions of point, lines, and planes are called *flats* or *affine subspaces* or *linear varieties*. Therefore, homogeneous coordinates map k-dimensional flats, or simply k-flats, to $(k+1)$-flats that contain the origin. A k-flat can be thought of as a k-dimensional space, say determined by the first k coordinates of a d-space, to which an arbitrary d-dimensional affine transformation has been applied. They are also defined as the intersection of hyperplanes, where a hyperplane is a $(d-1)$-flat defined by the equation $a_1x_1+a_2x_2+\cdots+a_dx_d=a_{d+1}$, i.e., a linear equation in d variables. In 2D a line is a hyperplane, and in 3D a plane is a hyperplane. The intersection of n hyperplanes is in general a $(d\text{-}n)$-flat, $0\leqslant n\leqslant d$.

1.2 Polytopes

Points, line segments, polygons, and polyhedra are the most commonly used geometric sets, and they are respectively the 0D (zero-dimensional), 1D, 2D, and 3D instances of the dimension-independent class known as *polytopes*. These are objects with "flat faces" (Fig. 2). One method of defining polytopes is by a recursive definition in terms of their boundary. Observe that a line segment, which is a 1D polytope, has for its boundary two points, which are 0D polytopes. Similarly, the boundary of the 2D polygon is comprised of a set of the 1D line segments, and the 3D polyhedron is bounded by a set of 2D polygons. In general, a d-polytope is bounded by a set of $(d-1)$-polytopes, which are referred to as the $(d-1)$-faces of the polytope. If one unwinds this recursive definition, it becomes evident that a d-polytope has a boundary comprised of k-dimensional faces for all k, $0\leqslant k<d$.

One can construct a data structure representing a polytope based on this property. Given the 0-faces (vertices), each 1-face (edge) is represented by its two vertices. Each 2-face (polygon) is then a list of 1-faces, and in general each k-face is represented by a list of $(k-1)$-faces. These lists of k-faces are further organized into connected sets, called manifolds. This method of representing each polytope by its boundary is called a *boundary representation*, and there is a one-to-one correspondence (an isomorphism) between connected components of the boundary and elements of the data structure (Fig. 3). This data structure is a graph in the form of a hierarchy

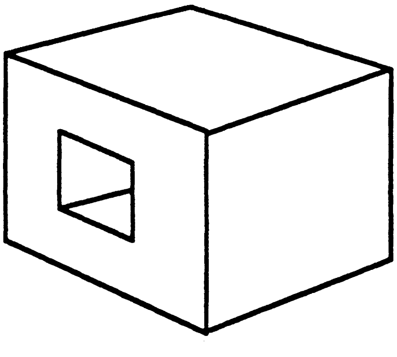

FIG. 2. A polyhedron.

of lists: nodes at one level correspond to all faces of a particular dimension. Arcs in the graph are of two types: between a k-face node and the nodes of its bounding $(k-1)$-manifolds, and between elements of the same manifold. The only purely geometric information is the coordinate values of the vertices; all other information is topological, i.e., information indicating which faces are connected to which other faces. Thus, a boundary representation, also denoted as *b-rep,* is often characterized as being a topology-based representation.

A crucial property of polytopes is that all of the faces are flat; that is, each k-face is contained in a k-flat. This restriction to sets defined in terms of linear equations (hyperplanes) greatly simplifies computations, as the intersection of two flats is another lower-dimensional flat. The fact that any k-face lies in the intersection of $d-k$ hyperplanes can be used as a basis for a representation of polytopes.

First note that a hyperplane h partitions space into two half-spaces, denoted as h^+ and h^-. The intersection of any set of half-spaces is a convex polytope (or the empty set), where a convex set is one for which the intersection of it with a line is a single line segment (or single point). All faces of a convex polytope lie in the hyperplanes that form the half-spaces. However, since a half-space is a convex set, and the intersection of convex sets is always another convex set, this approach can only represent convex polytopes.

The approach can, nonetheless, be extended to represent any polytope, not just convex ones, by allowing both half-spaces of a hyperplane to contain parts of the polytope. This is achieved by recursively subdividing space by the hyperplanes that contain the faces of the polytope. A single local operation is needed: partition a region r by a hyperplane h that intersects r. Usually, h contains a face that lies in r. This binary partitioning of r creates two subregions $r^+=h^+\cap r$ and $r^-=h^-\cap r$, where the subregions are open sets, i.e., they do not include h (*open sets* are sets that have had their boundary points removed). This process can be represented by a three-node graph in which the nodes correspond to regions r, r^+, and r^-, and arcs are between r and its two "child" regions (Fig. 4). The right arc can be interpreted as corresponding to the operation $h^+\cap x$ for any set $x\in r$, and the left arc to $h^-\cap x$. Now the two subregions can be treated just like r; that is, they can be partitioned by hyperplanes containing faces lying in them, and then their children can be partitioned, and so on recursively. The result is a hierarchy of regions, and the coresponding graph is a binary tree in which each node of the tree corresponds to one region, and arcs indicate the relation between parent and child regions of creating the later from the former by partitioning. Such a geometric structure is called a *binary space partitioning tree* or, alternatively, a *partitioning tree* or *bsp tree.*

Generally, the initial region is all of d-space, and a consequence of inducing a partitioning tree structure on d-space is that a disjoint convex decomposition/partitioning is formed by the unpartitioned leaf regions, called *cells.* Convexity arises from the fact that

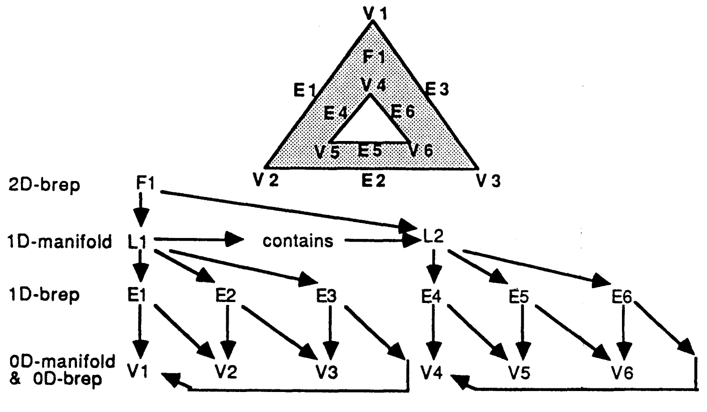

FIG. 3. Boundary representation of a polygon.

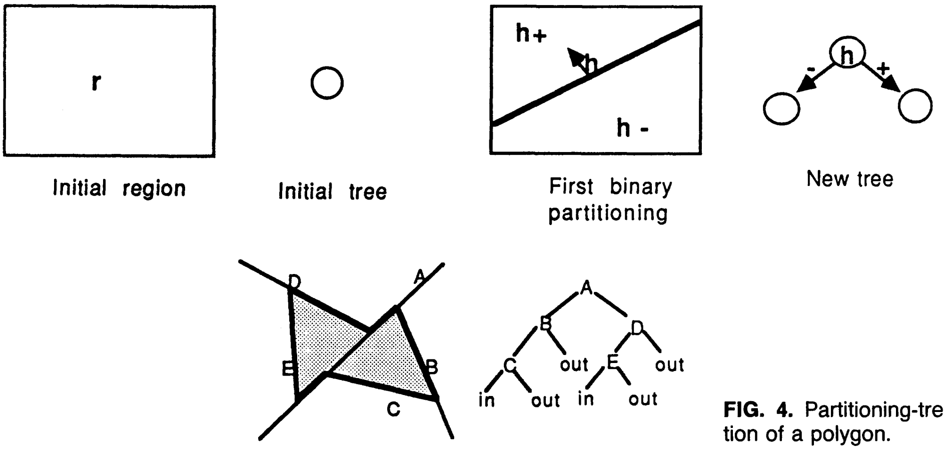

FIG. 4. Partitioning-tree representation of a polygon.

each region *r* of the partitioning tree is created by the intersection of half-spaces corresponding to the arcs in the path of *r* starting at the root of the trees. Since the partitioning tree has been constructed so that all polytope faces lie in the partitioning hyperplanes, none of the boundary lies in any cell, and so each cell with be either entirely in the polytopes's interior or in its exterior. The interior cells then form a convex decomposition of the polytope (and the out-cells form a convex decomposition of the exterior as well). The polytope is defined to be the union of the in-cells, which are open sets, followed by a closure operations that adds boundary points and fills in the cracks between in-cells.

The development of polytopes has implicitly assumed that the flatness of faces is an intrinsic property. However, it is easy to imagine warping the faces of a polytope into curved faces, In fact, systems have been developed that use nonflat polyhedral faces (called *algebraic polytopes,* if the faces lie in polynomials). So flatness need not be considered an intrinsic property of polytopes. However, the idea of a geometric set whose boundary is a set of "smooth" faces, i.e., faces without "interior edges," is intrinsic to the concept of polytopes; that is, polytopes have *piecewise* smooth boundaries. Thus the intrinsic properties of polytopes are that they have smooth faces, and they have a finite number of faces. The former is satisfied through the use of continuous functions, developed in classical mathematics, whose gradient (tangent function) is continuous. The latter is a combinatorial property, which together with the computational setting is an issue addressed by computer science; in particular, it is concerned with the development of representations and efficient algorithms providing operations on those representations. The boundary representation and the partitioning tree are examples of this.

1.3 Nonlinear Sets

While using only linear expressions to define a geometric set simplifies considerably all computational aspects, restricting faces to being flat is too limiting, since many desirable surfaces are not piecewise flat. Defining surfaces that are curved requires using nonlinear functions, such as polynomials of degree greater than 1, or transcendental functions such as sine or cosine or exponential functions, or any easily computable function whose gradient is continuous. Unfortunately, nonlinear functions can be considerably more complicated than linear functions. Because of this, it is very common to use the nonlinear functions to define the model, and then to construct a piecewise linear approximation of the nonlinear sets so that the difficult computations are performed using linear polytopes.

There are two fundamental forms for defining sets: the *characteristic function* that determines whether a point is a member of a set, and the *generating function* that enumerates the points that are members of the set. For sets of integers, the computable sets, or *recursive sets,* are those that have a computable characteristic function, and the semicomputable sets, or *recursively enumerable sets,* are those with a computable generating function. For polynomials, implicit representations provide characteristic functions and parametric functions provide generating functions. The implicit form defines the sets in d-space as $\{\mathbf{x} \mid \mathbf{f}(\mathbf{x})=0\}$, where $\mathbf{x}$ is a d-dimensional vector and $\mathbf{f}$ is a scalar-valued function. For example, $x^2+y^2-r^2=0$ is the implicit form defining a circle of radius r centered at the origin. The parametric form uses a set of parameters to generate the set $\{\mathbf{x} \mid \mathbf{g}(\mathbf{t})=\mathbf{x}\}$, where $\mathbf{x}$ is a d-dimensional vector and $\mathbf{t}$ is a vector of dimension $<d$. The dimension of the set is that of t. A parametric form of the circle above using parameter t is $x=r \cos t$ and $y=r \sin t$, for $0 \leqslant t < 2\pi$.

Any set whose characteristic function is given by a polynomial is referred to as an *algebraic set*, and the 1D and 2D algebraic sets are known, respectively, as algebraic curves and algebraic surfaces. The study of algebraic sets is the principal topic in the branch of mathematics known as *algebraic geometry*. While algebraic geometry considers polynomials of any degree, the lower-degree algebraic sets are the most widely used. For example, the second-degree polynomials in 2D define the conics: circle, ellipse, hyperbola, and parabola. In 3D they are the quadric surfaces: sphere, ellipsoid, hyperboloid, paraboloid, and cone. For sets defined by higher-degree polynomials, comparable classifications are not always known; and, unlike first- or second-degree sets, they may intersect themselves, creating singularities, and they may not admit a simple parametrization. In general, the greater the degree of the polynomial, the greater the computation that is involved and also the greater the numerical error due to the floating-point representation of reals. Thus, in practice, only polynomials of relatively low degree are computationally viable if the polynomial is an *irreducible* polynomial. A polynomial is said to be reducible if it is the product of two or more lower-degree polynomials, and irreducible if it is not. Thus $x^2 \equiv x \times x$ is reducible, whereas x^2+y^2 is irreducible. Irreducible polynomials are an important class in that they provide the primitive algebraic sets from which all other algebraic sets can be constructed, and they are referred to as *algebraic varieties*. Planes and spheres are examples of algebraic varieties.

1.3.1 Parametric Curves and Surfaces. Defining a complicated surface using only a single polynomial requires using one of high degree, which as noted above is computationally unattractive. An effective alternative is to define a set piecewise, where each piece is defined by a low-degree polynomial. The pieces then connect to each other in a patchwork manner to form a continuous set. Since each piece is a subset of an algebraic set, it is continuous for all derivatives. But at the places where the pieces join together, the continuity varies according to need. Tangent continuity C^1 is required to ensure that at each join the set does not form a corner, whereas curvature continuity C^2 is used to induce greater smoothness; only rarely are higher degrees of continuity needed.

An important instance of constructing piecewise polynomial curves with smooth joins in the class of curves known as *splines*, which are usually piecewise cubic curves with C^2 continuity at the joins. Piecewise definitions are most often formulated using the parametric rather than the implicit form because the desired piece of the polynomial can be specified by restricting the parametric domain. For example, a set in 3D is defined by the coordinate functions $x=X(t)$, $y=Y(t)$, and $z=Z(t)$, where each coordinate function is a polynomial, and a piece can be defined by limiting the coordinates of t to be in the interval [0 1]. If t is a 1D vector, i.e., a scalar, then the set is a space curve. If t is a 2D vector, a *biparametric* surface is defined. The biparametric surfaces, often denoted as $P(u,v)$, can in fact be interpreted as being a set of parametric curves: holding one parameter constant determines a curve in the other parameter (Fig. 5). This property has given rise to calling these surfaces *cross-product surfaces or tensor product surfaces.*

If one wants to design curves and surfaces interactively, that is, to use a person's visual esthetics to select the shape, the method of shape specification must be simple and intuitive. Specifying the coefficients of polynomials directly does not provide this. Consequently, geometric methods, rather than algebraic ones, have been developed for the interactive design process. A classical approach is *interpolation:* given a set of user-defined points, compute a piecewise polynomial curve or surface that goes through the points and provides the desired degree of continuity at the joins. In fact, splines were developed for exactly this purpose. Interpolation is sufficient if one does not want to adjust

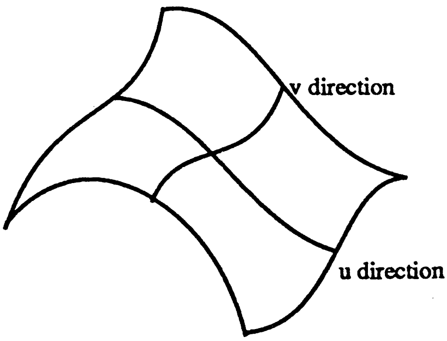

FIG. 5. A parametric surface patch.

the points subsequently, for doing this may cause the shape to change everywhere. With interpolation, any change can have a global effect, whereas the intent is usually to make a local modification, that is, to move only one point and the part of the curve around that point. To circumvent this problem, methods have been developed based on the idea of approximating a set of points rather than interpolating them. The points that are approximated are called *control points* since the designer uses them to control the shape; but the set only lies near the points, not through the control points (in some cases a few of the control points are indeed on the set).

The most well known of these are the Bezier curves and surfaces. A Bezier curve, which is defined by a single polynomial of degree n, is determined by $n+1$ control points, numbered P_0, P_1, ..., P_n (see Fig. 6). To obtain local control, a curve is constructed piecewise from a set of Bezier curves. Thus, only a subset of each Bezier curve is used. The end points of that curve segment are given by the first and last control points, P_0 and P_n. These two control points lie on the curve itself and are the only control points that do so. The tangent line at P_0 is the line through P_0 and P_1, and similarly the tangent line at P_n is the line through P_{n-1} and P_n. An analogous relation holds for higher derivatives at the end points (e.g., the curvature at P_0 is determined by P_1 and P_2), and so there is an intuitive geometric relation between control points and the curve.

The control points taken by themselves as a list of points can be linearly interpolated to form what is called the "control polygon" (a bit of a misnomer, since the first and last control points are not considered "connected," and so it is really a piecewise linear curve). The importance of the control polygon is that the Bezier curve is an approximation of it, and this is why Bezier curves are considered an approximating method. The algebraic analogue to the geometric formulation of Bezier curves is the approximation of functions using the Bernstein basis. Any polynomial of degree n can be represented exactly by the weighted sum of $n+1$ Bernstein basis functions $B_{i,n}(t)$, $0 \leqslant i \leqslant n$, where each is a polynomial of degree n. In particular, $B_{i,n}(t) = C(n,i)t^i(1-t)^{n-i}$ where $C(n,i)$ are binomial coefficients. They have the property that they sum to 1, i.e., $\Sigma_i B_{i,n}(t) = 1$. The control points are used to determine the weights of each basis function; that is, P_0 is the weight for $B_{0,n}$, P_1 for $B_{1,n}$, and so on, so that the curve is $P(t) = \Sigma_i B_{i,n}(t) P_i$. While the algebraic form is important for analysis and computation, it is the geometric characteristics of manipulating control points that has made the Bezier form appealing for geometric design.

When one is constructing a curve by joining several Bezier curve segments, maintaining continuity at the joins requires that the control points of the two segments at a join be geometrically related. For example, tangent continuity between curve segments A and B requires that the control points $A_n = B_0$ and that the tangent line at the join contains control points A_{n-1} and B_1. Constraining control points to achieve continuity is a consequence of the fact that the definition of each segment is independent of every other; and so, only constraining the control points can induce a relation between segments.

An alternative that performs this correlation intrinsically is the *B-spline* method. It retains from Bezier curves the idea that the curve is a piecewise polynomial and that each segment is the weighted sum of $n+1$ basis functions with the weights being the control

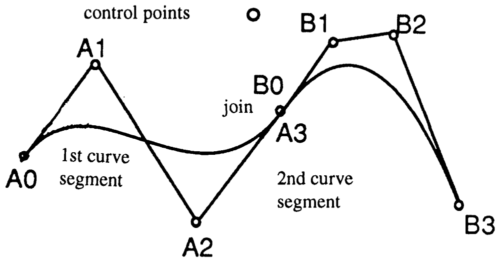

FIG. 6. Cubic Bezier curve with two segments.

points (the unweighted basis functions sum to 1 as well). The difference lies in the fact that a single control point is used as a weight in $n+1$ consecutive segments, and this then provides a means of ensuring continuity at the joins up to C^{n-1}. Thus, a cubic *B*-spline curve is piecewise cubic with C^2 continuity at the joins. Control point P_i is used as a weight in curve segments $S_i, S_{i+1}, \ldots, S_{i+n}$, but it is the weight of a different basis function in each of the segments. Since P_{i+1} is used in segments $S_{i+1}, S_{i+2}, \ldots, S_{i+n+1}$, two consecutive control points contribute to n common segments, which result in the desired automatic correlation between segments to ensure continuity.

Unfortunately, parametric piecewise polynomial curves in 2D of any degree cannot exactly define a conic, which is an important class of curves. However, if the curves are defined in projective space, they indeed can define conics. This is because the perspective projection of a 3D, degree 2, parametric space curve can be exactly a conic. Thus, it is common to use projective space for defining parametric curves, and such curves are called *rational curves,* because the perspective division of $X(t)$ and $Y(t)$ by $Z(t)$ results in a ratio of two polynomials. Analogous reasoning yields rational surfaces.

1.4 Constructive Methods

The methods just described define a shape directly, primarily in terms of its boundary. These direct methods can be supplemented by constructive ones in which two or more of the direct methods are used in conjunction to construct a new shape. The most common such method is the use of Boolean set operations: union, intersection, and both symmetric and asymmetric difference, which correspond to the Boolean functions of "or," "and," "exclusive-or," and "subtraction" (A&~B). Figure 7 illustrates their use in forming a new polygon from set operations on two other polygons. The result can then be used in subsequent set operations, resulting in a hierarchy of shapes. This method of shape creation is called, when in 3D, *constructive solid geometry.*

Another constructive method, called *instancing,* creates multiple copies of a shape, or "instances," by applying a unique affine transformation to the original for each copy. Inherent to this concept is the property that any subsequent change to the original will cause all instances to change; that is, the instances are always defined to be the current value of the original transformed by the current value of the transformation.

A third basic constructive method utilizes the idea of a shape moving in time. For example, if a line segment is moved some distance along a particular direction, all of the points "visited" by the line segment form a quadrilateral. If a line segment is rotated 360° about one of its points, the locus of points swept out is a disk. If instead the center of rotation is not on the segment but is on the line containing the segment, a disk with a hole in it is formed. There are all methods of creating *swept objects.* The technique of moving a shape along some path, i.e., along a curve, is called *translational sweeping,* while rotating a shape about some axis is called *rotational sweeping* (also called, in 3D, generation of surfaces and solids of revolution).

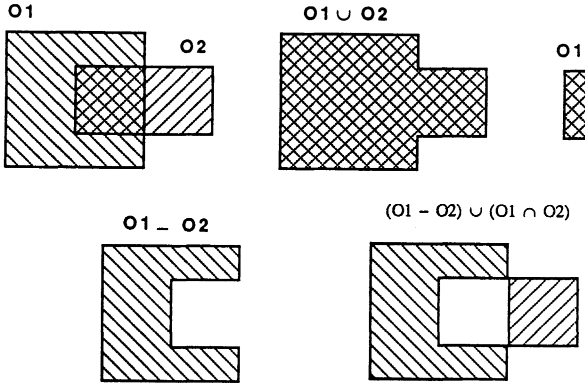

FIG. 7. Constructing sets with set operations.

1.5 Discrete-Space Methods

The methods discussed so far have all made explicit use of the idea that space is continuous. An alternative is to treat space as discrete in the form of a regular lattice of points created by restricting the coordinates to the integers. At each lattice point, an arbitrary set of attributes, like color, can be defined, and a *d*-dimensional space can then be represented computationally by a *d*-dimensional array of attributes. In 3D, each point is referred to as a *voxel* (derived from "volume element"). This representation is typically generated by discretely sampling the analog output of a sensing device, such as a TV camera, which detects some form of electromagnetic energy. Medical devices used for imaging the human body are another example of such devices.

While the array representation is very simple, it can require substantial amounts of memory when compared to typical continuous space representations. An approach to reducing this is to find connected regions of elements that have the same attributes, called *homogeneous regions,* and to represent each such region as one element in the data structure. A standard approach to this is to subdivide space into homogeneous regions using recursive subdivision, as was done by the partitioning tree discussed above. For discrete domains a commonly used method is called the *quadtree* in 2D and the *octree* in 3D. A quadtree is formed by recursively partitioning a square region into four "quadrants" (Fig. 8), and an octree is formed by recursively partitioning a cubic region into eight "octants." During the recursive subdivision, the partitioning terminates whenever a region is produced that is homogeneous; otherwise the region is partitioned. The limit to the subdivision occurs whenever a lattice point is reached, as this is a homogeneous region by definition.

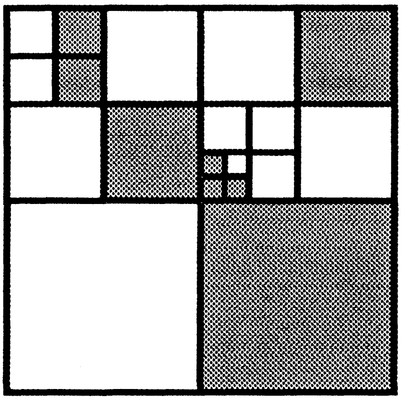

FIG. 8. Quadtree representation.

2. RENDERING

Given a geometric model representing a 3D scene, defined using any of the above techniques, the most important and computationally intensive operation is to synthesize a 2D image of the scene for display with video, film, or print media. This is called *rendering.* The goal is to create an image that will resemble, to some degree, what a person or camera would see if the scene were in some sense real. If the scene is a realizable 3D world, then rendering may try to achieve photorealism; that is, the image generated is indistinguishable from a photograph of a real scene. However, an alternative objective is simply to communicate information of some sort without being concerned with photorealism. This information may have an intrinsic 3D geometric form, such as weather data, or the 3D setting may be used simply as a means of communication, as in the display of statistical data points. But even when photorealism is not an objective, the appropriate rendering algorithms are essentially simplified versions of those needed for photorealism, since the human visual system has evolved for the express purpose of perceiving a 3D physical world.

Rendering algorithms simulate, to varying degrees of accuracy, the physics of the propagation of light through a homogeneous media and the interaction of light with matter, such as reflection, transmission, diffraction, and scattering. However, to do this accurately, one might think that all such propagation and interaction with objects in the scene would need to be simulated at the level of photons. It would, however, be computationally intractable to perform such a simulation. Fortunately this is not necessary since the resolution of the human visual system is limited, and so every detail provided by such a simulation could not be perceived. Therefore, the real challenge in rendering is to develop computationally attractive algorithms that produce realistic-appearing replicas of as large a class of phenomena as possible. Over the last two decades, many such algorithms have been developed that can indeed effectively simulate at reasonable costs a variety of optical effects; among these are reflections, refraction, transparency, shadows, and surface texture.

Synthesizing an image using a geometric model of a 3D scene composed of a variety of objects and sources of illumination requires, in addition, a virtual camera described by its viewing position, orientation, and field of view, as well as an image plane that models the display surface onto which the scene will be projected. Rendering can then be understood as being performed in two distinct steps: *visibility calculations,* which compute the propagation of light through homogeneous media, and *shading,* which performs the computation needed to simulate interaction of light with matter. (While in a number of algorithms these steps may not be very distinct, such a distinction will simplify the presentation.)

For visibility calculations, we consider the light that reaches the viewing position along rays emanating from the object's surfaces. However, objects closer to the viewing position will occlude objects farther away, and this occlusion must be computed. If we then consider rays emanating from the viewer instead of from the surfaces ("antioptic" rays), then any such ray may intersect any number of surfaces, but it will intersect the image plane on which we will create the picture at only one point. From which of these surfaces will the light reach the image plane point? Only the light from the closest surface will, and so this surface point is considered visible. If for all rays emanating from the viewing position the visible surface point is determined, then we will have solved what is called the visible surface or hidden surface problem.

The second component, called *shading* or *local illumination,* computes how incident light is reflected, refracted, and absorbed within a small area on a surface, on the basis of its geometric and optical properties. Models have been developed, based on physics, to cover the spectrum from purely diffuse matte surfaces to purely specular mirrorlike surfaces. Diffuse surfaces are characterized by radiation heat-transfer models (blackbody radiation), and specular surfaces by geometric optics (including refraction and Fresnel effects). Modeling the range between these two extremes is achieved by combining models for the extremal cases.

Since the geometric model is defined in continuous space whereas the image is defined in discrete space as a set of pixels, care must be taken when converting between these two different fundamental forms of space. For example, an inclining line will be represented as a set of pixels that, when examined closely, will resemble a staircase instead of a smooth line. This effect is called *aliasing.* It arises from attempting to represent rates of change (frequencies) that are greater than the spacing of the pixel lattice. Visible artifacts due to aliasing can be reduced by higher sampling rates combined with low-pass filtering; this is called *antialiasing.*

2.1 Visibility Determination

Visibility can be computed in a number of ways. For example, one can directly simulate the propagation of light by constructing a ray from the viewpoint through each image point, determine the objects it intersects, and choose the object that has the smallest distance along the ray. This approach is called *ray tracing.*

An alternative is to transform the model to the coordinate system shown in Fig. 9 in which the viewing position is at the origin and the x and y coordinates correspond to the horizontal and vertical directions of the display, respectively. In addition, the image plane is orthogonal to the z axis and at unit distance from the origin. As a consequence, the z coordinate corresponds to depth. One can then apply a perspective projection to all the points in the model by mapping each point (x,y,z) to $(x/z, y/z, -1/z)$. This has the effect of mapping a ray through the image plane point P to one that is parallel to the z axis but still contains P, and also preserves the depth ordering along the ray. As a consequence of this mapping, the visible surface at image point (x,y) is the surface that has the smallest z coordinate.

2.1.1 Z-Buffer Algorithm. This algorithm is the most commonly used visible surface algorithm. It operates on any set of 3D points in the above post-perspective space whose xy coordinates lie on the pixel lattice. All points with the same xy coordinates project onto the same pixel. Since the visible surface is composed of those points that are closest, we

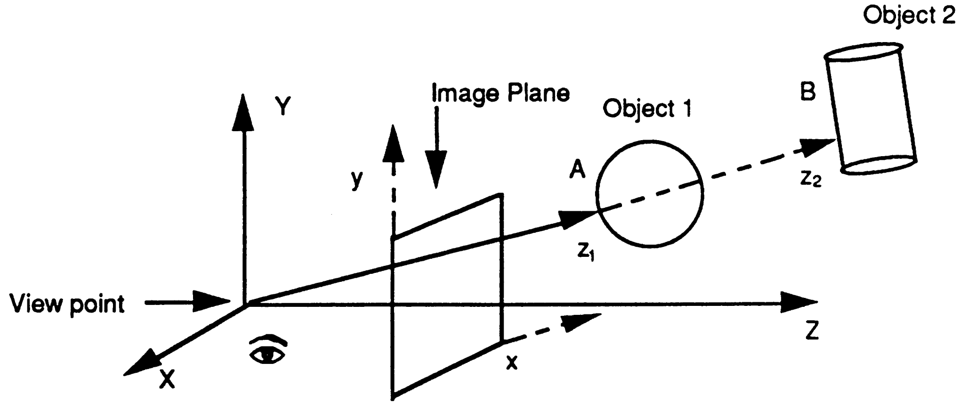

FIG. 9. Visibility: A ray intersects object 1 at distance z_1 and object 2 at z_1, $z_1 < z_2$. Only light from object 1 reaches the image plane.

simply need to sort the points into buckets, one for each pixel denoted as *pixel*[*x*,*y*], while keeping only the point with smallest depth (z value). This can be accomplished by maintaining both a color buffer, *pixel*[*x*,*y*].*color*, and a z buffer, *pixel*[*x*,*y*].*z*, which are set initially to the background color and maximum depth, respectively. Each surface is quantized, one at a time, into a set of 3D points. For a point (x,y,z), if $z < pixel[x,y].z$, then this point is closer than any previous point with those xy coordinates, and its color and z value replace the contents of *pixel*[*x*,*y*]. Otherwise, the point is known to be occluded and so is discarded. After all points have been processed, the contents of the color buffer is the desired image.

2.1.2 Scan-Line Algorithms. Here the image is treated as being composed of a set of horizontal *scan lines*, and it is synthesized one scan line at a time, going from top to bottom. For each scan line, the plane consisting of the viewpoint and the scan line is extended to determine the objects it intersects. If the objects are described by polygons, then such intersections are easy to calculate and this results in a collection of horizontal line segments, called *spans*, one span for each intersected polygon. Visibility calculation can then be carried out on these spans, thereby reducing a 3D problem to a set of 2D problems. These spans are kept in an "active polygon" list sorted left to right by their left end points. Between two consecutive end points, only one polygon can be visible. The algorithm sweeps left to right, computing at each span end point the closest span, and then drawing that span. When a scan line is completed, the next scan line in the top-to-bottom order is processed. This requires updating the active list of polygons by deleting old polygons that do not intersect the new scan line and adding new polygons that do. Polygons remaining in the list have the end points of their spans updated to reflect the change in position between two consecutive scan lines.

2.1.3 Visibility Priority. Another method is based upon visibility priority. If a ray from the view intersects two surfaces A and B such that A is closer to the viewer than B, then A is said to *occlude* B. If it is also the case that A occludes B for every ray that intersects both of them, then A is said to have visibility priority over A. If this fact is known, then it is possible to draw B entirely first, and then draw A "on top of" B; as a consequence the part of A that occludes B will overwrite it. This has been dubbed the *painter's algorithm*, alluding to the occasional practice of painters to overpaint a background with a foreground. If a visibility priority ordering of all surfaces can be generated, then drawing the surfaces "back to front"—that is, lowest priority to highest priority—will produce an image with correct visibility. If one uses the partitioning-tree representation of polyhedra, as discussed in Sec. 1.2, one can generate such a priority ordering by simply traversing the tree in an order determined by the current viewing position.

2.1.4 Ray Tracing. All three of the methods just described are not suitable for computing interobject reflections and transmittance. To accomplish this, ray tracing can be employed (Fig. 10). Here for each pixel on the image plane, a ray is propagated from the viewpoint through the pixel into the object space. Among all the objects that this ray intersects, the object that is the closest to the viewpoint is chosen. From this point of intersection, a second ray is traced toward the light sources. If this secondary ray encounters an object between the surface and the light source, then the intersection point is considered to be in shadow. Rays are also propagated in the directions of reflection and refraction. Such rays may intersect other objects and so generate other reflection and refraction rays, and so on recursively until the ray goes out into empty space or hits a light. This process creates a tree of reflection, refraction, and shadow rays forming a geometric network by which light flows back to the viewer. The intensity and chromaticity of the light is determined by the local illumination models at each surface in the network.

Ray tracing is capable of generating photorealistic images that contain most of the optical effects, except those that can only be modeled using the wave nature of light. There are two principal difficulties, however. As the number of objects in the scene increases, ray-surface intersection calculation increases, particularly if there is a large number of secondary rays. To give an indication of the magnitude of the problem, consider an image (1000×1000) containing a million pixels generated from a scene containing a thousand objects. If there are, say, three secondary rays per primary ray (a very modest estimate), and if each object is represented by a cubic polynomial, then intersection calculations could require computing the real solutions of cubics 4×10^9 times, which is quite formidable.

The second problem for ray tracing arises from the infinitely thin nature of the rays that result in point sampling of the scene. This generates aliasing artifacts. Several techniques have been proposed to overcome these difficulties. Ray-surface intersection can be simplified if surfaces that do not lie near a ray can be excluded. A hierarchy of bounding boxes that enclose objects has been used for this purpose. If a ray does not intersect a box, which is easy to check since boxes are simple, then it does not intersect any object in that box. However, if it intersects the box, then the ray is tested for intersection with each of the smaller boxes contained within this box. This process is continued until the smallest box is reached, at which point the ray is tested for intersection with all the objects in that box.

Another similar technique is to divide the object space into disjoint cells using, for example, a partitioning tree or an octree. A list of all surfaces that intersect a cell is stored with that cell. A ray can then be inserted into the tree to quickly find the cells that it intersects, and the cells can be visited in a near-to-far priority order. Ray-surface intersections are then limited to those surfaces that lie in the cells traversed by the ray, and can be performed in the near-to-far ordering. The first intersection is then the visible surface, and so the rest of the surfaces in the remaining cells need not be tested. Such algorithms

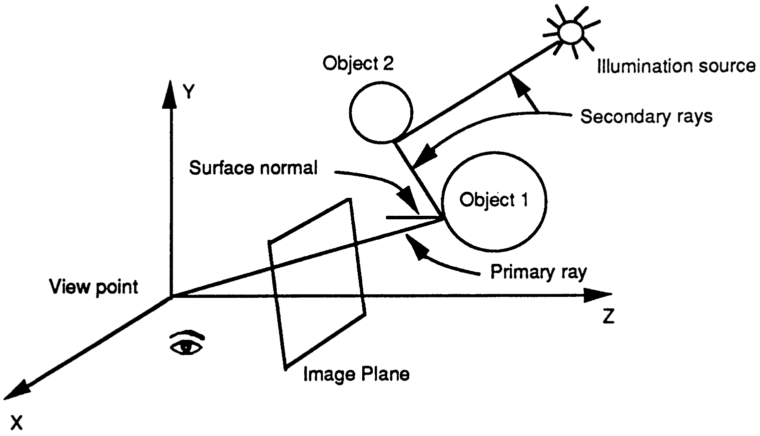

FIG. 10. Primary and secondary rays in ray tracing.

can improve the efficiency of ray-surface intersection calculations by orders of magnitude. But despite these improvements, ray intersection continues to be the principal computational burden for ray-tracing algorithms.

2.2 Illumination

Having determined the point on a surface in the object space that is visible, one must determine the color of light traveling in any particular direction, for example, from a visible surface to the viewer. This requires modeling the interaction between light incident upon a surface with the surface itself. As an example, for reflection, the intensity I in any direction can be modeled as a sum of three components:

$$I=I_d+I_s+I_a,$$

where I_d is diffuse reflection, I_s is specular reflection, and I_a is reflection due to ambient light. The diffuse component is due to light being reflected by a rough surface uniformly in all directions and is treated as being direction independent. Specular reflection corresponds to reflections along the direction of reflection, determined by the angle of incidence and the surface normal. For mirrors this is the only illumination term, but for less perfect reflectors this component is what models highlights. For matte surfaces, the specular component is 0 and reflections are modeled soley by the diffuse term.

I_a is determined by light reflected off of other nearby surfaces. This can be treated simply as being a constant level of direction-independent illumination or it can be computed exactly. *Radiosity,* originally developed for studying radiation heat transfer, can be employed for this. The radiosity of a surface is the total light emanating from it. It consists of all the reflected light and, for light-emitting surfaces (lights), all emitted light. The objects must be subdivided into surface elements that are small enough so that the radiosity term can be treated as being constant over the element. The unknown radiosities are then computed from a system of simultaneous linear equations, one for every pair of these surface elements, expressing the quantity of light transferred between the two elements.

2.3 Antialiasing

Since objects are modeled as having value-continuous, but not tangent-continuous, surfaces, they may have arbitrary sharpness; i.e., they can have edges. Sharpness represents a high rate of change as one moves, say, horizontally across an image, and this rate of change may be thought of in terms of frequency. More exactly, one can in principle perform a Fourier transform on a spatial function to obtain its representation in terms of frequencies. Thus edges correspond to spatial regions with high frequencies since the function changes very rapidly. (If the function is value discontinuous, then there is no bound on the highest frequency.) The displays, being physical systems, are capable of showing only images whose bandwidth is limited. It is, therefore, necessary to carry out low-pass filtering on the signal before it is displayed. If filtering is not done, artifacts such as jagged edges (spatial aliasing) and backward spinning of wagon wheels (temporal aliasing) are clearly seen. However, too much filtering reduces the sharpness of the images, and certain filter shapes can cause other visible artifacts (e.g., ringing). Thus the filter design represents a trade-off between a number of subjective factors such as sharpness and visibility of aliasing artifacts.

Prefiltering a signal by an amount such that the bandwidth of the resulting signal makes the sampling rate a Nyquist rate is a preferred mode of overcoming aliasing. In a number of situations, this can be easily done. However, in ray tracing such prefiltering may require computing a large number of samples by tracing many rays. It is typical, for example, to compute 8 or 16 ray-traced samples for each pixel and then filter them. Another method is to filter the objects directly in 3D space to make them smoother. Unfortunately, such filtering, if properly done, must depend on the direction and distance of the viewpoint and the image plane relative to the object. Moreover, only simple surfaces such as spheres and polygons can at this time be handled, and special effects such as shadows and transparency are quite difficult. A preferred approach is to do adaptive sampling of the image plane. In areas of high detail (or uncertainty) the density of the rays is increased and the location of the rays is randomized. The former method allows more local bandwidth where needed, and the latter makes aliasing noise more random and makes it contain higher frequencies, thus reducing its visibility.

2.4 Surface Color Variations

Visibility calculation and shading described in the last section can, in many cases, create images that look artificial because their surfaces look too smooth. Metallic objects may look fine, but natural objects such as fruits and human skin will not. Realism can be increased in many cases by adding detail, i.e., texture, on the surface of the objects. This is usually done either by adding a prespecified two-dimensional pattern of colors on top of a smooth surface or by making the surface rough. The former can be considered as a mapping of a 2D "image" onto a 3D surface with associated warping of the image, whereas the latter can be modeled as randomization of one or many of the surface attributes, such as the reflection property or surface normal. Since the addition of texture patterns on the object's surface can be thought of as a mapping from texture space onto the object space, it can be done in one of two ways:

1. compositing the mapping from texture space to object space with the mapping from object space to the image plane used in visibility calculation; or
2. utilizing an inverse mapping from the image plane to texture space.

A different approach to varying the color across a surface is to interpolate the color. As mentioned earlier, nonlinear surfaces can be approximated by polygons in order to reduce the complexity of the algorithms dealing with such surfaces. However, the illumination will be discontinuous at polygon edges even though the nonlinear surface would have been continuous in this region. If, however, the color is known at the vertices, then these values can be easily interpolated across the polygon. This guarantees that two polygons that share an edge will have the same color along that edge, and so the image will remain value-continuous at any edge not lying on the silhouette. This method is called *color interpolation* or *Gouraud shading.* A similar idea is to interpolate surface normals defined at the vertices across the polygon and compute the illumination using these normals at each interpolation point. This method is called *normal interpolation* or *Phong shading,* and it allows polygonal models to display highlights.

3. ANIMATION

Computers have been used in creating image sequences showing animation. Techniques of the previous section can be used to create a set of *key frames* in an image sequence. Key frames are those frames where a discontinuity in motion or content occurs during the animation sequence. Computer algorithms are then used to create the "in-between" frames. Smooth trajectories of motion are traditionally used to compute these in-between frames.

In traditional commercial animation, the motion is selected directly by the animator without any explicit reliance upon physics (other than what is contained in the animator's mind). In contrast, *physically based modeling* incorporates the physics of moving bodies explicitly using kinematics or dynamics to determine differential equations for modeling motion. Here the objects, environment, motion equations, and constraints are modeled directly and can be used to generate a significant quantity of the motion in an animation. Fairly sophisticated motion models, such as for the motion used in walking and running by human beings, have been developed.

4. HARDWARE

Computer graphics has from its outset required computing hardware specific to the task of generating images. This arises both from the basic requirement of displaying an image (for example, on a TV screen), and from the performance requirements needed to synthesize the image in an acceptable length of time. For real-time applications, such as simulators for aircraft training, acceptable means 60 images per second, while interactive applications require at least 1–6 images per second. Given the significant performance requirements, hardware designers have turned to creating special-purpose VLSI (very large scale integration) ICs and to designing parallel computer architectures.

A digital image is represented by a 2D array of color values, called *pixels* or *pels.* Each pixel value encodes the color to be drawn at the corresponding point of the display surface. It may be only a single bit if a bilevel black and white display is used; or it may be as many as 24 bits if full color is desired, so that the three primary colors of red, green, and blue (RGB) each have 8 bits, for a total of 24 bits per pixel. Alternatively, one can add one level of indirection and let the value at each pixel be an index into a 24-bit wide *color table*. This allows, for example, a system with only 8 bits per pixel to select, at any one time, any 2^8 colors from a palette of 2^{24} possible colors. This can be used to introduce color into a grey-scale picture (called pseudocolor), as is common with satellite images.

For display on a standard TV monitor (NTSC), a typical resolution is 640 pixels horizontally by 480 pixels vertically for a total of $640 \times 480 = 307{,}200$ pixels displayed at 30 Hz. Higher-resolution monitors are widely used, and are commonly $1280 \times 1024 = 1\,310\,720$ pixels displayed at 60 Hz. Thus, a full-color high-resolution display requires almost 4 Mb of memory accessed at a rate of around 250 Mb/s. Current memory technologies cannot easily provide this video refresh rate in addition to the image-drawing access rate, so special memory chips called VRAMs (video random-access memory) have been designed that provide an additional access mechanism specifically for video refresh. Many of these used in parallel (e.g., 128) can provide the required bandwidth over today's bus technology. The specific block of memory formed from these VRAMs that is used to hold the pixels being drawn on the CRT is called the *frame buffer*, since it holds at any one time a single frame/image of a sequence of frames/images.

Rendering the geometric model at high rates has always relied on specially designed graphics systems. Performing the basic operations of transforming, clipping, and drawing visible polygons, in that order, has led to a number of pipelined architectures, using a variety of hardware implementations. One such design used as many as 16 copies of a graphics VLSI processor to implement the transformation and clipping operations, while an alternative implementation used nine programmable DSPs (digital signal processors) to provide the same functions. Similarly, the drawing of visible polygons (possibly with texture mapping and individual shading calculations for each pixel) has been performed by specially designed VLSI chips (e.g., 20) or programmable DSPs (up to 64). The image computation is partitioned among the k drawing processors so that each is responsible for one out of every k pixels. To obtain a uniform load balancing among the drawing processors, the pixels assigned to a single processor are distributed uniformly throughout the image.

5. APPLICATIONS

Since geometry and images are fundamental components of our experience, it is not surprising that computer graphics has been applied widely. The most common and simplest use is the depiction of statistical data using graphs, bar charts, pie charts, etc., and the creation of illustrations to accompany text, such as the figures in many papers and books. This kind of applying computer graphics carries on activities in the computational domain that were mature long before computers. Since by and large they represent a transference of manual tasks, their computational complexity is not great, and the principal software issues are those dealing with the design of good user interfaces.

Engineering has from the outset been a significant consumer of computer graphics. Electrical engineering uses graphics for designing printed circuit boards on which the IC chips are mounted, for designing the logic diagrams specifying the function of a circuit, and for creating the physical layout of the ICs themselves. All of these, however, are treated as multiple layers of 2D sheets, even though printed circuits and chips are 3D physical objects.

Mechanical, aerospace, civil, chemical, and industrial engineering are concerned with the creation of physical objects that are inherently three-dimensional. To exploit computer graphics fully, interactive design capabilities are essential, as well as nongraphics computations that determine physical properties such as mass, effects of stress, and heat-transfer properties. In certain cases, the designed object can be manufactured directly from the computational representation using numerically controlled milling machines, or, if the target material is plastic, "drawn" directly using lasers.

Closely allied to the needs of these engineering disciplines are those of architecture. In this case, the esthetic dimension is of greater importance than physical properties, and much more of the design is decided by visual criteria as opposed to functional requirements, such as heating and power distribution. Since architecture is concerned with designing spaces for people to be in, having the ability to "walk through" a computer model of a building is considered to be an important capability, a goal yet to be satisfactorily attained. Ideally, the user would be completely enveloped in a *virtual reality* by wearing a head-mounted display. Such a display has separate images for each eye, forming a stereo pair, and everything in the person's field of vision is computer generated. The position of the head is tracked as the person moves, and the images correspond to what would be seen if the environment were physical, thus giving a feel of authenticity to the environment.

Physical scientists are increasingly using computer graphics both to visualize data and to observe simulations of physical processes, which has been dubbed *scientific visualization.* This can provide considerably more insight into the nature of a physical process than just the equations that describe state transitions. It can also provide access to processes whose space-time scale is significantly different from ours. Thus astronomers can see a process entailing millions of light-years develop in a few minutes of computer animation, and similarly for processes at the atomic level involving only a microsecond or less.

Another important area of data visualization is medical imaging. Various sensing devices, such as CAT scan or MRI, produce a set of slices where each slice is a 2D array of values correlated to the kind of tissue at each point in the sample. These slices, when stacked on top of each other, form a 3D array of voxels (volume elements) showing the part of the body that was scanned. Medical diagnosis can then be greatly enhanced if it is possible not only to see a static view of this data, but to manipulate it interactively as well. Providing such capabilities is called *volume rendering.*

Since computer graphics generates pictures, one should expect that it could be of great use to the visual arts. This is indeed the case, and has been since its very beginnings. Initially, much of this work was 2D in character, emulating painting, and in fact many computer paint programs have been written. More recent efforts have included 3D sculptures seen through stereographic viewers. Another visual art form, film, has its computational correlate, namely computer animation, which has been used for both artistic and commercial purposes. Much use has been made in the making of commercials for TV and for traditional graphics, such as the introductions to TV shows (referred to as "flying logos"). More ambitiously, several full-length movies have employed computer graphics to generate an appreciable percentage of the footage, while still more have utilized it for special effects.

GLOSSARY

Affine Subspace: Any subspace defined by the intersection of hyperplanes; *flat* is an alternative name.

Affine Transformations: Transformations that preserve flatness (linearity): translation, rotation, scaling, and shearing.

Algebraic Set: Any set of points that satisfies a polynomial (i.e., its solution set).

Antialiasing: Various filtering operations to remove the artifacts due to discretizing continuous functions, such as those that define curves and surfaces. A discrete image of a line without any filtering appears "jagged" or "staircased."

Binary Space Partitioning Tree: A computational representation of polytopes that partitions space into disjoint sets of convex cells. Each cell is in the interior or the exterior of the polytope.

Boundary Representation: A computational representation of polytopes in which there is a one-to-one correspondence between faces of the polytope and elements of the representation.

Constructive Solid Geometry: Defining 3D solid objects using set operations, affine transformations, and instancing (copying).

Diffuse Reflection: Reflection from a rough or matte surface that is perceived as uniform in all directions within the hemisphere above the surface.

Frame Buffer: A special 2D array of memory containing the image that is displayed on a CRT monitor 30–60 times a second.

Geometric Model: The computational representation of geometric objects and any of their attributes such as color.

Homogeneous Coordinates: Coordinates used in projective space; a normal 2D point (x,y) has in projective space the coordinates (wx,wy,w) for any $w \neq 0$.

Hyperplane: Dimension-independent entity defined by a single linear equation. Examples are a plane in 3D and a line in 2D. Always one dimension less than the embedding space.

Illumination: Modeling the interaction of light with surfaces. Local illumination is concerned with how the light that is incident upon a very small area is reflected, refracted, and absorbed. Global illumination is concerned with the interaction of light among all of the surfaces.

k Flat: A set in d-dimensional space of dimension k, $0 \leqslant k < d$, that can be defined by the intersection of $d-k$ hyperplanes or as all the weighted (affine) combinations of $k+1$ points. For example, a plane is a 2-flat and a line is a 1-flat regardless of the dimensionality of the space.

Nonlinear Sets: Sets defined by nonlinear equations.

Nyquist Rate: The minimum rate at which a continuous function can be sampled and then subsequently reconstructed without introducing errors (aliasing). That rate is twice the highest frequency present in the function.

Parametric Set: A set of points defined by a one-to-one mapping of a parameter t to a point p, where t is a vector whose dimension determines the dimension of the set. The parametric representation of a line through the points p_0 and p_1 is $p=tp_1+(1-t)p_0$.

Pixels: The points of color out of which an image is composed when represented in discrete space. The pixels lie on a uniformly spaced 2D array.

Polynomial: An expression that is the weighted sum of a set of monomials. A monomial is a constant times any product of coordinate variables where each coordinate is raised to some nonnegative integer power. Example: $x^2y^3+3x+2y^2-5$ ("missing" coordinates in a monomial have been raised to the zeroth power).

Polytope: Any set of points with an interior and an exterior, and whose boundary lies entirely in hyperplanes. The boundary is composed of a set of faces. A polyhedron is a 3D polytope, and a polygon is a 2D polytope.

Ray Tracing: Rendering a scene by tracing rays throughout the scene, analogous to geometric optics. The rays originate from lights and viewing positions, and are reflected, refracted, and absorbed by surfaces.

Rendering: Modeling the propagation of light and its interaction with surfaces to generate an image of a geometric model.

Set Operations: Forming the union, intersection, or difference of two sets.

Specular Reflection: Reflection of light from perfectly smooth surfaces; the light is concentrated along one direction, as with a mirror.

Splines: Curves that are comprised of pieces, each defined by a polynomial, in which the pieces fit together to form a smooth curve (tangent or curvature continuous).

Texture Mapping: Defining the color of a surface by a function that varies the color across the surface. A common example is mapping an image onto a surface lying in 3D.

Virtual Reality: Computer-generated sensory input correlated to human motion so that the subjective experience is interpreted as having a realistic quality.

Visibility: Determining for each member of a set of rays that surface the ray intersects first, i.e., what is the visible surface along these rays.

Volume Rendering: Generating images of 3D data that was produced by sampling space using electromagnetic radiation. Common example is medical data generated by scanning a body.

INTRODUCTION

Computers are now ubiquitous in industrialized society. While the cost, performance, and capacity of computer hardware span several orders of magnitude, the vast majority of machines are stored-program digital computers built of common subsystems. Our focus will be to describe and discuss hardware aspects of these machines, including common contemporary peripheral devices.

Computers have helped fuel the worldwide electronics industry, providing a ready market for semiconductors, especially dynamic memories, which are the key to driving advanced semiconductor technology. Advances in semiconductors have, in turn, helped create the worldwide consumer electronics market. With the advent of the personal computer, computer hardware has become a mass market item, and consumer electronics technology such as compact disks and digital audio tapes are now found in both industrial and personal computers. Over all, the demand for computer hardware has helped create and shape the worldwide electronics economy as we know it today.

Preceded by many mechanical devices and electronic analog computers, the first generation of electronic digital computers was built

with vacuum tube technology in the 1950s. The advent of the discrete transistor ushered in the second generation of cheaper, smaller, and more reliable machines in the 1960s. The third generation in the 1970s introduced minicomputers, made practical by small-scale integrated circuits. With the advent of large-scale integrated circuits in the 1980s, the personal computer and workstation emerged as the leading products of the fourth generation. The fourth generation also saw the widespread use of high-speed networks and the addition of optical storage devices in addition to traditional magnetic storage media. The fifth generation of machines, still in their infancy with no one architecture having emerged as dominant, will likely take advantage of the low cost and high density of very large-scale integrated circuits and rely on multiple-processor techniques. Different and promising approaches include massively parallel machines, neural networks, systolic arrays, and data-driven machines (see NEURAL NETWORKS; PARALLEL COMPUTING).

1. GENERAL ASPECTS

Today's general-purpose digital computers, be they common personal computers or large supercomputers, have many hardware similarities (Fig. 1). They all incorporate one or more central processing units (CPUs) which execute the instruction stream and process data. The CPU retrieves data and instructions from a main memory, and writes modified data back to it. The ability to interpret items in memory as either instructions or data is a key attribute of a stored-program digital computer.

Often the CPU is much faster than the main memory, and a memory cache is employed to match CPU and memory speeds better. Data travel between main memory and the CPU over a pathway called a bus, to which input/output (I/O) adapters (also called peripheral controllers or adapters) are also attached. These controllers connect the CPU and memory system to other devices such as user interfaces, data storage, or communications devices.

Contemporary computer hardware relies on fast and dense electronic integrated circuits for processing logic and main memory. Rigid magnetic or optical disks are used for persistent mass storage, and flexible magnetic media, be they floppy disk* or magnetic tape, for archival storage and data transport. The primary human interface is usually a cathode-ray-tube display, with an electromechanical keyboard and pointing device (such as a mouse or tablet) for human interaction. Despite this common technology, the performance, capacity, and cost of these machines vary widely. The number, size, speed, and configuration of these hardware elements determine the overall characteristics and cost of the computer system.

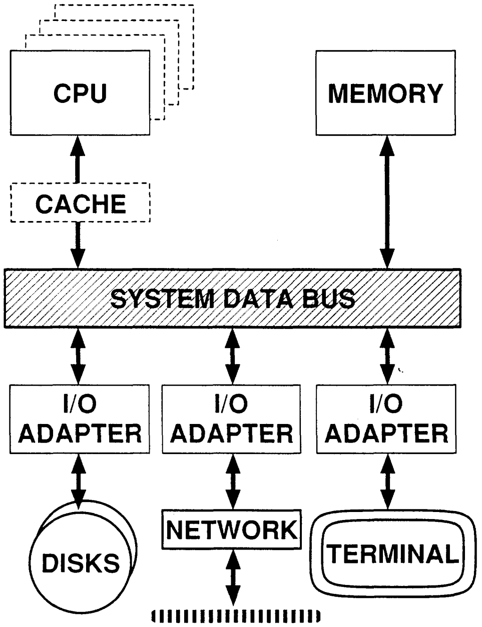

FIG. 1. The major functional blocks of a typical stored-program digital computer. Optional components are shown in dashed lines. Not shown is the possibility of separate memory and I/O busses, used to improve performance by not burdening the CPU memory bus with lower speed I/O traffic.

1.1 System-Wide Characteristics and Metrics

1.1.1 Data Representations. Computer hardware directly interprets only a small number of data representations; more complex data representations are created by software building upon these basic entities.

---

*Some inexpensive or older personal computers use floppy disks for persistent magnetic storage instead of a hard disk.

The fundamental unit of information in a digital computer is the bit (short for Binary digIT). A bit can have one of two values, 0 or 1, and easily maps to mechanisms in the underlying technologies, such as the presence or absence of electrical charge or the polarity of a magnetic field.

In order to represent data that has more than two values, bits must be aggregated into sets that can represent computer instructions or data. There has been widespread convergence towards representing data in multiples of 8 bits, called a byte, which has one of 256 (2^8) values. Common uses for the byte include

1. representing one of 256 possible characters,
2. representing an unsigned integer in the interval of 0 to 255,
3. representing a two's-complement signed integer in the interval of -128 to $+127$, and
4. representing a simple computer instruction.

Sets of bytes are used to represent larger integers, floating-point data, memory addresses, or complex computer instructions. Common sizes for integer data are 2, 4, and 8 bytes, and floating-point data are typically 4, 8, or 16 bytes in length. While these types are nearly universal, many machines implement additional hardware data types, such as linked lists, character strings, or decimal integers.

1.1.1.1 Data Representation Standards. Character data first became widely standardized with adoption of the American Standard Code for Information Interchange (ASCII), which was based upon a 7-bit character code (ANSI, 1977). While ASCII is still in widespread use, more recent standards issued by the International Standards Organization are beginning to supersede it. ISO Standard 8859 offers 1, 2, or 4 byte-per-character representations (in ISO terminology, an 8-bit grouping of bits is an Octet) which permits simultaneous use of many character sets, a growing requirement in international markets and in desktop publishing. For example, ISO Latin-1 is a one-octet character set in which characters 32 through 126 map directly to the popular 7-bit ASCII set; other standardized single-octet character sets include Arabic, Greek, Cyrillic, and Hebrew. Many Asian character sets, with their rich store of characters, are standardized as two-octet sets, including Katakana, Kanji, Hanzi, and Korean.

Integer data have not been formally standardized, but a *de facto* standard does exist. The vast majority of current computing hardware uses integers sized in multiples of 8-bit bytes (8, 16, 32, 64, and 128 bits being most common) for both signed and unsigned data.

Two's-complement notation for signed integer data has become standard in the industry, being selected over one's-complement and sign-magnitude notations used in some earlier machines. It has the advantage of being able to perform arbitrary signed operations on the same hardware that handles unsigned addition, and it has a unique representation of zero (the other representations have both a positive and negative zero). Given an N-bit word, two's-complement notation can represent numbers in the range of -2^{N-1} to $+2^{N-1}-1$ (for example, an 8-bit byte can represent -128 to $+127$). To convert a number to two's-complement notation, convert the absolute value of the number to an unsigned binary integer. If the original number was negative, then invert (logically complement) each bit and add 1 to the result.

Floating-point data format and floating-point data operations have been standardized through the Institute of Electrical and Electronics Engineers (IEEE) standard 754, commonly called IEEE Floating Point (IEEE, 1985). While many proprietary formats are still in widespread use, largely for historical reasons, the IEEE format is steadily becoming accepted and is supported by most newly designed computer architectures. The standard defines

1. single (32-bit) and double (64-bit) precision basic formats, and single ($\geqslant$ 43-bit) and double ($\geqslant$ 79-bit) precision extended formats (Fig. 2);
2. add, subtract, multiply, divide, square root, remainder, and compare operations;
3. conversions between
    a. integer and floating point formats,
    b. different floating point formats, and
    c. basic floating point formats and decimal strings; and
4. floating-point exceptions and their handling.

1.1.2 Word Width or Word Length. The word width (word length is used interchange-

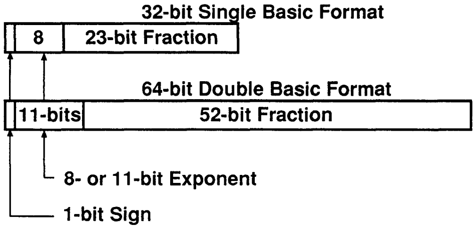

FIG. 2. The sign, exponent, and fraction fields of the IEEE-754 single and double precision basic floating-point data formats. The standard defines the most significant bits of each field to be on the left.

ably) indicates how many bits of data can be processed at once; the wider the word, the higher the performance of a machine compared to a similar machine with a smaller word width. Also, larger word widths provide added precision or range of values in computations directly (the same precision can be achieved by using multiple smaller words and appropriate software; the penalty is reduced speed). Typical word widths in current machines are 8, 16, 32, or 64 bits. Word widths may vary between different parts of the machine; currently popular personal computers based on the 386SX microprocessor have a 32-bit word width in the central processor, a 16-bit word width to memory, and 16- or 8-bit word widths to peripheral devices. Reducing the word width reduces required hardware, reducing hardware costs, but also reduces overall system performance.

1.1.3 Addressing Characteristics. Addressing granularity, or the smallest addressable unit, describes the smallest unit of memory that may be uniquely addressed. Current practice is to address memory at the byte level, which greatly facilitates character processing. This usually does not preclude addressing and accessing larger units, including and up to the word width of the machine.

There are two different conventions for addressing bytes within multiple-byte words (which includes integer, floating-point, and address data): Does the address indicate the most significant bits of the word or the least? Because of a famous paper by Cohen (1981) these two conventions have come to be known as "Big Endian" and "Little Endian." While on an isolated computer either convention works just as well, there are problems to overcome when exchanging programs or data between machines that use different conventions. Both conventions are in widespread use on contemporary machines.

Data alignment is an important, and sometimes restrictive, characteristic of how data may be accessed in memory. Memory subsystems are designed with a natural word width, usually in multiples of 2, 4, 8, or 16 bytes. Access to full words that are aligned to occupy a single word in memory is naturally fast and efficient. Unaligned memory access to full words requires access to two aligned memory locations, selection of the proper bits from each aligned word, and assembly of the bits into the requested unaligned word, as illustrated in Fig. 3. Needless to say, support of unaligned access to memory requires additional hardware and/or software and almost always incurs a performance penalty.

Some computers, particularly the newer reduced instruction set computer (RISC) designs, do not provide any hardware support for unaligned memory access, and if it is supported at all it is usually done with low-level software. Other machines, including several popular complex instruction set computer (CISC) models, provide transparent hardware support for unaligned access, although in most cases aligned data has a noticeable performance advantage.

Total address space is another key characteristic of a machine and is the number of unique addresses that are provided by mem-

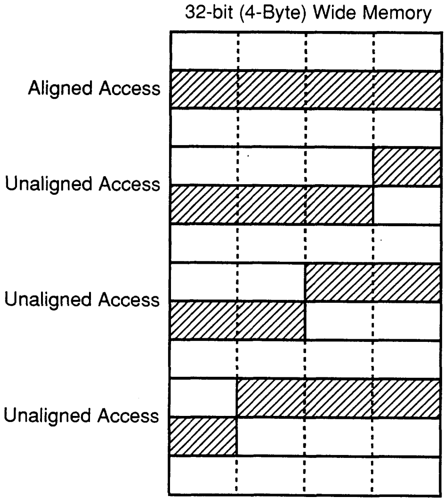

FIG. 3. Aligned and unaligned memory access. Depiction of an aligned memory access of a 32-bit word from a 32-bit byte addressable memory. Also depicted are the three possible cases of unaligned access.

ory. This has direct impact on the data and instruction capacity of the machine. Machines that utilize a 16- to 32-bit address space are very common today, with 48- and 64-bit address machines now arriving on the market. The following table indicates the relationship of the number of bits in the machine address and the number of uniquely addressable items in memory:

Bits in Address	Uniquely Addressable Memory Items
16	65 536 (2^{16})
32	4 294 967 296 (2^{32})
48	281 474 976 710 656 (2^{48})
64	18 446 744 073 709 551 616 (2^{64})

1.1.4 Performance Metrics. "How fast is that computer?" This is a complicated question to answer; even if theoretical or measured performance characteristics of the major subsystems are known, at best they will provide an upper bound of the machine's overall performance. The actual performance of the system is a function of the application to be run, its data, the compilers and operating system being employed, the hardware configuration, and operating environment overhead factors. Benchmark programs have had a particularly difficult time keeping up with the rapid increases in main-memory size and cache sizes; many benchmark programs now fit completely within the machine's high-speed caches and give unrealistically good results (an actual application would likely not be able to fit entirely within the fast cache memory, and would perform significantly slower, because of cache misses which cause reference to the slower main memory). Despite these difficulties, computer users and vendors still like to sum up their system performance in a simple numerical rating.

Millions of instructions per second (MIPS) attempts to quantify the performance of a computer by how many instructions it can execute per second. Computations performed per instruction is not well defined and varies widely over different hardware. Instruction mix and frequency varies widely over different workloads. With these ambiguities, the MIPS number is often ridiculed as the "meaningless indicator of performance." Nonetheless, the MIPS rating of a computer is still often quoted and serves at least as a first-order approximation to relative performance.

Millions of floating-point operations per second (MFLOPS) is used to quantify overall floating-point performance (as MIPS quantifies integer and logical performance). MFLOPS numbers are also widely quoted. As all current computers have comparable sets of floating-point instructions, the use of MFLOPS as a performance indicator between different machines is less problematic than the use of MIPS is for integer and logical performance.

In the personal computer area, clock speed in megahertz is often used as a performance indicator. This has worked well to date as an overall indication of performance between different models of PCs because most PCs are based on a common family of processors and have common hardware configurations; in general the faster the clock runs, the faster the processor will execute instructions and process data, assuming the overall system is reasonably well balanced to operate at that clock speed. Between processor families, however, the number is largely meaningless.

Recently, the Systems Performance Evaluation Cooperative (SPEC) was formed by hardware vendors to promote the use of standardized benchmarks of representative problems of realistic size. A suite of benchmarks which stress different performance aspects and applications of a computer system are provided, with the results summarized by a single figure of merit, the SPECmark.

The SPEC suite consists of four integer-intensive benchmark programs written in C and six floating-point-intensive benchmarks written in FORTRAN. SPECmark numbers are reported for each individual benchmark program, and are combined via a geometric mean to give integer, floating-point, or overall computer system performance. The overall performance of a Digital VAX-11/780™ using VMS™ compilers is defined to be 1.0 SPECmark; in late 1991 the fastest RISC workstations are reporting SPECmarks of about 70, current model VAX processors are about 40, and an Intel™ 50-MHz 486™ is near 18 SPECmarks. See Weicker (1990) for further information on benchmarks and performance measurement.

2. DIGITAL COMPUTER COMPONENTS

2.1 The Central Processor

The central processing unit (CPU) executes a program stored in main memory, manipulating data to achieve a desired calculation. A minimal CPU will have an instruction unit that retrieves instructions from the memory and controls the elements of the CPU to execute the instruction; high-speed temporary storage called registers or accumulators to store intermediate calculations; and an arithmetic/logic unit (ALU) which actually performs the logical or arithmetic operations on the data. The program counter is a register that holds the address of the next instruction in main memory to be executed; a change in program flow (a branch or jump) can be accomplished by modifying its value. A program status word (PSW) register is usually implemented to record specific state information, such as whether the last add instruction resulted in carry or if an interrupt should be generated on a divide by zero operation.

2.1.1 Operation of a Basic CPU. The following example illustrates the operation of a basic CPU, as shown in Fig. 4. A RISC-like machine is used for this example (see Sec. 2.1.2 for a discussion of RISC and CISC machines). The example illustrates the operation of the two instructions:

1. load the contents of a word of memory into a CPU register, and
2. add that register together with a small constant integer and store the results into another register.

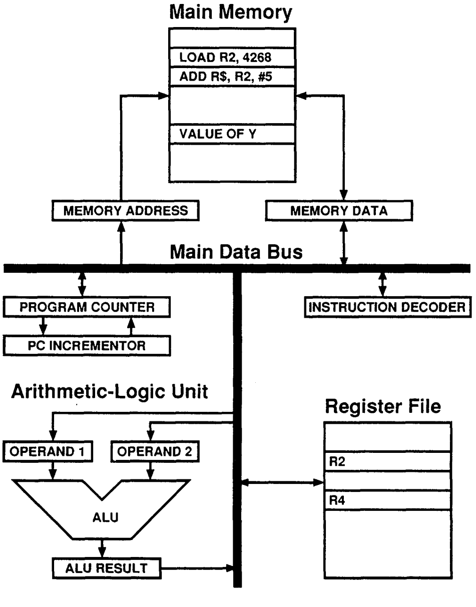

FIG. 4. The CPU used in the example of instruction execution in Sec. 2.1.1.

In a high-level programming language, the programmer might express this operation as $X = Y + 5$. After compilation to machine instructions, this statement is comprised of two instructions:

1. Load the value of variable *Y*, which is stored in main memory at a known address, into a CPU register, and
2. add the value of *Y*, now in a register, with the integer constant 5 contained in the add instruction itself, and place the result in another CPU register (which holds the value of *X* in our example).

In summary, we are assuming the following locations of integer data:

Y in main memory at address 4268, temporarily stored in CPU register *R*2.
X stored in CPU register *R*4.
5 a constant, embedded in the add instruction as an immediate operand.

The first instruction is LOAD *R*2, 4268. This instructs the CPU to load the value stored at main memory location 4268 into CPU register *R*2. Our example starts with the program counter register in the CPU containing the address of the example LOAD instruction and proceeds as follows:

1. The CPU uses the value of the program counter to fetch (read) the next instruction from main memory. It sends the value of the program counter to the memory address register, and the main memory returns the instruction to the memory data register. The memory address register and memory data registers are invisible to the programmer, as are several other registers we will encounter in this example, being part of the internal workings of the CPU.
2. The program counter is incremented by the length of an instruction, so that it now holds the address of the next instruction to execute. Typical of many machines, the program counter is incremented with a dedicated piece of hardware to make this

frequent operation efficient.

3. The fetched instruction is moved from the memory data register to the instruction decoder. The instruction is a "load from memory to register" instruction. The decoding circuits separate out two important fields of information within the instruction: The memory address to read from (4268) and the destination register ($R2$).
4. The decoded memory address is used to read the value of the data from memory, by moving it from the instruction decoder to the memory address register. The returned data from memory is temporarily held in a memory data register awaiting storage.
5. The data returned from memory is moved to the specified destination, CPU register $R2$ in the register file (an array of programmer-visible registers).

The second instructions is ADD $R4$, $R2$, #5. This instructs the CPU to add the contents of CPU register $R2$ to the integer constant held in a field of the instruction (in this case with a value of 5) and to place the result in CPU register $R4$.

1. The CPU uses the value of the program counter to fetch (read) the next instruction from main memory.
2. The program counter is incremented by the length of an instruction, so that it now holds the address of the next instruction to execute.
3. The fetched instruction is decoded inside the CPU. It is an "add constant to register" instruction. The decoding circuits separate out three important fields of information within the instruction: The value of the constant (5); the source register ($R2$); and the destination register ($R4$).
4. The value of the constant is sent to the first operand holding register of the arithmetic logic unit (ALU).
5. The value in the source register is sent to the second operand holding register of the ALU.
6. An ADD operation is done by the ALU, and the result is temporarily held in the ALU result register.
7. The value in the ALU result register is stored in the destination CPU register ($R4$).

As the above simple example illustrates, even the simplest instructions require several steps, the movement of data within the machine, and the control of various registers and logic units.

2.1.2 RISC vs CISC. Until the middle of the fourth generation of computers, the richness and complexity of the instruction set understood by the CPU continued to grow. Machines with literally thousands of instructions were designed and are in widespread use. These were later dubbed CISC after RISC appeared in the mid-1980s. RISC computers gain a significant speed advantage over CISC machines by keeping both their CPU and instruction set simple and uniform. They usually employ large numbers of registers to improve performance further. The availability of high-level language optimizing compilers allows programmers to be productive while shielding them from the simple yet often difficult to program underlying machine instructions. The compilers could effectively optimize the small set of fast RISC instructions, while they often could not effectively optimize or even use many of the large set of CISC instructions. RISC machines are now broadly accepted and are the basis for most new designs.

CISC machines are characterized by

1. variable-length instructions formats,
2. a large number of often specialized instructions,
3. a small number of general-purpose registers ($\leqslant 16$),
4. performing arithmetic and logic operations directly to memory, and
5. instructions that have multiple results, such as adding two numbers and incrementing an address of one of the operands in the same instruction (autoincrement)

RISC machines are characterized by

1. fixed-length instructions formats, often only of one basic size,
2. a small number of very general instructions,
3. a large number of general-purpose registers ($\geqslant 32$),
4. arithmetic and logic operations performed only on registers; operands must be loaded and stored from memory with separate instructions, and
5. instructions having only one result with no other side effects (change of machine state).

2.1.3 Pipelining and Super Scalar (Multiple Issue). Pipelining is a technique to improve CPU performance by processing more than one instruction at a time. A typical instruction has several distinct phases of execution: fetch the instruction; decode the instruction; fetch the operands; process the operands; and store the result. In many CPUs, these various phases are performed by distinct pieces of hardware that sit idle during part of the instruction execution cycle. A pipelined CPU will process multiple instructions simultaneously, by overlapping the end of one instruction with the beginning of another. A continuous flow of instructions moving through the CPU "pipeline" overlapped by phase keeps more of the CPU hardware productive, improving performance (Fig. 5). The simplicity of RISC instructions allows pipelines to be built generally with less hardware and to perform more effectively than comparable CISC implementations.

A super scalar, or multiple-issue, machine has several replicated elements, and can process and complete multiple instructions simultaneously. While the pipelined machine processes instructions sequentially with partial overlap, the multiple-issue machine processes instructions in parallel with full overlap (Fig. 5).

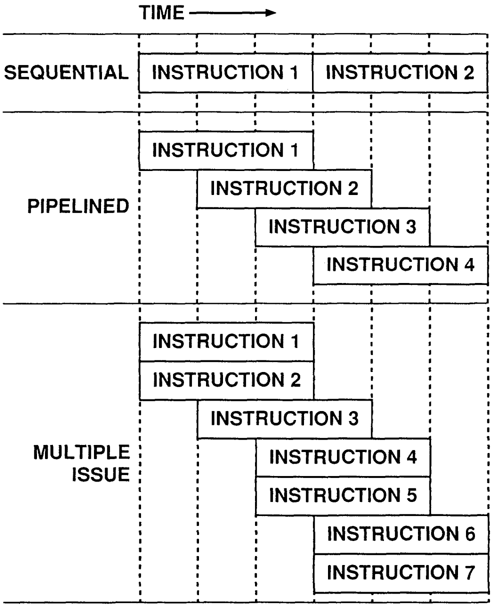

FIG. 5. Instruction execution sequences in sequential, pipelined, and multiple-issue machines. Only one of two possible instructions is being issued in the multiple-issue machine in the second time period, presumably because of a dependence that prevents instruction 4 from being issued with instruction 3.

The standard sequential processor executes only one instruction at a time. In a pipelined machine, instruction execution is overlapped to improve performance, taking advantage of the inherent multiple phases to complete most instructions. Super scalar machines have sufficient additional hardware to process multiple instructions in parallel through multiple pipelines. In both pipelined and super scalar machines, interinstruction data or control dependencies usually limit the theoretical maximum performance, as some instructions must wait for results of previous instruction to become available.

2.1.4 Floating-Point Processors. Floating-point processors are hardware especially designed for floating-point computations; they perform floating operations which the main CPU's arithmetic and logic unit cannot do (it is designed for integer and logical operations). A floating-point processor typically has its own set of registers and control unit, and the main CPU "hands off" entire floating-point instructions to the floating-point processor for rapid execution. Many floating-point units are designed to let the main CPU continue to process other instructions while the floating-point unit completes the floating-point operation independently. Current practice is for most computers to include floating-point processors; low-end personal computers are about the only common machines in which a floating-point processor is optional. When it is not present, floating-point operations can be performed in software by the integer unit at a considerable performance penalty.

2.1.5 Vector Processors. Vector processors are special hardware that can process vectors of data faster than a general-purpose CPU. A vector processor has its own vector register set, with each register holding from 64 to 256 vector elements. A single vector-machine instruction will operate on all elements of a vector or pair of vectors, completing the operation on all vector elements much faster than a scalar processor could complete the operation iteratively. Typical operations would include arithmetic or logical operations on a vector by a constant or between two vectors. Vector processors are usually implemented as pipelined scalar machines which are optimized for vector operations.

2.1.6 Multiprocessors. A multiprocessor is a computer system with multiple CPUs that share a common main memory. Each CPU executes its own set of instructions and operates on data that is possibly shared with other processors. With a properly designed program, a multiprocessor can execute portions of a computation in parallel, achieving a significant performance improvement over a single processor. Because of simultaneous memory access limitations, most multiprocessors in use today have between 2 and 64 CPUs. Programs that wish to exploit the speedup offered by a multiprocessor currently must contain special instructions to control the splitting (and later merging) of parallel instruction streams. Software technology to automate this task fully is still maturing and a programmer is usually required to obtain satisfactory results. The extra development effort required for creating parallel programs, and the lack of parallel programming standards, has limited the availability of programs that take advantage of parallel processors. Multiprocessors are most easily exploited by multitasking operating systems; they can assign each task to a specific processor and effectively use them without special programming effort by their users.

Multiple processors with local main memory avoid the bottleneck of shared memory, but the new bottleneck to performance becomes interprocessor communication. This is the approach taken by massively parallel machines, discussion of which is beyond the scope of this article (see PARALLEL COMPUTING).

2.1.7 Interrupts. Most every processor supports some form of interrupt mechanism. When this mechanism is enabled, the receipt of an interrupt causes the current instruction stream to be suspended and an interrupt service routine program to be executed. The interrupted program can be resumed transparently when the service routine completes. Interrupt hardware usually supports a number of distinct interrupt types, and a priority scheme so that the most important interrupts can preempt ones of lesser importance. Individual interrupts can usually be enabled, which allow them to interrupt the processor, or disabled, in which case they do not effect the processor.

Interrupts allow computer systems to respond to events as they occur without the overhead and possible delay of explicitly checking to see if an event of interest occurred (polling). They are particularly important for computers involved in real-time control of equipment, for efficient interfacing with computer peripherals, for time-keeping and scheduling functions, and for handling unexpected conditions and errors. On pipelined machines, excessive interrupts can adversely affect performance, as the switch in the instruction stream caused by the interrupt causes a delay while the new instruction stream is fetched.

2.2 Main Memory

Computer memory is arranged in a memory hierarchy (Fig. 6) in order to strike a balance between cost, capacity, and performance. The fastest, most expensive memory in the machine is the CPU registers, which have a small total data capacity. Successively larger, less expensive, and slower memory is arranged in order of decreasing speed (and cost) and increasing capacity. A well balanced memory hierarchy is key to good overall system cost and performance. This section will discuss main memory and main memory caches.

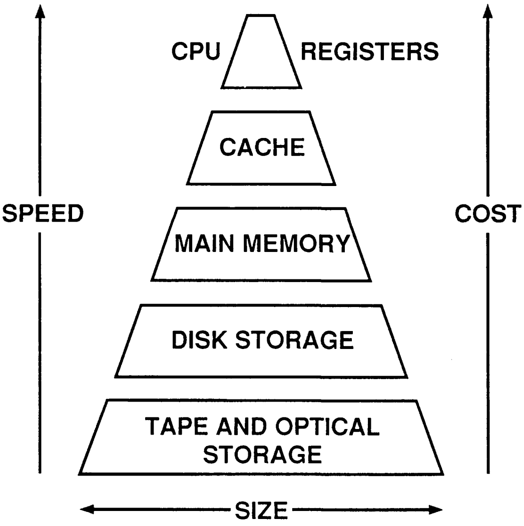

FIG. 6. The relationship between cost, size, and speed in the hierarchy of computer memory systems.

2.2.1 Main Memory Organization and Interleaving. Main memory is random-access: when presented with a memory address, it will directly read or write a given word (or smaller unit if the addressing scheme is so organized). The word width of the memory is usually the word width of the CPU, but designs in which the memory word is twice the size of the CPU to increase performance or half the size to reduce cost are not uncommon. In both cases additional hardware makes the size mismatch invisible to the computer user. Physical memory sizes of computers varies widely: personal computers will have from a few hundred kilobytes up to 16 megabytes; workstations typically have from 4 to a couple of hundred megabytes; larger machines may have hundreds of megabytes or several gigabytes. Memory access times also vary widely, but are generally in the range of 1 to 100 ns. Semiconductor memory density has quadrupled every two to three years throughout the 1980s permitting ever larger main memories and caches, and this trend continues unabated.

Memory systems require a fixed amount of time, called the cycle time, to perform a read or write operation and become ready to perform the next operation. There are usually three or more distinct time periods within the memory cycle:

1. accept an address and operation code from the CPU;
2. accept data (write cycle) or return data (ready cycle); and
3. perform internal operations to complete the cycle, which ensures that the data are properly stored, and to prepare for a new memory cycle.

Interleaving is a technique, similar to pipelining in the CPU, which offsets the cycles of two or more banks (sections) of memory so that the CPU does not have to wait for the entire memory cycle before it can issue a new memory operation.

For example, imagine we had a memory system with two banks or sections, with one section handling even-numbered addresses and the other handling odd-numbered addresses. Further imagine that the third phase of the cycle takes half of the memory cycle time. These memory banks are configured such that the memory cycle of second bank always starts halfway through the cycle time of the first (conversely, the first always starts halfway through the cycle time of the second). With such a scheme, if the processor alternately accesses even and odd memory addresses, it can complete memory transactions at twice the basic memory cycle time. The portion of the memory cycle that does internal operations completes while the processor works with the alternate bank on new memory operation in the early phases of its cycle.

Memory refresh is required for data retention in dynamic semiconductor memories, which are most commonly used in main memories. These devices store information as the presence or absence of electric charge in memory cells of 1 to 4 metal–oxide–semiconductor (MOS) transistors. When a charge is present, it will leak away over time and requires periodic replacement. The memory refresh process periodically reads all memory cells and rewrites them, thereby recharging all previously charged cells. Memory refresh cycles typically need to occur every few milliseconds, while normal memory operations are measured in nanoseconds, and so the overhead is not too large.

Some memory systems provide for protection of sections of memory. Memory protection schemes are commonly used on multiprocessing systems, to prevent independent programs from inadvertently or maliciously reading or altering another program's memory.

2.2.2 Parity and Error-Correcting Code (ECC). To protect against hardware errors in the memory, parity or an error-correcting code (ECC) is used to detect and correct memory errors. In the parity scheme, an additional error-detection bit, the parity bit, is stored with every byte by the memory subsystem. This bit is set by the memory hardware such that the total number of "1"s that are stored is odd (odd parity). Should a read operation result in an even number of ones, a parity error has been detected. This scheme detects single or triple bit errors, but cannot correct errors or detect double bit errors.

ECC memory (error correction code) stores several additional bits with each word of data both to detect memory errors and, in many cases, to correct them. A common scheme is to store 7 ECC bits with each 32-bit word. Such a scheme uses a Hamming code (Hamming,

1950) to create the 7 ECC check bits, which duplicate enough information from the stored 32-bit data to allow all single-bit errors to be corrected and all double-bit errors to be detected (Siewiorek and Swarz, 1982).

2.2.3 Memory Mapping. When the address space available to programs is smaller than the available physical memory (typical of 16-bit machines), techniques are employed to allow access to the larger physical memory within the confines of the smaller program address space.

One popular technique is memory mapping. In this scheme the upper portion of the logical address is used to select one of several mapping registers. The contents of the selected mapping register are used as the upper portion of the physical address while the remaining low bits of the logical address form the low bits of the physical address. In Fig. 7 this is illustrated for a system with a 16-bit logical address space and a 28-bit physical address space. The upper four bits of the logical address are used to select 1 of 16 mapping registers which each provide the upper 16 bits of a physical address. They are concatenated with the lower 12 bits of the logical address to produce a 28-bit physical address. By manipulating the contents of the mapping registers, all of a large physical memory can be accessed.

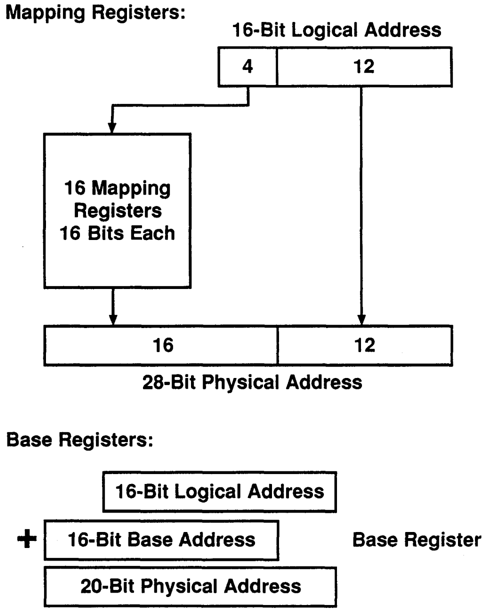

FIG. 7. Typical configurations of mapping registers and base registers.

Another technique is the use of base registers. These registers contain high-order memory addresses, and they are offset and added to the logical address automatically by the hardware. Often the choice of base register is based upon the context of the reference, be it for an instruction, to a stack, or for data. Figure 7 illustrates the scheme used by the 8086 family of processors used in PCs; the 16-bit base register is offset from the program address by 4 bits to produce a 20-bit physical address. There are many variations on these two techniques; see Siewiorek *et al.* (1982) for further examples.

2.2.4 Virtual Memory. Virtual memory is a technique that permits a physical memory to appear to be very much larger than it actually is, giving the illusion of a large, linear address space, which makes programs easier to write and more independent of the physical resources of a particular computer. The illusion of virtual memory is accomplished with additional logic in the memory subsystem, a large backing store which is usually a disk, and supporting software (Hennessy, 1990). Both virtual and physical memory is divided into blocks called pages. Each virtual page has an entry in a section of memory called the page table, which keeps track of the location of a page, whether it is currently resident in physical memory or paged out onto backing store. When a referenced page is resident, the translation of the virtual page address to a physical page is handled entirely through hardware via the page table, with only a very slight delay. However, when a referenced page is not resident, the supporting software is signaled that a page fault has occurred by the memory hardware. This supporting software will then suspend the requesting program, make the requested page resident (which may involve making room by moving another page out to backing store), and then resume the requesting program. The program is not aware that a page fault occurred, except for the fact that some additional time elapsed while the physical memory was being rearranged to satisfy the virtual address reference.

In order to improve virtual memory performance, a cache of recently translated virtual addresses is kept in a translation buffer. When a virtual address is found in the translation buffer, the computer hardware can accomplish the memory access without reference to the page tables, further improving performance.

Virtual memory systems depend on an observed characteristic of most all programs known as locality—that when a reference to memory is made, there is a very high probability that subsequent references will be to a location near the previous ones. Consequently, the probability that a subsequent reference is to a page already in memory is high, and overall system performance will be good. Thrashing is a problem that occurs when a program accesses virtual memory in such a way it is constantly page faulting, usually because it does not exhibit locality. It therefore has a very high page fault rate and consequently poor performance.

2.2.5 Caches. Caches are fast memories located between the main memory and the central processor and used to buffer the CPU from the relatively slow main memory. They maintain a copy of selected items in main memory, and rely on the fact that most programs make repeated references to clustered areas of memory (see discussion of locality in Sec. 2.2.4). Caches are designed to have a high probability of a cache hit (finding the required information in the cache), so that the faster cache can supply the information to the processor without incurring the speed penalty of a main memory reference. When the information is not in the cache, it is fetched from main memory and supplied to both the processor and the cache. Many caches maintain information in blocks larger than one word, and the cache will fill the entire block on the first cache miss, betting that other references will be made to that block.

Multiple-level cache systems are used with large main memories and fast processors, each cache successively smaller and faster. A system with a multiple-level cache would have several trapezoids in Fig. 6 in place of the single one shown.

Cache memory usually uses static semiconductor memories (static RAM). These devices, while significantly less dense then the dynamic RAMs used in main memory, are usually an order of magnitude faster and do not require refresh cycles (each memory cell is active and can maintain its state while the part is powered up).

While reads dominate cache access, information must also be handled on write. A write-through cache writes both the cache and the main memory, slowing the processor. A write-back cache writes only to cache initially, and the main memory is not updated until the cache block is replaced by other information. Other design issues include the lookup (mapping) scheme, block size, total size, and block replacement scheme (Hennessy 1990). Cache coherency is an important issue in multiple processors where several processors may be writing and reading simultaneously. If each processor in a multiple processor has its own cache, there can exist several copies of the same data. Should one processor modify a piece of data, it must ensure that all other copies of the data in other caches or in main memory are either updated or marked as invalid. Various schemes to maintain cache data coherency have been invented, with various performance characteristics and hardware complexities; see Dubois (1990) for approaches to this issue.

2.3 Busses

Busses (see BUS SYSTEMS AND COMPUTER INTERFACES) connect various subsystems together in the computer, moving addresses and data over a well-defined interface. Many computers have just one major bus that connects the CPU, memory, and input/output (I/O) adapters together (Figs. 1 and 4). Faster machines usually employ separate busses for the slower I/O, connecting the I/O busses to the faster CPU memory bus through an adapter or directly to memory.

2.3.1 Standardized Busses. Standardized busses allow peripheral devices to be designed once and used on a variety of machines, and for machines to be expanded after they have been designed and manufactured. The bus of the IBM PC-AT, probably the most used bus in the history of computing, is a *de facto* standard. A few of the most common formally standardized busses include the VME bus (IEEE 1014) and the SCSI bus (ANSI X3.131).

2.4 Input/Output

Input/output, or I/O, is the general term used to describe the movement of data between main memory and any peripheral device, such as disks, tapes, networks, terminals, or printers. Peripheral devices connect to the computer's I/O bus through an adapter. Adapters convert the specialized interfaces of the peripheral to a series of registers that can be read to or written from the I/O bus. Most adapters have some form of buffering, a small local memory that temporarily stores I/O data and helps to overcome processor and peripheral speed differences.

Programmed I/O is the simplest technique, using the central processor to read and write data, peripheral control, and peripheral status to or from the adapter registers and move the data to or from memory. Direct memory access (DMA) logic in the controller allows the CPU to set up a data transfer by writing control information to the adapter registers, with the actual data movement to or from memory being performed by the adapter, freeing the CPU for other work. Some of the most powerful computers employ separate I/O processors (sometimes called channels) that run specialized I/O programs to provide high-speed I/O within minimum impact on the CPU.

3. PERIPHERAL DEVICES

There is a wide variety of peripheral devices for use with computers. We will discuss the main features of the most common ones in this section.

3.1 Persistent Mass Storage

The vast majority of mass storage is electromechanical, in contrast to the purely electronic main memories discussed previously. While access to information is much slower, the data capacity of these devices is much larger, and the cost per bit of information stored is much lower. The stored information is said to be persistent, i.e., the information is retained when the device is powered off.

Fully electronic persistent storage is available, but currently with very low capacity and high cost, such as flash memories used in some portable computers. Vigorous development continues on these technologies and there are predictions that they will have a significant presence later in the decade.

3.1.1 Magnetic Disks—Floppy and Hard. A magnetic disk stores information on a disk-shaped platter coated with a thin magnetic film (see MAGNETIC STORAGE OF INFORMATION). The disk rotates at constant velocity under a read/write transducer called a head. The head is moved over one of many tracks on the surface of the disk, each track occupying a specific radial distance from the center of the disk. The head can detect previous magnetic patterns stored on the disk in a read operation, or write new magnetic patterns to store information. Information is stored in sectors, which is a subsection of a track. A sector will store from a hundred to a few thousand bytes of data, along with overhead bytes that synchronize the read/write circuits, identify the sector, and store error detection and correcting codes.

Disk striping is a technique used to improve performance in situations where files are large and there are multiple disks available. A file is distributed over several disks (members of a stripe set) such that when a section of a file fills an entire track, the next part of the file is found on the next disk in the stripe set. The goal is to eliminate the delay that moving the disk head from track to track causes, by switching the operation to another disk that has prepositioned its heads to the proper track. Switching the data stream among disks is done at electronic speeds, while moving heads is done at mechanical, inertia-limited speeds. Consequently, a stripe set of several disks with good controlling software can significantly outperform single drives in many situations.

A floppy disk is so named because the magnetic disk is made of a thin flexible plastic disk packaged in a flexible or rigid covering. Information may be stored on one or both sides of the disk. Floppy disks come in 8-, $5\frac{1}{4}$-, and $3\frac{1}{2}$-in. diameters with data capacities up to 2.8 megabytes. Floppy disks may be removed from the disk drive, and consequently a single drive may service a library of disks, or the disk may be used to transport data from one computer to another.

A hard disk is made of rigid material, and usually has several disks stacked on a common hub. Heads are ganged together and moved in unison by a single positioner, with each disk surface being serviced by a single head. 14-, 9-, and 8-in. diameter disks are produced usually for use with large computers, while $5\frac{1}{4}$- and $3\frac{1}{2}$-in. units are popular in workstations and PCs. The advent of laptop computers has kept sizes shrinking, and 2-in. and smaller models are now on the market. Disk capacity for $5\frac{1}{4}$-in. and larger units is now above 1 gigabyte and increasing; $3\frac{1}{2}$-in. hard disks can currently store about half that. Removable hard disks are available but declining in popularity; most hard disks today are built for permanent installation with the disks sealed inside the drive.

The key performance criteria for disks are transfer rate and average access time. Transfer rate, in megabytes per second, indicates how fast information may be moved to or from the disk once it is located. Average access time describes how long it takes to access any piece of information on the disk. Access time depends on seek time (how fast the heads can position to a given track) and rotational latency (how long it takes to rotate the desired information under the head).

3.1.2 Optical Disks. Mechanically, optical disks are very similar to magnetic disks, employing a rotating disk and positionable heads. However, the disk surface is designed to store data on the basis of altering the reflectivity or polarization of light, and storing information involves changing these characteristics, usually by heating a small area with a laser pulse (Hamacher, 1984) (see OPTICAL STORAGE). All current optical disk drives have removable media.

Initial optical disks were read-only devices (most drives could not write information on them). CD-ROM is the most popular format, and stores 600 megabytes of data on a $4\frac{3}{4}$-in. diameter compact disk identical in size and technology to compact audio disks. In fact, many newer CD-ROM drives for computers include headphone jacks and volume controls, and will also play audio CDs.

Write-once read-many (WORM) optical disks are available, useful mainly for archival storage. 14-, 8-, and 5-in. units are available with capacities from 600 megabytes to over a gigabyte.

Finally, read-many/write-many devices are becoming available. Capacities and sizes are similar to the CD-ROM and WORM devices.

3.1.3 Magnetic Tape. Magnetic tape, lacking random access, is the slowest mass storage technology currently in use. However, its low cost per bit and large capacity make it a popular archive and transport mechanism. While nine-track reel-to-reel tapes are still in use, a variety of less expensive and more convenient cartridge-based devices are now more popular. The quarter inch cartridge (QIC) is widely used in workstations, and 8-mm video tapes and 4-mm digital audio tapes (DAT) are now being used, often with stack loaders that can automatically change up to 16 tapes. Cartridge capacities of 5 gigabytes are available.

Tapes store data in a thin magnetic film layered on flexible tape. Nine-track and QIC tapes store data linearly along the length of the tape, using one head per track. 8- and 4-mm units use helical scan technology, similar to that used in video cassette recorders, storing bits on diagonal stripes. Helical scan technology is more complex, but permits much higher bit densities.

The useful capacity of all types of magnetic tapes is improved by data compression technology, which uses hardware and/or software to encode the stored data in such a way that it occupies less space on the storage medium. Extremely effective data compression schemes have been devised and it is not unusual to be able to double the raw capacity of a tape for many common data storage situations. The same technology is finding application in portable computer disk drives, where the user is willing to accept the lower performance caused by the compression/decompression process in favor of significantly increased storage capacity.

3.2 Communications and Ports

3.2.1 Serial and Parallel Ports. A port is a defined interface on the computer that can read and/or write digital data to an external device. A parallel port transfers all the bits of a word at once, or in parallel. A serial port transfers the bits one at a time in sequence, at rates that typically range from 300 to 38,000 bits per second (MaNamara, 1988). Most terminals and modems attach to serial ports, while printers may use either.

3.2.2 Modems. A modem (MOdulator/DEModulator) is used to transfer serial data over an audio channel such as a telephone line or radio link. Common modem speeds are 1200, 2400, and 9600 bits per second. Many newer modems have data compression and error correction features. A typical modem attaches to a serial port and to a modular telephone jack, and can dial the telephone under computer control. As all-digital telephone services, such as ISDN, become widely available, the need for modems will be eliminated.

3.2.3 Networks. Networks allow a group of computers to share programs and data easily, and usually provide shared facilities such as file and printer servers. See NETWORKS, COMPUTER for additional information.

3.3 User Interface Devices

3.3.1 Hard-Copy Devices—Printers and Plotters. Hard copy is a term used to refer to printed output. While printers have traditionally focused on character-based documents and plotters drew charts and graphs, the distinction is blurring as newer hard-copy devices, including laser, ink-jet, and 24-pin printers can do both. Laser printers use much of the same technology as a plain-paper office copier; the optical input used by the office copies is replaced by a computer-controlled laser to form the image (see XEROGRAPHY). Resolutions of 300 dots per inch (DPI) on $8\frac{1}{2}$ by 11 or 11 by 17 in. sheets are available, and color laser printers are now available. Ink-jet printers squirt ink drops out of a nozzle to form dots on the paper. Ink-jet printers are quiet and can print at 150 DPI in both single color and multiple colors. Impact printers, now predominantly using thin wires in the print head to strike an inked ribbon and then the paper, also can produces 150-DPI text and graphics. Multiple-color ribbons offer the ability to produce limited multiple-color output slowly.

3.3.2 Soft-Copy Devices—Terminals and Displays. Computer terminals and displays (see DISPLAY TECHNOLOGY) are used to produce soft-copy output on a screen. They may be character only or mixed characters and graphics, in color or monochrome. The basic character display today displays 80 columns and 24 or 25 rows of characters. Each character may be displayed with a small number of special characteristics, such as an underline, high intensity, or blinking. Color displays usually allow each character to have selected foreground and background colors.

While character displays model the display space in terms of character cells only, a graphics display models the display as a two-dimensional array of picture elements (pixels) which can display both characters and arbitrary graphics. Typical PC displays have 640 by 480 pixel displays, while workstations commonly have 1024 by 768 or 1280 by 1024 pixel displays.

Monochrome displays use one bit per pixel to indicate whether a pixel is on or off. Grayscale displays use multiple bits per pixel (usually 2, 4, or 8) to represent the brightness of a particular pixel. Color displays also use multiple bits per pixel (up to 24). Frequently, color displays use the value of a pixel to index into a color map, which then selects the displayed color from a very large palette of potential colors. A typical color display uses 8 bits per pixel, so that 256 different colors can be displayed simultaneously. The color map translates 8-bit pixel values to 24-bit color values, allowing the selection of 256 colors from a palette of 2^{24}.

Most terminals use cathode-ray tube (CRT) technology, with diagonal measures of 10 to 19 in. The demand for laptop computers has driven the development of flat-panel display technology. Liquid crystal displays (LCDs) are in widespread use in laptops, with early units offering 640 by 480 notebook-sized grayscale displays. 16-color units are available at higher cost. With strong worldwide demand for portable high-resolution color LCD displays for both computer and television use, the technology is expected to evolve rapidly to high resolutions and lower cost.

3.3.3 Input Devices. Input devices have remained remarkably stable in an otherwise rapidly changing field. Keyboards still dominate, and the mouse has established itself as the predominant pointing device. A mouse is a palm-sized device that may be rolled across a work surface and transmits relative movement to the computer. Software or hardware then moves a cursor on a display to mimic the motion of the mouse. From one to three buttons on the mouse allow a user to signal some action to software, usually manipulating a displayed object that the cursor is positioned on. A trackball is a partially exposed sphere that a user may roll in place; the relative motion is transmitted to the computer as in the case of a mouse. An advantage of a trackball is that it does not require desk space for motion. Tablets have a rectangular surface over which a puck with buttons is moved (not unlike a mouse); a tablet transmits absolute coordinates to the computer, based upon the position of the puck on the surface of the tablet.

Recent work in handwriting recognition software foreshadows the introduction of so-called "pen-based computers" in the near future, where the keyboard and mouse would be replaced by a stylus which "draws" on a display panel.

3.3.4 Optical Scanners. Optical scanners convert printed or handwritten copy into bit-mapped images, so that they may be manipulated, displayed, or printed by the computer. Hand-held and single-sheet scanners are low in cost and typically produce 300 to 600 dots per inch monochrome or gray-scale images. Color scanners are available at greater cost and at various resolutions. Software is available to convert scanned-in character images to computer character codes, permitting further processing by most existing programs.

4. SUMMARY

Computers continue to evolve, providing ever higher performance and larger capacities at lower costs. Despite this constant evolution, the majority of successful machines over the first four generations have had a common gross structure and similar subsystems, which we have reviewed in this article.

The advent of the personal computer has moved computing into the mass market, and consumer electronics technology such as compact disks and digital audio tape are being applied to solve computing problems. Other mass market technology, such as cameras that use floppy disks as "film," cellular radio networks, handwriting recognition software, and voice recognition systems (Kamel, 1990) all indicate a healthy and vigorous future for computers with even broader application.

ACRONYMS

ALU: Arithmetic logic unit.

ASCII: American standard code for information interchange, a character encoding standard.

CD-ROM: Compact disk—read-only memory.

CISC: Complex instruction set computer.

CPU: Central processing unit.

CRT: Cathode-ray tube.

DAT: Digital audio tape.

DMA: Direct memory access.

ECC: Error correction code.

ISDN: Integrated services digital network, a packet-switching digital telephone service.

MFLOPS: Millions of floating-point operations per second. A popular but nonstandardized figure of merit for floating-point performance.

MIPS: Millions of instructions per second, a popular but nonstandardized figure of merit for integer performance.

PC: (1) Personal computer, (2) program counter.

QIC: Quarter-inch (tape) cartridge.

RAM: Random access memory. While ROM is also random access memory, the term has come to be used almost exclusively to refer to read-write memory based upon charge storage in semiconductor chips.

RISC: Reduced instruction set computer.

ROM: Read-only memory, written once with a fixed set of instructions and/or data can be repeatedly read thereafter.

WORM: Write once read many.

GLOSSARY

Bit: The smallest unit of information represented by a digital computer, which can have one of two values: 0 or 1. From Binary digIT.

Byte: A set of eight bits, commonly used to represent a character. On many computers, the smallest addressable entity.

Core or **Core Memory:** Random-access read-write memory based upon information storage in magnetic cores. Some operating systems refer to any type of main memory as core for historical reasons.

Pixel: A single dot or picture element on a graphic display.

SPECmark: An overall figure of merit of computer performance, based on benchmarks distributed by the Systems Performance Evaluation Cooperative (SPEC).

Word: An addressable collection of bits. In current practice, words are usually a multiple of 1, 2, 4, or 8 bytes (8, 16, 32, or 64 bits, respectively).

INTRODUCTION

Computer programming languages are used by people to specify the actions to be taken by computers in solving problems. As the needs of different types of users to solve problems with computers vary, so do the computer programming languages that have been developed. In this article we concentrate on the aspects of computer programming languages of interest to physicists, both for major scientific calculations and for control of experiments. Thus we will give only brief attention to languages and approaches to languages that, while of major importance in other fields, such as computer science, are not critical to working physicists. The so-called imperative or statement-oriented programming languages, which specify sequences of actions to be taken on objects (such as adding a list of numbers, and then dividing by the count of things in the list to get an average), are the major tools of modern physics.

In the space available we cannot fully describe the rich structure of even this small subset of computer programming languages. At best we can give some of the essential terminology, and examples of the most heavily used features. Languages used by people to communicate with people are learned by using them. The same is true of languages used by people to communicate with computers.

Computers have their own internal languages, private jargons of strings of numbers that are difficult for most people to learn and rarely used as programming languages. A single computer may have more than one such language, and different types of computers, even though made by a single manufacturer, may have different languages. The lists of numbers direct the machine to perform certain simple actions. Because the choice of numbers may vary from machine to machine, the number 103344 might be an "instruction"

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

(an "order" or "command") to add two numbers stored in locations 33 and 44 on one machine, and an instruction to print the character in location 3310 on another. Such lists of numbers are almost as cryptic as the codes and ciphers used to hide secrets from spies. These "machine languages" require a programmer to specify in full detail what is to be done, and slight conceptual changes can require large portions of a program to be rewritten.

In order to save the effort of writing a new and different program for each machine to solve the same problems, to make computers accessible to more people, and to increase the chance of writing instructions for computers correctly, many programming languages for computers have been created, languages that express the actions to be performed in terms more comprehensible to people, and in ways that allow the same programs to be used on many different types of computers.

There is a large range of problems in physics for which computer languages are used. For problems expressed as formulas and equations, there are languages, such as FORTRAN, that accept formulas in ordinary scientific notation. For problems of process control and control of scientific experiments, languages that allow a finer control over a machine and facilitate management of real-time processes running in parallel, such as C and assembly languages, are used. For many problems it is important to be able to make rapid changes in a program, and the efficiency of execution is not as critical. In such cases, interpretive languages, such as APL, BASIC, and FORTH, that allow "on-the-fly" changes are used.

Some languages are close in style to the operation of computers, consisting of sequences of actions to be taken on objects. Such a style simplifies efficient translation of a problem specification into the internal language of a computer, but may force a strained interpretation of the original problem, increasing the chances of programming errors, and increasing program maintenance costs. To reflect more naturally the demands of theproblems to be solved rather than the demands of computers, languages using other styles of programming have been developed: object-oriented, functional, and logic programming. These offer promise of increased productivity for appropriate problems, but for the classic problems of theoretical and experimental physics, FORTRAN and its statement-oriented, imperative relatives predominate.

We will begin by considering the history of computer programming languages and the differing programming styles that have been developed. Then we will look in some detail at the languages for major scientific calculations, exemplified by FORTRAN, C, and PASCAL, and the additional languages used in control of experiments, exemplified by BASIC and FORTH. For each we will give some of the vocabulary of the languages: the "operators," which are effectively the verbs of the language, and the "data structures" and "data types" that define the nouns and their modifiers.

1. HISTORY

The history of computer programming languages is intimately related to the history of computers themselves (see COMPUTERS; COMPUTER HARDWARE). Many of the restrictions and inconveniences in early languages were reflections of the limitations of the computers of the time. Because our focus here is on languages, rather than computers, we will omit many critical contributions to the design of computers and discuss only some examples of the changes in hardware that had a significant impact on the development of languages.

The first consideration of programming was for Charles Babbage's proposed Analytical Engine by Augusta Ada, Countess of Lovelace, in 1842 (Morrison and Morrison, 1961, pp. 245–295; Hollingdale and Toothill, 1965). The programming was in a direct machine language, with a manual translation from normal mathematical notation. Babbage's machine had a memory, a processor for arithmetic and control, and input-output capabilities. At this early date, the fundamental concepts of operations (actions to be performed), variables (information that may change during the calculation), and constants (numbers, such as e or π, that would not change) were established.

1.1 Plug-Board Programming, Punch Cards, and Paper Tape

In Babbage's time, cardboard cards with holes punched into them were used for the control of looms, and he chose such punch cards as a mechanism for specification of both operations and variables. In 1890, Herman Hollerith invented a series of electromechanical punch-card devices that could do census calculations under the control of a wired-in program of simple actions, such as adding, subtracting, or printing certain columns of numbers. The numbers were stored as holes punched into cardboard cards; hence the name "punch cards." "Programming" such machines consisted of throwing switches and inserting jumper wires into plug boards (like an old-fashioned telephone switchboard). Programs were saved by simply keeping the entire plug board with its wires, and putting in a fresh one for the next program. These electromechanical machines were put to increasingly complex and general tasks, culminating in the design and construction of the Automatic Sequence Controlled Calculator, the Mark I, by Howard Aiken from 1937 to 1944 (Slater, 1987, pp. 81–90). In addition to its internal plug board wiring, it accepted a general program of instructions on paper tape. The operations of the machine were composed from addition, subtraction, multiplication, division, and retrieval of previously computed variables. Data came from three more paper tapes and two stacks of punch cards. The values of 60 constants were set from 1400 rotary switches. Programming the machine was a complex process of preparing tapes, cards, and switch settings. The program on the control paper tape consisted of lines of 24 holes each, broken into three fields, two for operands and one to specify the operation (Bashe *et al.*, 1986).

1.2 Stored Programs and Machine Language Programming

A great simplification of programming came with the creation of digital electronic stored-program computers because a program was stored in memory as numbers. The concept was pioneered during work on Eckert and Mauchly's Electronic Numeric Integrator and Calculator (ENIAC); see Rosen (1969). ENIAC was programmed by wiring, but Wilkes' EDSAC in 1949 fully implemented stored-program computer design. Early internal memories were small, and would have greatly limited program size, so that programs still existed primarily as holes in cards and paper tape external to computers. However, having the ability to store large portions of a program internally made it possible to reuse the same sequence of instructions rapidly without having to reload them for each execution from cards or tape, thereby having efficient "loops" and "subroutines." Commonly used modules of code, e.g., routines to do calculations on floating-point numbers (i.e., real numbers in which the decimal point might be at different places) or complex numbers on machines that did not have built-in hardware for such calculations, were programmed in the native language of the machine, "machine language," and saved for use with many programs. Machine languages settled down to a variety of simple numeric representations of operations of the form

Operation Operand-Address Operand-Address...

where the number of operand addresses (the places from which data was to be fetched, or to which results were to be stored) was determined by the design of the machine and the particular operation being done. Sometimes all the operands were explicitly listed with the instruction, and sometimes one or more operands were implicit in the operation chosen. On some machines the address from which the next instruction would be fetched had to be explicitly given as part of the instruction. In others, that was needed only to create conditionally executed sections of code—loops and subroutines.

If the computer used decimal numbers internally, programming could be a simple transliteration of operations into appropriate decimal digits, and laying out of locations of instructions and operands in memory. This was a complex extension of the problem of seating many people for a large dinner party.

Hardware economies could be found by building computers based on binary numbers (base 2) rather than decimal (base 10), so, for such machines, instructions had to be created in that numbering system. Octal (base 8) notation was sometimes convenient for creating such instructions.

1.3 Assemblers

Translation of names for operations and names of the things that need to be fetched and stored is itself a calculation, one for which the computer itself is well suited. Thus, in the 1950s machine-language programming was replaced for most purposes by assembly-language programming (e.g., the work of Rochester and McClelland; see Bashe *et al.*, 1986, pp. 323 ff.). An assembler translates names for operations, such as "ADD" and "SUB," into the appropriate numbers, and keeps track of which memory locations have already been used for instructions, variables, and constants, so that the programmer might refer to them by name instead of by number. Though each machine had its own assembly language, at least the pieces of code for that machine saved in symbolic form did not have to be rewritten when used with other code that would force changes in addresses.

For example, let us invent a decimal machine that has the following instructions:

01ssdd:

MOV ss [source to] dd [destination]

02ssdd:

ADD ss [source to] dd [destination]

03vvll:

IF vv [variable to test is] NOT-ZERO [then goto location] ll

04ssdd:

READ [a number from source device] ss [and store in] dd

05ssdd:

PRINT [the number in location] ss [on device] dd

060000:

END

and assume that the source of input data is device 5 and the printer is device 6. Then to read in 10 numbers, add them, and print the result, we might write

```
TEN:       DATA      10
NEGONE:    DATA      -1
ZERO:      DATA      0
INPUT:     VARIABLE
ICOUNT:    VARIABLE
ISUM:      VARIABLE
START:     MOV            TEN,ICOUNT
           MOV            ZERO,ISUM
LOOP:      READ           05,INPUT
           ADD            INPUT,ISUM
           ADD            NEGONE,
                           ICOUNT
           IF             ICOUNT NOT-
                           ZERO, LOOP
           PRINT          06,SUM
           END
```

rather than

```
      10
      -1
      0
      0
      0
      0
      010004
      010205
      040503
      020305
      020104
      030408
      050506
      060000
```

This was a significant improvement in making it easier to write programs. However, programmers still had to write out every instruction in full detail. To save time in writing similar sequences, assemblers were expanded to become macro-assemblers, in that sequences of instructions could be given names.

1.4 Compilers

Assemblers were and still are useful tools, but even with macro facilities, they are still strongly linked to particular machines, not to the problems of primary interest to users of the machines. Translators for languages that do not directly represent machine language, but that require compilation of the meaning of an entire program or major segments of a program into appropriate instructions as large units, are called "compilers." In 1952, Grace Hopper created a more user-oriented computer language called A-O for UNIVAC computers. By 1955, a group at IBM led by John

Backus had designed a language called FORTRAN (for IBM Mathematical Formula Translating System), which would take statements written in ordinary algebraic mathematical notation and translate them into a program in machine language. This language, and its successors, became the workhorses of scientific calculations in the United States, first on the IBM 704 and its descendants, and then on other computers.

In FORTRAN, the example of adding ten numbers, above, might be written as:

```
        ISUM=0
        DO 100 ICOUNT = 1,10
        READ (5,1000) INPUT
100     ISUM=ISUM+INPUT
        WRITE (6,1000) ISUM
1000    FORMAT (I6)
        STOP
        END
```

For business applications, compilers for a "Common Business Oriented Language" (COBOL) based on earlier work by Grace Hopper were developed in 1959, and for such applications the language is still in heavy use. The style is closer to English than the mathematical formulas of FORTRAN, as in

```
ADD MYVALUE TO MYSUM
```

The great success of FORTRAN and COBOL and the increasing power of computers led to attempts to create better languages. Starting in the late 1950s, Peter Naur and others worked on "Algorithmic Language" (ALGOL), intended to provide code more structured and easier to read and to maintain than FORTRAN. Partially because it was oriented toward character sets not well supported on the card punches in the United States, and because FORTRAN was adequately meeting the scientific programming needs of the time on the computers available in the United States, ALGOL did not achieve great popularity in the United States, but did attract a wide following in Europe in the 1960s. By creating PL/I in 1964, IBM attempted to correct some of the limitations of FORTRAN and combine it with all the business-oriented features of COBOL. PL/I is still in use, but has not attracted a large following. ALGOL evolved into two different languages. ALGOL-68 addressed the need for more general data structures, but was hard to read. In 1971 Niklaus Wirth proposed an alternative language, called PASCAL, that proved effective for that purpose, and was simple and clear. Use of ALGOL-68 faded out.

The special needs for computing in the military environment were addressed by Jules Schwartz's JOVIAL ("Jules' Own Version of the International Algebraic Language"), but real-time programming for control computers was done in a mixture of assembler and FORTRAN. This produced a body of code that was hard to debug and maintain as computers changed, and in the mid-1970s development of a language specially suited to programming computers operating in real time and embedded in military hardware was begun. Attempts were made to address all aspects of the cycle of creation and maintenance of software by providing tools needed for effective software engineering in the language, and to learn the lessons of the languages developed up until then. The result, developed primarily by J. Ichbiah and colleagues in 1979, was called ADA, in honor of the Countess of Lovelace; see Booch (1983). We will return to this language in considering software engineering below.

A compiled language called C was designed in 1972 by D. Ritchie (Kernighan and Ritchie, 1978). C provides the user-oriented economy of expression of FORTRAN and PASCAL with the intimate access to hardware features of assemblers, and has replaced a major portion of the use of assemblers for time-critical real-time programming in operating systems and device control code.

1.5 Interpreters

A compiler takes the user source code as a whole and translates it all to machine language before executing any of it. This can imply a long delay between changes in a program and seeing the results, and also causes difficulty in highly dynamic decisions about the use of memory. For applications requiring a more immediate response to code changes or highly dynamic uses of data structures, interpretive languages have been developed. The computer is effectively programmed to simulate a machine closer to the user needs. The first such interpreter, called the Speedcoding Interpreter, was developed by John Backus and others at IBM in 1953. Interpreters have been used for many significant languages since. Examples are APL ("A Programming Language"), developed by Kenneth Iverson in 1962, BASIC, developed by Kemeny and Kurtz in 1965, LISP, developed by John McCarthy in 1962, and FORTH, developed by Charles Moore in 1971.

The languages implemented by use of interpreters often also have compilers to allow for more efficient execution once the programmer is past the debugging stage. Many languages that are more appropriate to compilation because of complex context, such as FORTRAN and C, also have had interpreters created to aid in debugging programs.

1.6 Software Engineering

As an increasing investment was made in programs for use on computers, it became clear that the costs of software development would exceed by far the costs of the computers on which the software would run, and that the major source of failures of computer-based systems would be unreliable software, rather than unreliable hardware. Languages were proposed that more closely reflected the functions to be performed, rather than the internal workings of computers. John McCarthy developed LISP (for List Processing) from 1956 to 1962 which, though it could be used in the step-by-step style of statement-oriented (or imperative) languages, introduced the ability to solve problems simply by evaluating functions made up of yet more functions, perhaps defined recursively. LISP became the basic tool of artificial intelligence research and computerized symbolic algebra. PROLOG, in 1972, introduced an extremely high level of functional programming, permitting general statements of problems to be effectively their code. The development of ALGOL and PASCAL had provided a basis for programming in a hierarchical structure or routines using hierarchical structures of data. These approaches were the beginnings of a serious attempt to convert the art of programming into a process of engineering—creation of a quality product in a predictable time that would perform according to its specifications, and that could be maintained in an operational state over considerable periods of time despite changes in the hardware being used. It was also hoped that an engineering approach would allow the rapid and reliable development of new software products and new versions of existing products in response to new problem specifications.

The most serious effort in this direction, of creating an environment for "software engineering," has been in the ongoing development of ADA, where, because of the large expenditures on software in the military, and the high risks from failures of that software, an engineering approach is desirable. The degree of success of that particular effort is not known as of this writing. It is clear that a highly disciplined and organized approach to creating programs, in which each part of the software is self-documenting and small enough to be thoroughly understood and tested, with the cleanest possible interfaces to other pieces, greatly increases the chances of producing correctly functioning programs in a reasonable length of time.

One of the most significant changes in approach to programming adopted by software engineering has been in the area of "object-oriented" languages. Beginning with work on SMALLTALK from 1971 to 1980, languages supporting this concept allow the creation of objects that respond to messages from other objects by taking appropriate actions, shifting the emphasis in software design from complex sequences of actions to more modularized actions within the mechanisms of objects. Such an approach is particularly appealing when one works with systems requiring many interacting parallel threads of execution. Languages for object-oriented programming provide the ability to define new "abstract data types," in which the user may specify not only the representation of data within memory, but the operations that may be performed on that data, and hide the internals of the representation from processes using the type, so that unneeded dependences on the specifics of a representation will not proliferate.

For more on the history of software engineering, see Ghezzi and Jazayeri (1987).

1.7 Supercomputing

In the major mathematical calculations of physics, the largest and fastest computers of the moment, so-called supercomputers, are pressed into service. The programming languages used are adapted to the special capabilities of those machines. In 1963, Control Data introduced the 6600, a computer capable of 1 million floating-point operations per second and the supercomputer of its day. The machine had a complex and subtle interaction among its operations because some of them happened in parallel, making it difficult to get maximum execution speeds from ordinary FORTRAN compilers. It was common to code critical sections of programs in assembler for speed. Since then, supercomputer hardware has become more complex. The CDC 7600, the Cray-1, CDC Cyber 200 series and NEC SX series, Fujitsu VP series, and Hitachi S-800 series pushed the limits of available hardware speeds for properly organized programs and data. The present generation of machines combines the processing of entire vectors of data in single instructions with the availability of more than one processor to handle a single problem. Preprocessors to FORTRAN, highly optimizing compilers, extensions to FORTRAN, and use of C allow close to optimal execution without having to resort to assembler code, but the programs often have to be extensively redesigned when moved from one machine to another in order to realize maximum speeds.

See Perrott and Zarea-Aliabadi (1986) for more detail on supercomputer languages.

1.8 Parallel Computing

It appears that we may be reaching the limits of speed achievable by a small number of powerful processors, and that the supercomputers of the future will have much greater parallelism. Languages designed for sequential execution of instructions on one processor may not be appropriate for this new generation of parallel computers. Suppose we have a machine with 1000 processors that are able to work in parallel, and we try to convert an existing sequential code to run on our new system. We must ensure that the result of the parallel execution is the same as that of the sequential execution of the program, so we introduce code to synchronize the use of data that must be updated to ensure that it is updated in the desired ordering. If, as a result of this synchronization, we force, say, 1% of the executed instructions to execute on just one processor in total control of the machine, then we can never gain a speed improvement of even 100 times, much less the 1000 times we would like to see from 1000 processors (see PARALLEL COMPUTING).

Many paradigms need to be considered in the design of a language for parallel processing: shared memory versus message passing, tightly coupled versus loosely coupled processors, homogeneous versus heterogeneous processors, many small processors versus a few powerful processors versus many powerful processors. When a large number of processors attempt to share a common memory, mechanisms must be provided to synchronize their use efficiently, or access to a single location may force the processors to "serialize" execution, i.e., to run one after the other, rather than in parallel. When many processors use private memories instead, then careful estimation of the network traffic needed to keep feeding each one of them data is needed. The 1980s have seen an explosion of new languages and extensions of existing languages to handle various types of parallel systems. Of particular interest is the language LINDA (see Ahuja *et al.*, 1986) with data structures based on the concept of Tuple Space. Tuples are ordered sets of values, usually given as a parenthesized list. In a sequential language we would expect to have a fixed address telling us where the tuple is to be found. In the Tuple Space approach, we find the tuple partly by the contents of its fields and partly by its structure, so that the necessary addressing information is carried by the tuple.

The basic operations are "out," which adds a new tuple to Tuple Space, "read," which reads a tuple but leaves it in Tuple Space, and "in," which reads a tuple and removes it from Tuple Space. Trying to "read" or "in" a tuple that is not yet in Tuple Space causes the requester to wait until someone else puts the desired tuple there. This provides the essential interlock to allow effectively simultaneous access to the same data. See Bal *et al.* (1989) for more on the subject of languages for distributed computing.

As with existing supercomputers, there is a certain attractiveness to programming in a variant of FORTRAN, and then having the parallel conversion done by a preprocessor or the language translator. An example is Alliant FX/Series FORTRAN (see Alliant, 1988).

1.9 4GLs, Packages, and Nonprogramming

In the early days of computing, there was a feeling of moving from one generation of computers to another, and from one family of languages to its descendants. With the faster pace of development today, it is hard to distinguish any clear boundaries marking the end of one generation and the start of another. However, the term "4GL," for "Fourth-Generation Language," has come to mean packages and systems of powerful tools for programming that allow someone who is not particularly familiar with the intricacies of programming to solve problems with computers. This includes powerful database query languages, spreadsheet systems, graphics tool boxes, and systems integrated with text processing for the production of complex compound documents. In many cases the need to program is avoided by the use of menus or graphic user interfaces allowing the nonprogrammer to piece together the solution to his problem out of simple known steps and objects. It is to be hoped that the fourth-generation packages will be followed by a "Fifth Generation" of even more powerful systems functioning as expert systems able to assist the user actively in finding the solution to his problems.

With the spread of individual workstations and the decentralization of the management of information, the 1980s have seen the rapidly increasing use of more powerful tools by a wider community of users. Solutions to problems can be pieced together with much greater speed than ever before, but with that speed also comes the risk that the solution, being composed of unexamined black boxes, may not be what was initially intended. There may no longer be a rigorous trace of what was done to achieve that solution, nor even of what it actually is. With powerful tools comes the risk of large mistakes.

For more background on fourth- and fifth-generation languages, see Chorafas (1986).

2. PROGRAMMING LANGUAGE CONCEPTS AND STYLES

The wide variety of uses to which computers may be put has led to the creation of more languages than any one person could learn or use in a lifetime. Indeed, it is common to extend languages, effectively to invent whole new vocabularies, when faced with even modest new problems. Good programmers write extensive libraries of "functions" and "subroutines" that they try to use and further extend for additional applications.

In order to deal with this veritable Tower of Babel, we will present the general concepts of programming languages, with supporting examples from some of the more popular languages used in physics. In any particular application on any particular machine, the specific instructions for use of the dialects of languages used there must be consulted.

Digital stored-program computers provide the means to manipulate numbers and other data by sequences of operations. The data and the memory locations within which they are stored are "objects" on which a computer performs a sequence of "actions." Computer programming languages are tools to perform actions, explicitly or implicitly, on objects. They are designed either to work directly with representations of concepts that derive from the structure and function of digital stored-program computers or to work with representations of concepts that derive from representations of other concepts. In that case, the language translator must translate those other representations into terms appropriate to computers. The objects that must be manipulated are the equivalent of nouns and pronouns in human languages. These objects are called "variables," "constants," "parameters," "arrays," "strings," "pointers," "arguments," etc. in programming languages. There are the actions that may be taken either simply as actions by themselves or on some of these objects, the equivalent of intransitive and transitive verbs in human languages. These actions are called "operations," "functions," "subroutines," "procedures," "handlers," "drivers," etc., in programming languages. The basic elements of a language are enriched by additional descriptive elements that describe various properties of objects and actions, and provide a context that may change the meaning of the objects and the actions. Think of these as descriptive sentences involving adjectives and adverbs. Thus, if we were writing a procedure for cooking a chicken, we might begin with descriptive sentences setting the environment for our procedure:

1. The oven should be at 350 degrees.
2. The chicken should be at room temperature.

Then we might list the actions to be taken on the objects involved:

1. Clean and season the chicken.

2. Put the chicken into the pan.
3. Put the chicken and pan into the oven until 2 hours have gone by.
4. Baste the chicken every 15 minutes.
5. Remove the chicken from the oven.
6. Let the chicken set for 15 minutes.

In this example, we can think of the "chicken," the "pan," and the "oven" all as objects, and "clean," "put . . . into," "baste," "remove," and "let . . . set" as the actions in a programming language.

In programming languages we usually use the name "statement" for sentences of the language. As with human languages, the actions (verbs) and objects (nouns and pronouns) may be in a variety of relative positions, and some of these objects and actions may be understood, rather than explicitly included, in the statement. The three most common orderings of actions and objects are these:

1. Put an action before the objects it affects (prefix notation).
2. Put an action after the objects it affects (postfix notation).
3. Put an action between the objects it affects (infix notation).

For example, if we wished to add the numbers 5 and 6 to get 11, this would be expressed as "+ 5 6" in prefix notation, "5 6 +" in postfix notation, and "5 + 6" in infix notation.

When our emphasis is on the sequence of actions, on doing one thing after another, we consider a statement-oriented, or "imperative" programming, approach. When our emphasis is more on the objects, and we consider the actions as an internal mechanism of the objects that communicate by passing messages among themselves, we are concerned with "object-oriented" programming. Instead of giving the detailed steps involved in chicken cooking, we might define a "chicken cooker" as an object, which might contain a raw chicken or a cooked chicken. We would still have to define somehow the internal mechanisms of the chicken cooker, but we could hide the choice of gas stove versus microwave, basting, etc., from the user of the chicken cooker. If we divorce ourselves entirely from considerations of the order in which actions are to be performed, but consider only the most pure function evaluations, then we are concerned with "functional" programming; and if we refuse to consider actions at all, but only the relationships among objects, we are concerned with "logic" programming. In this last case, we might simply define the relationships between characteristics of a raw chicken and a properly cooked chicken, and leave it to the computer to find a way to transform raw chicken into cooked chicken.

2.1 Imperative Programming

FORTRAN, BASIC, ALGOL, PASCAL, C, and MODULA-2 are examples of languages that support statement-oriented programming, following the approach of our chicken-cooking example above. FORTRAN established the accepted programming style for these languages. BASIC is a simplified, FORTRAN-like language often run interpretively to allow rapid changes and experimentation with a program. ALGOL was a competitor to FORTRAN that allowed a more hierarchical structuring of a program. PASCAL is a descendant of ALGOL with a rich control over data structures and types. C is a more flexible language with less rigid enforcement of data structures and types. MODULA-2 is a descendant of PASCAL that provides support for the concepts of modules and information hiding (see below).

A program in such an imperative programming language will consist of some number of related modules containing some declarations that establish the environment in which the work is to be done (primarily specifying the data structures of the objects to be manipulated) and then a well-defined sequence of steps to perform on those objects. The most powerful high-level action to be taken is the execution of an assignment statement, i.e., a statement that puts new information into an object, usually based on the evaluation of arithmetic expressions, possibly containing references to functions of previously computed data. This statement is a generalization of the simple computer order to "store." It looks like an algebraic equation, but has a different meaning.

Consider the FORTRAN statement

```
X=X**2
```

As an algebraic equation, it would have two solutions, 0 and 1. As a statement in FORTRAN, it is an order to take what is currently stored in the variable X, multiply it by itself, and store it back into X. If X started out as 0.5, it would now become 0.25. It need not be 0 or 1 or any other particular value. Thus, in order to determine the state of an object, what value is stored in a variable or whether any value has been stored at all, we must follow the sequence of actions taken from the beginning and see what has been done to the object. This makes debugging of statement-oriented language programs difficult. Special programs, called debuggers, are used to provide traces of all changes to an object or even of all steps taken.

In order to improve the readability and maintainability of imperative programming language programs, it is desirable to keep small the context of objects that any actions may affect. This is done by breaking up the program into procedures, modules, packages, etc.

A consequence of breaking up a program into small pieces in an imperative programming language is the possibility of "side effects." A procedure may have internal data structures, objects only it knows about, or access to less-than-obviously accessible global data structures. By changes in the state of these hidden objects, different invocations of the same object may produce totally different results. Consider the analogy of an employer dealing with an employee who is having problems outside of work, perhaps with bills that are piling up. On a day when his bank is threatening to foreclose on his house, the employee may simply ignore what his boss tells him and sulk. On a day when he has caught up on his payments, he may perform his job quickly and efficiently. In a global sense, the behavior of the employee is deterministic, but from the point of view of the employer, the employee seems to respond differently at different times to the same inputs. Such variability can be highly desirable when, for example, a procedure for printing pages puts a heading on at the top of each page because it is keeping an internal counter of lines, but in general side effects make it difficult to write reliable software.

2.2 Object-Oriented Programming

In object-oriented programming, we attempt to solve problems by working with objects that can send messages to one another. Those messages may then cause the objects to take some appropriate actions, but, essentially, the actions are hidden, internal mechanisms within the objects. This is a realistic model of the behavior of systems such as trucking companies. Goods delivered to them cause them to dispatch trucks to appropriate destinations. Thus we might define objects called "warehouse" and "restaurant A," "restaurant B," and "restaurant C." The warehouse might contain a variety of inventories of goods, say, "chickens" and "ducks," and allow the operations "arrival" (i.e., store) and "dispatch." The arrival of a truckload of ducks might result in the dispatch of three smaller truckloads of ducks, one to each of the restaurants. The mechanism of computing the quantities of ducks to dispatch to each restaurant need not concern us; it is an internal mechanism of the warehouse, perhaps relating to earlier messages (e.g., standing orders from the restaurants). In a similar way we might define a chicken-cooking machine, which accepts the message that a raw chicken has arrived, and which dispatches a cooked chicken by some unspecified internal means. Other than timing, we would not be concerned that the chicken cooker used a gas oven or a microwave, just that the arrival of a raw chicken resulted in the production of a cooked chicken.

An early example of a computer system operating in a similar manner was the CDC 6600 of 1963, a complex of 11 processors communicating via messages left in mail boxes. This approach was used to provide a highly efficient operating system, but was not made available for user programs. SIMULA-67 introduced the concept of "class," which allowed a data structure to be associated with the code that would manipulate that data structure. MODULA-2, SMALLTALK, and C++ provided similar modularization of "objects."

The important distinction from the norms of simple imperative languages is that in, say, FORTRAN, one could organize data and create routines to manipulate those data. The entire mechanism of how the data would be manipulated normally remained visible, so that a programmer could and often did build assumptions about the internals of that manipulation into the programs that used it. Then when any change was made at the lower level, say to improve the efficiency of the routines handling the data structure, or to add new features to the data structure, every piece of code that used those routines had to be examined, and perhaps changed. In an object-oriented language, by associating the manipulations of the data with the data structures themselves, the internal mechanisms can be hidden from the higher-level routines, and the effects of changes within the lower level routines can be kept purely internal.

However, there can still be side effects in an object-oriented language. Indeed, because of the hidden nature of actions within objects, side effects may become the dominant problem-solving mode. Also, even though there is a considerable relaxation of concern about strict sequential execution of actions on objects by allowing many messages to be outstanding at one time, there is still a strong preference for solving problems by performing actions in some sequence on objects.

2.3 Functional Programming

In functional programming (or "applicative" programming) problems are solved by pure function evaluations, without any possibility of side effects. The concepts began with work of Church on the "Lambda Calculus" in the 1930s and found a viable programming language expression in McCarthy's LISP. Iverson's APL, while not a purely applicative language (nor is LISP for that matter), allows and encourages programming in that style. ML is a more recent example of a functional programming language.

In such a language, the procedures that express functions themselves are valid data, which will be evaluated in some manner consistent with their definition, but not in a strictly determined order. Thus if we were doing a problem in surveying, and were using some lengths and the sine, cosine, and tangent of an angle to compute the boundaries of a field, we would simply write the equations for each of the boundaries in terms of the known quantities, and leave it to the computer to decide on the actual order in which to compute the sine versus the cosine versus the tangent. This functional style can be combined with concepts from other programming styles to achieve a richer language. For example, the abstract data types of object-oriented programming, with their hidden internal mechanisms for performing required actions, can be viewed as valid data types in a functional programming language and the actions recast simply as operators on data to be used in functions without side effects.

Languages for symbolic manipulation of equations are often based on one of the functional programming languages, such as LISP, since they are oriented toward evaluation of formulas.

Because the order of execution is not of concern in functional programming, this programming style may have significant application in efficient use of parallel processors.

For more background on functional programming, see Hudak (1989).

2.4 Logic Programming

We may move still one step further in trying to focus on the application rather than on the operation of computer hardware and consider only the relationships among objects of interest rather than even the implicit actions of functions. This style is called logic programming.

PROLOG was developed by A. Colmerauer in 1972. It deals with the specification of problems on a high level, as statements about objects and the relationships among them, and then allows the user to ask questions about those relationships, making the logical inferences from what is known to what has been asked. This leads to the term "logic programming." PROLOG is an appropriate language for work in artificial intelligence. However, it may be argued that any application of a computer to any problem is an exercise in artificial intelligence, and that the normal human specification of a problem in terms of objects and their relationships could be addressed directly by PROLOG without further programming.

In PROLOG, if we wish to state as a fact that "the child is father to the man," we would write

```
father (child,man).
```

In general we state a fact by putting the relationship first, before a parenthesized list of objects associated by that relationship. Questions about relationships are posed by placing "?-" before the hypothetical relationship. If it can be inferred from the known facts, PROLOG answers "yes"; otherwise "no."

If an object is named starting with a capital letter, then it is treated as a variable that may stand for known or unknown objects. In

PROLOG, when the object for which the variable stands is known it is called "instantiated." When asked a question involving an uninstantiated variable, PROLOG tries to find a match to facts that will allow it to instantiate the variable. The answer may be accepted or rejected by the user. If rejected, the attempts to match continue.

PROLOG uses a comma between facts to indicate "and," and ":-" to show that a fact depends on other facts (making a "rule"), so that we could say "Sally loves men who love dancing and dining" as

```
loves(sally,Men):- loves(Men,dancing),
  loves(Men,dining).
```

PROLOG can work with numbers (integers or real) as well as symbolic identifiers. It has the arithmetic operators + (add), − (subtract), * (multiply), / (divide), and mod (take the remainder), and the relational operators > (greater than), < (less than), >= (greater than or equal to), =< (less than or equal to), and =\= (not equal to). For more detail on programming in PROLOG, see Clocksin and Mellish (1987).

2.5 Concurrent Programming

With all concerns about evaluation as well as order of evaluation taken out of the hands of the programmer, a logic programming language has the maximum freedom to adapt the solution of a problem to parallel and distributed execution. By adopting the view that the system is in open-ended continuous operation, reacting to an environment, rather than transforming input data into output data, and by adopting the attitude that partial problem solutions are interesting, logic languages such as PROLOG have been changed into "concurrent logic" programming languages, one of which is CONCURRENT PROLOG. The approach blends naturally with object-oriented programming style in which objects send messages to other objects, and perhaps delegate them (passing them on) to yet other objects to handle when they are not understood.

These languages are not a particular improvement over imperative languages such as FORTRAN for straight numerical algorithms, since they may execute orders of magnitude more slowly, and not even produce the expected result. They are better suited to solving the challenging problems of making computers able to make humanlike decisions in reasonable times, to reason, and to display artificial intelligence. The role of such languages would then not be in the execution of a numeric algorithm but in helping with the design of the algorithm, or the design of an experiment on the basis of an expert system.

For more on this subject, see Shapiro (1989).

3. LANGUAGES FOR MAJOR SCIENTIFIC CALCULATIONS

When a problem pushes computer resources to their limits, languages that will make optimal use of those resources are needed. This is most easily achieved with languages whose structures correspond to the structures of computers, in terms of sequences of actions to be taken on appropriate data. The first and most enduring of these languages is FORTRAN. It is an evolving language with many dialects and variants, but (with minor modifications) routines written to do numeric calculations in 1959 could still be used in 1989, and most likely will still be useful in 2019. For some things, however, even with the best optimization, FORTRAN may not allow a machine to achieve maximum performance. In earlier days, an assembler would have been used to allow instructions to be written that would extract that last bit of efficiency. Today, this would more commonly be done in a FORTRAN-like language such as C.

We will also look at ALGOL and its descendant, PASCAL, which avoids some of the clumsiness of FORTRAN and which was a popular competitor to FORTRAN for a while. Many important algorithms were published in ALGOL, and an ability to read the language is important. PASCAL is used extensively to handle complex data structures.

FORTRAN is evolving and picking up features from PASCAL and other languages. It is not clear whether the resulting language will be able to retain the performance capabilities of the simpler, existing language.

If one looks carefully at FORTRAN, C, and PASCAL, it is obvious that almost anything one might wish to program could be programmed in any of the three, and with almost equal ease. Indeed, aside from the "syntactic noise" of different statement delimiters, programs in the three languages can be hard to distinguish, and the same well-written codes can be, and often are, transliterated from one to another of the languages to good effect. The significant differences among these languages lie in two areas: ability to help detect errors in writing a program, and what we may call "depth of context."

In any language it is possible to write a program that is expressed correctly in that language, but that does not do what we had intended. PASCAL provides very strong cross-checks to make such errors less common than in FORTRAN or C. However, it is precisely those cross-checks that often make it difficult to use PASCAL for applications that must efficiently push the limits of a computer, as in device drivers for experiment control, which would be more likely to be written in FORTRAN and C.

C, however, shares common ground with PASCAL in allowing a depth of context lacking in FORTRAN. In FORTRAN, the environment of definitions within which we work is usually on one level. Everything about the definition of a name in FORTRAN as a particular type of data structure is visible within the routine manipulating it, because in most dialects of FORTRAN it is not possible to nest complete routines, with their definitions, within other routines. Such nesting can be done for both procedure and data structure definitions in PASCAL and for data structure definitions in C. This allows some of the definitions being used to be brought much closer to the point where they will be used, allowing a disciplined programmer to keep the context that someone reading the code needs to understand to a page or two, but also allows an undisciplined programmer to create a complex hierarchy of contexts, within the depths of which one can get lost.

The difference between approaches is similar to differences between English and German. In normal English, sentences work on a small number of levels of structure; while in German, a single sentence may go on for a paragraph, with complex nested subordinate clauses, and verbs gathered far away from the rest of the sentence. FORTRAN encourages a style familiar to English speakers, while C and PASCAL encourage a more Germanic style of coding. It must be emphasized, however, that such stylistic biases need have little effect on most programs, since the common practice now is to write most programs as sets of independently compiled routines, each of which is so small as not to be likely to make use of many levels of internal structure, providing a depth of context in the chain of external calls, rather than in internal blocks. This approach can be followed in any of these languages, and produces code that is easy to move from one language to another.

3.1 FORTRAN

The family of FORTRAN languages has a simple, imperative style. These languages work with data as integer, real, double-precision real, complex, or logical, and arrays of up to three or more subscripts of such data types. They form expressions by applying the arithmetic operators + (addition), − (subtraction or negation), * (multiplication), / (division), or ** (exponentiation) to numeric constants, variables, array elements (elements of vectors or matrices), and function calls (values returned by other pieces of code that evaluate the value of a function of some given arguments), and assign the values of those expressions to variables or array elements.

Though many variations are allowed on different systems, the following rather restrictive approach is valid on almost all systems. This rigid format is relaxed in many modern dialects, to make typing of programs from terminals simpler and to make it easier to read programs.

A program consists of statements.

Each statement is formatted as a sequence of fixed-length lines (originally intended as the images of 80-column punch cards), with four fixed fields:

Columns 1–5 may contain a number (a nonzero integer in some machine-dependent range, but rarely restricted to less than 32767) to be used as a statement label or may indicate a comment by a "C" in column 1.

Column 6 may contain a continuation mark (not blank, and not the digit zero), indicating that the line on which it appears contains a continuation of the statement that was on the prior line.

Columns 7–71 contain the body of the statement itself.

Columns 72–80 may contain an optional comment (often used for a line sequence number).

The only valid characters that may be used are blanks, the uppercase letters, the digits 0 through 9, the special symbols “=”, “+”, “−”, “*”, “/”, “(”, “)”, “,”, “.”, “$”, and, on all except the oldest systems, the single quote “ ' ”. Most newer systems now allow the use of lowercase letters and additional special symbols, but a program written in the limited “FORTRAN character set” is portable from machine to machine.

Blanks and leading zeros are not significant in statement numbers, and, with minor exceptions, blanks are not significant within a statement and may be introduced or removed as needed to make a program more readable.

A program consists of its main-line code (the “main program”) and whatever subroutines and functions it may need to perform its functions. Each such routine consists of a list of statements, the first group of which (the declarations and other nonexecutable statements) establish the environment within which the following executable statements will work.

The main program is distinguished from the other routines by not having a special header, or, in some dialects, starting with a “PROGRAM” statement. Thus, the general structure of a FORTRAN program would be

PROGRAM name
declarations and other nonexecutable statements
executable statements
END
SUBROUTINE name (argument,argument,...,argument)
declarations and other nonexecutable statements
executable statements
END
FUNCTION name (argument,argument,...,argument)
declarations and other nonexecutable statements
executable statements
END
⋮

continuing with as many subroutines and functions as may be needed in any order.

Logically, these routines may be intended to fit into a multilevel hierarchical structure, but visually there are only two levels: the main program and the other routines. This simple structure may cause visual confusion in large systems with many routines.

Variables in FORTRAN are named with one to six letters and/or digits, but the name of a variable must start with a letter. (More than six characters are allowed in a variable name in most modern dialects.) If the first letter of the name of a variable is “I”, “J”, “K”, “L”, “M”, or “N”, it is assumed to be an integer unless declared otherwise. It is assumed to be (single precision) real for the other letters. Use of variables of other types requires an explicit declaration. The implicit typing of the most commonly used data by the first letter of its name is a distinctive feature of FORTRAN, significantly reducing the need for declarations of variables, but also removing an opportunity for the compiler to check the declared use of a variable against the ways in which it is used by a program.

Arrays are indicated by a name formed according to the rules for variable names followed by a parenthesized list of up to three (or in some dialects more) integer indices. The set of indices picks which element of an array is of interest, as with XX(1) or XX(3) to select the first or third elements of one-dimensional array XX, or ZZ(3,4) to pick the fourth element of the third row of a two-dimensional array. Functions are referenced in the same way as arrays, except that the parenthesized list contains arguments of the function. The arguments are used in some internal calculation of the resulting “return value” of the function and, unlike array indices, need not be integers. The objects upon which the language acts may be constants, variables, array elements, the values returned by function calls, and, via special input-output statements, values found in files of data stored on disks, tapes, or other external media.

The constants and variables are of type INTEGER (whole numbers), type REAL (numbers with decimal points, usually floating-point numbers in scientific notation), type DOUBLE PRECISION (real numbers of higher precision, often double the precision, than those of type REAL), type COMPLEX, and type LOGICAL (having values “.TRUE.” or “.FALSE.”)

There is also a way to handle characters. Early FORTRAN compilers supported character strings in a very limited way, given as “nnHaaaaaaaaaa”, where the “nn” was a count of the characters “aaaaaaaaaa” that followed. Newer compilers, since the mid-1970s, have supported a type CHARACTER, quantities that may have values that are character strings of a known length, given as "'aaaaaaa'", i.e., strings delimited by single quotation marks.

In FORTRAN, files of data are an important construct, but the language does not handle them like other data types. Considering all types except files, the actions that may be taken are the following:

Assignment. A statement of the form destination = expression, where the destination is a variable or array element, first computes the value of the expression and then stores it into the location implied by the variable or array element. If the expression is of a different type than the destination, a conversion of type is done before the value is stored. Thus, the statement

```
I=X+2
```

is a directive to fetch the contents of the variable "X", add the constant "2", and store the result converted by truncation to an integer into the variable "I". If "X" had contained the value 3.6, then, following the execution of this assignment statement, "I" would contain the value 5.

Arithmetic Operators. "+" for addition, "−" for unary negation or subtraction, "*" for multiplication, "/" for division, and "**" for exponentiation. The values being combined may be numbers of type integer, real, double precision real, or complex. In the strictest versions of FORTRAN, the objects being added (or subtracted or multiplied, divided or exponentiated) must be of the same type (or at least compatible types as with complex multiplied by real or real taken to an integer power), but more general mixed-mode addition is allowed in newer variants.

Relational Operators. For integers, reals, and double precision reals, under the same compatible mode restrictions as subtraction, numbers may be compared to produce a type logical result as follows:

".GT.": greater than
".GE.": greater than or equal to
".LT.": less than
".LE.": less than or equal to
".EQ.": exactly equal to
".NE.": not exactly equal to

Caution is needed in comparing type REAL values, since the reduced internal precision of calculations on a computer may make tests for exact equality fail unexpectedly.

Logical Operators. Expressions of type logical may be combined using the operators ".NOT.", ".AND.", and ".OR.". Some dialects define additional logical operators, but these three are sufficient to allow the most general logical inferences by forming expressions [e.g., .NOT.(A .AND. B) is the "nor" of A and B].

Expressions are formed by taking sequences of constants, variables, array elements, and function references separated by operators and grouped by balanced pairs of parentheses. Evaluation works from the innermost level of function calls and parenthesized groups out, subject to a hierarchy of operators. First all the arguments of function references within the expression are evaluated, and then the functions are evaluated on those arguments. Then parenthesized expressions are evaluated from the innermost level out. Operators are applied in the following order of precedence (highest on the list first):

"**"
"*" and "/"
"+" and "−"
".GT.", ".GE.", ".LT.", ".LE.", ".EQ.", and ".NE."
".NOT."
".AND."
".OR."

so that X/Y/Z+D−E+F is the same as (X/(Y*Z))+(D+F)−E, with the compiler having the right to reorder the evaluation to an algebraically equivalent expression and to evaluate common subexpressions fewer times than they actually appear.

In addition to the assignment statement, FORTRAN includes the following executable statements that control the sequence of execution:

The GOTO statement. Transfers control to the indicated statement, as in "GOTO nnnn", where "nnnn" is a statement label in the same routine, which will be the next statement to be executed. There are two additional GOTO statements, the "computed" GOTO and the "assigned" GOTO, which allow the choice of destination to be decided within the program while running, instead of being chosen beforehand.

The arithmetic IF statement. Transfers control conditionally, as in "IF (expression) nneg, nzero,npos", where the numeric value of "expression" is computed, and then control passes to the statement with label "nneg" if the value of the expression is negative, the statement with label "nzero" if the result is zero, and to the statement with label "npos" if the value of the expression is nonzero positive.

The logical IF statement. Executes a statement conditionally, as in "IF (expression) statement", where the logical expression is evaluated, and the statement is executed if the result is .TRUE.

The block IF statement. Similar to the logical IF statement, except, of the form:

```
IF (expression) THEN
   statements to execute if the expression
     is .TRUE.
ELSE
   statements to execute if the statement
     is .FALSE.
ENDIF
```

allowing most GOTOs to be avoided.

The DO statement. Executes a block of code repetitively, incrementing a control variable on each pass. Originally of the form

```
          DO nnnn ivar = ilow,ihi,istep
             statements
nnnn last statement of the loop
```

where the variable "ivar" would start at the value "ilow", and be incremented by the value "istep" (by 1 if "istep" was not specified) until it reached or exceeded the value "ihi". The statements between the DO statement and the statement with statement label "nnnn" would be executed for each value assigned to "ivar" between "ilow" and "ihi". In earlier dialects the statements would be executed at least once (for ivar equal to ilow), even if ihi was less than ilow. This is not done in more modern dialects.

In some dialects this is now written as

```
DO ivar = ilow,ihi,istep
   statements
ENDDO
```

avoiding the need to use a statement label.

The CONTINUE statement. A do-nothing statement convenient for attaching statement labels for the end of DO-loops.

The CALL statement. Transfers control to a subroutine, as in "CALL name(arg1,arg2, arg3,...)" or just "CALL name".

The RETURN statement. Returns from a subroutine to the statement just after the CALL.

The STOP statement. Terminates execution of the program.

The PAUSE statement. Temporarily suspends execution of the program. This statement is not appropriate in a batch environment.

Files are manipulated by a variety of statements, such as "OPEN", "CLOSE", "READ", "WRITE", "REWIND", and "BACKSPACE". Files may include complex formatting of data to and from external representations, either using separate "FORMAT" statements to hold the descriptions of the various fields or including appropriate character strings in READ and WRITE statements. The environment within which the executable statements are executed is established by the nonexecutable statements:

The COMMON statement. Declares that the variables or arrays listed should be made available to other routines listing the same COMMON statement. Otherwise variables and arrays are local to each routine. There may be more than one common area, distinguished by using labels conforming to the rules for variable names. The names for the same variables in different routines need not be the same. The shared use is determined by their physical position within the list of variables, and their types.

The EQUIVALENCE statement. Declares that particular variables or arrays will share the same storage locations. Originally intended to economize on memory when it was a scarce resource, it has come to be used as a way to view the same bit patterns as being of different types.

The DIMENSION and TYPE statements. These statements declare the types of both variables and arrays, and the size of arrays (by listing the maximum values of each of the indices) or, in the case of the DIMENSION statement, just the size of arrays.

FORTRAN includes a large library of built-in functions, which the programmer may replace or add to with his own routines.

For more on FORTRAN, see ANSI Committee No. X3J3 (1989).

3.2 C

C is a language that even more closely reflects the capabilities of the machine being used than does FORTRAN, allowing bit manipulations and use of internal registers so that an assembler need not be used. C normally produces well-optimized code. The syntax avoids much of the card-oriented clumsiness of FORTRAN, using some of the style of ALGOL-like languages (see below).

A C program consists of statements terminated by semicolons, made into nested blocks by "{" and "}" (the equivalent of "begin" and "end" in ALGOL, described below). The objects that may be manipulated in C are built from three precisions of integer, which may also be unsigned for use as bit patterns, from two precisions of real, and from data of type "character." The types of all variables must be declared. Arrays are declared by using brackets with the range of the index (the quantity that selects the array element desired), e.g., "int xx[10];", which has essentially the same meaning as the FORTRAN "DIMENSION xx(10)". Users may define types. Complex data structures may be created by listing the field names with their types in braces in the "struct" declaration. A "union" allows each field to be mapped to the same locations, acting somewhat like an "EQUIVALENCE" statement in FORTRAN. Bit fields can be given field names in structures.

In FORTRAN, most access to data was explicitly by variable name, but a limited ability to point to particular data items in a larger set of data items was implicitly provided by array indices. C allows for the explicit declaration of pointers to objects (including pointers to pointers, etc.) and extraction of the machine address of objects, and types of objects may be explicitly ignored. This flexibility helps in allowing C programs to be used in place of assembler code, but means that a valid C compiler may provide little protection against programming errors.

C names variables as strings of letters and digits, beginning with a letter, but, unlike FORTRAN, accepts both upper- and lower-case letters, and (in most dialects) treats them as distinct. Only the first eight characters of a C variable name are significant in some dialects.

C describes the objects it manipulates in terms of "storage class" and type. Storage class declarations allow the programmer to direct that a variable will claim storage only during the invocation of the block that uses it ("automatic"), or that the variable will have a life extending past that of any particular invocation of the block using it ("static"), or that the variable has a life external to the entire program ("external"). Variables may also be declared as being best stored in fast machine registers, if possible ("register").

The types are

1. short int, int, long int. The representation of three integer types, intended to provide access to the integer sizes natural to the machine.
2. unsigned int. The representation of an integer without a sign bit, obeying the arithmetic rules of "2's complement arithmetic" commonly used for manipulating machine addresses.
3. float. The representation of a real number. The format of type float constants is similar to that used in FORTRAN, except that all such constants are double precision.
4. double. The representation of a possibly higher precision real number than provided by type float.
5. char. The representation of characters appropriate to the machine. A character constant is given as a single character in single quote marks or by quoting special sequences starting with a backslash:

\n	newline (or line-feed)
\t	horizontal tab
\b	backspace
\r	carriage return
\f	form feed
\\	backslash
\'	single quote
\"	double quote
\nnn	the bit pattern given by the 1–3 octal digits nnn.

Character strings are given as "array of char" strings in double quote marks. A zero character ('\0') is appended to string constants to help programs scan for the end of a string.

C also provides an enumerated data type, in the style of PASCAL (see below).

C has FORTRAN- and ALGOL-like expression evaluation, with the addition of a combinedassignment and increment or decrement (a concept from ALGOL-68). The operator "=" is used for assignment. It is just another operator in C, not a special statement as in FORTRAN or PASCAL. The form "xx += 1" is the same as "xx = xx + 1", and "xx −= 1" is the same as "xx = xx −1". Other appropriate operators may be combined with assignment in the same way.

Another special feature of C is the use of "++xx" to mean increment xx before using it, and "xx++" to mean return the value of xx, and then increment it.

C has an even more complex order of precedence for the actions of its operators than does FORTRAN. Parentheses are recommended.

The operators available in C are

1. Unary operators. Indirection ("*") to retrieve the value pointed to by the object, address of ("&") to obtain a pointer to the object, arithmetic negation ("−"), logical negation ("!"), ones' complement ("~"), increment ("++"), decrement ("−−"), type cast (specified by a type-name in parentheses), size in bytes ("sizeof").
2. Arithmetic operators. The operator "*" is used for multiplication as in FORTRAN; the operator "/" is used for division as in FORTRAN; the operator "%" is used to get the remainder; the operator "+" indicates addition; the operator "−" indicates subtraction.
3. Shift operators. Left shift with zero fill ("<<"), right shift (">>"). The right shift has zero fill for unsigned expressions, but may be an arithmetic right shift for signed expressions.
4. Relational operators. Less than ("<"), greater than (">"), less than or equal to ("<="), greater than or equal to (">="), equal to ("=="), not equal to ("!=").
5. Bit-by-bit operations. And ("&"), exclusive or ("^"), inclusive or ("|").
6. Logical operations. And ("&&"), or ("||").
7. Conditionals. The question mark and colon are used to form an if-then-else operation, as in

```
e1 ? e2 : e3
```

   which returns e2 if e1 is nonzero (i.e., true), and returns e3 otherwise.
8. Assignment operations. Simple assignment ("="), other operations (+, −, *, /, %, >>, <<, &, ^ , |) combined with assignment in the form "op"= [e.g., x1+=x2 is equivalent to x1 = (x1) + x2].
9. Comma operation. The comma causes left-to-right evaluation of its arguments and returns the rightmost value.

Operators are applied in the following order of precedence (highest on the list first):

unary operations: * & − ! ~ ++ −− type-cast sizeof

multiplicative operations: * / %

additive operations: + −

shift operations: << >>

ordered relational operations: < > <= >=

equality relational operations: == !=

bit-by-bit and: &

bit-by-bit exclusive or: ^

bit-by-bit inclusive or: |
logical and: &&

logical or: ||

conditional: ... ? ... : ...

assignment = += −= *= /= %= >>= <<= &= ^= |=

comma

Control of the sequence of execution is provided by the following statements allowing compound statements, grouped by braces "{" and "}" with declarations private to the block of statements given after the opening brace, and statements similar to the FORTRAN "GOTO", "LOGICAL IF", and "DO", in this case "goto", "if", and "while", "do...while", and "for" statements.

Additional statements that improve the clarity of C code over FORTRAN in some cases are the following:

1. The "switch" statement. This statement executes one of several statements selected by the value of an expression. It is of the form

```
switch(expression){
  case c1 : s1;
  case c2 : s2;
       ...
  case cn : sn;
  default : sd
};
```

where c1, c2, ..., cn are integer constant expressions. The expression is evaluated and control transferred to the statement listed after the matching constant expression, or to the default if no match is made.

2. The "break" statement. This statement terminates the innermost repeated execution statement or switch statement, avoiding the need for some goto statements.
3. The "continue" statement. This statement ends the current pass of the innermost repeated execution statement, but allows subsequent passes, if any.
4. The "return" statement. This statement is used to return a value from a function and continue execution in the statement where the call was made.

C includes a preprocessor that translates lines beginning with the symbol "#" to allow replacement of identifiers by strings ("#define"), inclusion of lines from other source files ("#include"), and conditional compilation of lines ("#if", "#ifdef", "#ifndef").

Because of its intimate connection with major operating systems development, there is a very extensive library of functions for use with C programs for file manipulations and other useful activities. The libraries used in support of other languages often are written in C.

For more on the C language, see Kernighan and Ritchie (1978).

3.3 ALGOL and PASCAL

ALGOL is a FORTRAN-like language with a less card-oriented, more readable syntax. The major difference from FORTRAN is structuring into nested blocks, allowing a hierarchy of procedure declarations, and a more rigid requirement that the types of all variables be specified, rather than allowing the default integer and real declarations of FORTRAN. The current descendant of ALGOL in heaviest use is PASCAL.

Let us first look briefly at ALGOL syntax. A program is composed of statements terminated by semicolons, organized into at least one BEGIN-END block:

```
BEGIN
   statements declaring the types of variables
   executable statements and procedures
   comments
END
```

Procedures follow the same structure as the outer level after a statement of the form

```
PROCEDURE name;
```

immediately followed by declarations of variables to be used only in that procedure.

On any level the types of the objects to be used are declared by statements beginning "REAL," "INTEGER," or "BOOLEAN," possibly modified by the word "ARRAY" to indicate an array. In FORTRAN each array index implicitly starts with 1. In C indexing starts with 0. In ALGOL, a lower and an upper value for each index are given to allow indexing to start from other values.

The actions that can be taken on these objects are similar to those allowed in FORTRAN, but slightly different symbols are used, depending on the characters available on the particular computer. The FORTRAN "**" for exponentiation can be replaced by an up-arrow (often printing as "^"), and the relational operators by their usual mathematical symbols; the assignment operator is indicated by ":=" to distinguish it from the test for equality. Expression evaluation is similar in algebraic style.

Labels are symbolic, rather than numeric as in FORTRAN, and delimited by a ":", so that no special field needs to be reserved for them. There are the equivalent of the FORTRAN logical IF, the block IF, the GOTO, and the computed GOTO in ALGOL.

Only minimal file handling was specified in the language and varied from system to system until later languages, such as PASCAL.

PASCAL (see Jensen and Wirth, 1974; Wilson and Addyman, 1982) is sometimes referred to as "FORTRAN with semicolons," mixing some of the style of FORTRAN with that of ALGOL. Programs are written as sequences of statements in an imperative style, and formulas and equations translate into PASCAL similarly to the way it is done in FORTRAN and ALGOL. However, PASCAL provides a more natural set of data structures and control structures than was available in FORTRAN at the time PASCAL was introduced, which allowed the writing of cleaner, more comprehensible code, especially when dealing with problems that involved more than simple iteration of the evaluation of mathematical formulas.

The objects that can be used in PASCAL are constants or variables, and variables must have a "type," i.e., the attributes of the values and the legitimate range of values that may be assumed by a variable must be specified. The language starts by defining "simple" types, then provides "structure" types that may be built out of simple types, and "pointer" types that facilitate linking of data together. The four simple types are as follows:

integer-type. A subset of the whole numbers (..., −3, −2, −1, 0, 1, 2, ...).

real-type. A subset of the real numbers (such as 3.141 59, −6 483 221., 0.000 03, etc.).

char-type. The characters that can be handled on that machine, including the upper- and lowercase letters, and the decimal digits, with alphabetic and numeric ordering preserved.

Boolean-type. The logical values "true" and "false."

Except for the real-type, the simple types can all be ordered by integer values, and are called "ordinal-types."

The user can create new types. One can simply enumerate the values that may be taken on by a new type in their appropriate ordering ("enumerated-types"), or pick a range of values out of an existing type ("subrange-types"), or make more complex structures out of existing types. Structure-types may be packed for storage efficiency, or unpacked.

The possible "structure-types" are as follows:

array-type. Vectors ("tuples") of existing types specified by an index set. Because the elements of an array-type may themselves be of array type, matrices may be represented, with the usual comma notation to separate the indices.

record-type. A structure consisting of groups of named fields, where (unlike array elements, each of which must be of the same type) fields may be of different types. This ability to mix types allows one to, for example, create strings of characters with a field of integer-type giving the length and a field or array of char-type holding the characters. Unlike arrays, however, the value of a field identifier cannot be computed. It is just a name. Different record structures ("variants") may be used in a given record-type, determined by the value of a tag field used to select the variant to be used.

set-type. A set composed of elements all of the same type (the "base-type"), which must be an ordinal type. A PASCAL implementation imposes a limit on the cardinality of the base type, usually somewhere between 48 and 256.

file-type. A structure consisting of a sequence of values of a given component type. Such structures provide PASCAL with an input-output mechanism.

In order to facilitate working with lists that may grow and shrink, pointer types are defined:

pointer-type: Either "nil" (i.e., not pointing to anything) or having a value that identifies (points to) data of a type (the "domain-type") associated with the pointer.

This rich structure of types allows the user to build up complex data structures as the fundamental objects of the language. Objects and actions are used to create expressions. PASCAL does not have the same finely detailed precedence of actions seen in FORTRAN, and requires more use of parentheses to avoid ambiguities. The objects and expressions are used in invocations of functions (that return values) and procedures (that do not return values) and in assignment statements. Control over the sequence of execution of statements is provided by a variety of control structures, similar to those discussed for FORTRAN and C. The language allows portions of code and appropriate data structure to be packaged as procedures and functions, and for them to recursively call themselves.

A PASCAL program to add ten numbers and print the result might be written as:

```
program addnum (input,output);
var myinput,count,sum:integer;
begin
  sum := 0;
  for count := 1 to 10 do
  begin
    readln (myinput);
    sum := sum + myinput;
  end;
   writeln (sum)
end.
```

As with our other examples of this problem, we have ignored the niceties of what the program could (or should) do if there are not ten numbers to read, or if there is an error in reading.

For more on PASCAL, see Wilson and Addyman (1982) and Feuer and Gehani (1982).

3.4 Libraries and Language Extensions

Each application of computers and computer languages tends to develop a specialized set of language extensions and libraries appropriate to problems commonly encountered. There are extensive and well-tested libraries of mathematical routines for solving linear equations, differential equations, etc. By imposing a style of programming, of use of data structures, and file formats, these libraries extend the base languages into jargons appropriate to their applications. To pick one example among many, consider the "Basic Linear Algebra Subprograms" (BLAS) by Dongarra *et al.* (1988). This package provides routines for the manipulation of matrices and vectors, using a clear consistent style. The first letter of a routine specifies the precision ("S" for single precision real, "D" for double precision, etc.). The next two letters classify the kind of matrices being handled ("GE" for general, "HE" for Hermitian, "TR" for triangular, etc.), and the next two the operation ("MV" for matrix-vector product, etc.). Storage conventions are specified for triangular matrices.

By adhering to such conventions, the user not only gains the ability to use the routines in the library involved, but also the ability more efficiently to produce new programs that achieve clarity and maintainability by following known conventions; i.e., by speaking a known language.

4. LANGUAGES FOR THE LABORATORY ENVIRONMENT

Computers have become an integral part of the laboratory environment. They control the operation of instruments, move the data from instruments to storage, analyze the data, compare it to models, display it, and archive it. There is a wide range of specialized languages, packages, and systems for this purpose. In some cases the computer aspects are so well integrated with a set of instruments that the user need not be concerned with programming. The system functions as a black box. In other cases, detailed programming is required. In the latter cases, the choice of an appropriate language may be forced by considerations of what languages, if any, may be available for the computers involved. However, when the choice is unconstrained by such questions, typical choices are FORTRAN, PASCAL, C, Assembler, BASIC, and FORTH.

What drives such choices are questions of time—either of the computer or of the person using it. Compared to the demands of some modern experiment designs, computers are slow and can have difficulty moving all the data involved without falling seriously behind. In such cases, highly efficient code, or at least code of highly predictable timing, may be required. Languages oriented toward the automatic management of complex data structures can place demands on the computer for activities such as garbage collection, for which there simply may not be time. In the most extreme cases, use of C or an assembler that can give the maximum control over use of machine resources may be required. Since FORTRAN has a direct and static mapping of its data structures to machine implementation, and has benefitted from decades of effort at optimization of the code it produces, it can often provide almost the same efficiency. PASCAL has been used as a cleaner, simpler language for such applications, but in time-critical PASCAL work has not been as popular as mixtures of FORTRAN with C and assembler.

If, however, the primary consideration is time of the person, then interpretive languages such as BASIC and FORTH become attractive. The speed lost in interpretation with BASIC can be recovered by taking the final version and compiling it. FORTH manages to achieve good speeds by providing what is called threaded code (see Sec. 4.2) and by allowing embedded assembler code use.

The creation of device control code in FORTRAN or PASCAL is difficult because the languages themselves do not provide intimate access to hardware, nor is the timing of code execution easily predicted. They also do not deal directly with asynchronous parallel processes. They do, however, provide a comfortable environment for the creation of data structures, management of external files, and numeric data analysis. Thus a common structure of laboratory code is an outer layer of control logic in FORTRAN or PASCAL, using time-critical services provided by C or assembler subroutines.

Efficient communication among the pieces is essential. For large streams of data, the structure most commonly used is the "circular buffer" or "circular queue." In this structure, two pointers are used, each advancing from the bottom of the structure to the top, and then returning to the bottom to scan the structure again. One of these pointers designates the next location into which data are to be stored, and the other the next location from which data are to be taken. As the pointers chase each other, the gap between them may grow and shrink to deal with the vagaries of timing of the arrival of data and its processing, thereby compensating for the unknown timing of the higher-level language code.

When timing is less critical or ease of modification is the main issue, an interpretive language such as BASIC or FORTH may be used for laboratory work.

4.1 BASIC

There are many dialects of BASIC. The language was developed by Kemeny and Kurtz as a simplified FORTRAN and ALGOL derivative appropriate for students. It is most often used as an interpretive language on time-sharing systems and small computers. Programs consist of sequences of numbered lines. The variables used may be restricted to single-letter names, but it is more common to allow at least a letter and a digit or, in most recent versions, full strings of letters and digits starting with a letter. The types of variables may be either type real or type string, and most current versions allow additional types. The types are usually designated by an extra symbol appended to the name of the variable:

real single precision	!	(or nothing as the default)
integer	%	
double-precision real	#	
string	$	
long integer	&	(on some machines)

Arrays are indicated by a variable name followed by subscript indices in parentheses, and are declared by a "DIM" statement.

Expression evaluation is FORTRAN-like, using the following operations:

1. Arithmetic operations. Addition ("+"), subtraction ("−"), multiplication ("*"), division ("/"), exponentiation ("^").
2. Relational operations. Less than ("<"), less than or equal to ("<="), greater than (">"), greater than or equal to ("=>"), equal to ("="), not equal to ("<>").
3. Logical operations. "AND", "OR", "NOT".

The flow of program control is keyed to the numbers put on each line:

The "GOTO" statement transfers control to the designated line number.

The "GOSUB" statement transfers control to the designated line number. That line and following lines are executed as a subroutine to be executed until a "RETURN" statement. The "RETURN" statement transfers control back to the place immediately after the "GOSUB".

The "FOR" statement causes repeated execution of the following statements in statement number order until a matching "NEXT" statement.

The "IF" statement, of the form "IF expression THEN statement" or "IF expression THEN statement ELSE statement," evaluates the logical expression and executes the statement after the "THEN" if the expression is true.

The assignment statement is as in FORTRAN, except some versions require the word "LET" before the statement.

Files are manipulated by INPUT and PRINT statements.

For device control, many versions of BASIC add an "INP" statement to read device registers and an "OUT" statement to store new values into device registers.

In BASIC the example of adding 10 numbers might read

```
100  SUM = 0
110  FOR COUNT%= 1 TO 10
120     INPUT MYINP
130     SUM = SUM + MYINP
140  NEXT COUNT%
150  PRINT SUM
160  END
```

There are compiled, batch versions of BASIC, some of which avoid the need for statement numbers on every line and which allow the use of symbolic statement labels.

For more on BASIC, see Nolan (1974).

4.2 FORTH

FORTH is a simple stack-oriented, postfix notation language, with a highly structured programming style oriented toward use of small computers. A typical FORTH program is built up from function definitions that are used to create higher-level function definitions. The highest level created is invoked as the solution to the problem. Most implementations of the language make use of a programming technique called "threaded code," which is particularly effective in achieving a compromise between the ease of modification of an interpretive language, and the efficiency of execution of a compiled language.

In threaded code, we create a virtual machine for our application as a set of subroutine calls, and use lists of those calls as the instructions in the virtual machine. Suppose we start with a machine that has only integer arithmetic. Let us define a routine to do floating-point addition, and store it at, say, location 100, and let us define a routine to print a floating-point number and store it at location 200. To keep our machine simple, let us address all the objects we care about by a pointer, called a "stack pointer," which acts like a spring-loaded pile of plates at a buffet. We can only see the top item, the item to which we currently point. We can remove that item ("pop" it off the stack) by changing the pointer by one data object, and place a new item on top ("push" it onto the stack) by changing the pointer in the other direction. Then we can keep our new language simple, by having the addition routine add the two items at the top of the stack, removing both and replacing them by the sum, and having the print routine print what is on top of the stack. A routine to add and print then would just be the sequence 100, 200. This is a compact representation of a complex action. This routine can itself be stored and used as an extension to the language.

For more on FORTH, see Brodie (1981).

5. LANGUAGES FOR GRAPHICS

Computers are a useful tool for capturing, drawing, and modifying images. Their use in such applications increases as raw computing power and storage capacity increase, allowing manipulation of increasingly complex images.

Languages for computer graphics are implemented as extensions to more general languages. The objects to be manipulated are images and the pieces of images, such as lines and circles, as well as the devices that draw and display images, such as pens and graphics screens. A language for graphics must deal both with what is being drawn and the way in which it is being drawn.

The most elementary view is that of a pen being dragged along a piece of paper, as in the language LOGO (Abelson, 1982). The paradigm in LOGO is that of a turtle pointed in a direction, carrying a pen, which may be up or down. The pen is placed down by the command "PENDOWN" and raised by the command "PENUP". A stroke is made in the current direction or its reverse by the commands "FORWARD nnn" and "BACK nnn", where nnn is the length of the stroke. The direction of strokes is changed by "RIGHT ddd" and "LEFT ddd", which specify a rotation in degrees.

Similar minimal graphics can and have been added as libraries or language extensions of most procedural languages, providing at least a vector-drawing capability. However, management of images as objects is simplified when issues of scaling and presentation location are separated from the object definitions themselves by the establishment of windows and viewports. Three-dimensional graphics in particular benefits from separation of the definition of the object from the mechanism of viewing the object, so that orientation, hidden-line removal, ray tracing, and other considerations in looking at the object do not require redefinition of the object. There are many contending approaches to presentation of images, including GKS and PHIGS, with rapid changes being driven by rapid advances in the ability of computers to present increasingly detailed images in real time.

For more information, see COMPUTER GRAPHICS.

6. LANGUAGES FOR DATA RETRIEVAL

Computers manage information. They provide the tools to scan large amounts of information and extract what is needed. Data retrieval works with objects that are identified by their contents, rather than by their physical location. The contents may include explicit keys to help in the search or may stand by themselves.

The paradigm now most used for database languages is one in which data are considered as a set of tables, the columns of which identify attributes of data, and the rows of which are the data items of interest. Some column, or set of columns, serves as the key to identify uniquely the data items to be retrieved.

The operators used are union (combining the rows of two tables with matching columns to form one with the combined information from both), intersection (combining to retain only the common information from both), difference (combining to obtain information in the first table that is not in the second), Cartesian product (combining tables with different columns to make all possible combinations), select (extracting selected rows from a table), project (extracting selected columns from a table), inner join (combining tables by matching entries in a common column), outer join (like inner join, but including rows with no match), and divide (extracting particular rows and columns on the basis of a match in other columns).

A popular language for data retrieval is SQL (Structured Query Language). The typical command in this language has the form

SELECT	the names of columns
FROM	the name of a table
WHERE	the criteria to be satisfied in selecting
ORDER BY	the order of presentation of the columns

The criteria may include relational, arithmetic, and pattern-matching operators.

There are some difficulties in applying this paradigm to data that have search criteria based on considerations other than positions of values within tables. For example, a search on the shape of particular images, or on the symmetries of lattices involving experimental error, may strain this paradigm, and may require the explicit creation of inverted indices organized on the basis of the anticipated search.

For more information, see COMPUTER DATA BASES.

7. SUMMARY

In order to save the effort of writing a new and different program for each machine to solve the same problems, to make computers accessible to more people, and to increase the chance of writing instructions for computers correctly, many programming languages for computers have been created, languages that express the actions to be performed in terms more comprehensible to people, and in ways that allow the same programs to be used on many different types of computers. Some languages are close in style to the operation of computers, consisting of sequences of actions to be taken on objects. Such a style leads to efficient translation of a problem specification into the internal language of a computer, but may force a strained interpretation of the original problem, increasing the chances of programming errors, and increasing program maintenance costs. To reflect more naturally the demands of the problems to be solved, rather than the demands of computers, languages using other styles of programming have been developed: object-oriented, functional, and logic programming. These offer promise of increased productivity for appropriate problems, but for the classic problems of theoretical and experimental physics, FORTRAN and its statement-oriented, imperative relatives predominate.

ACKNOWLEDGMENTS

We wish to thank Frances C. Bernstein, Daniel J. Bernstein, and Lawrence C. Andrews for their helpful comments and suggestions.

GLOSSARY

Assembler: A translator for a symbolic representation of a computer machine language.

Compiler: A translator for a computer programming language that converts an entire program, or major segments of it, as a unit to machine language.

Constant: Datum that does not change.

Function: A self-contained portion of code that returns a single value computed from the parameters given in invoking the function.

Functional Programming: Programming in terms of function evaluations.

Imperative Programming: Programming in terms of a sequence of actions to be taken.

Infix Notation: Programming notation in which an operator is given between the objects upon which it acts.

Instruction: An elementary action that a computer may take, or that a computer programming language defines.

Interpreter: A translator for a computer programming language that converts small portions of a program to machine language immediately.

Logic Programming: Programming in terms of the relationships among objects.

Main Program: The outermost layer of code, which starts and controls the execution of code to solve a problem. It may invoke other routines to solve the problem, in which case control would eventually normally return to the main program, or it may pass on control to some other main program, without the expectation of the return of control.

Object-Oriented Programming: Programming in terms of objects that take actions on the basis of messages passed to them.

Operator: An elementary action on objects defined in a computer language. If there is only one object, the operator is called "unary"; if there are two, "binary," etc.

Order: An elementary action a computer may take; an instruction.

Prefix Notation: Programming notation in which an operator is given before the objects upon which it acts.

Procedure: A routine. See below.

Postfix Notation: Programming notation in which an operator is given after the objects upon which it acts.

Routine: A self-contained portion of code used by other code. It may be a main program, a function returning a value, or a subroutine performing an arbitrary calculation. It may invoke other routines.

Side Effect: A nonobvious change to the state of data structures resulting from the invocation of a function, subroutine, or other procedure.

Statement: The specification of an action to be taken (an executable statement) or the environment (a declaration) in which actions are to be taken in a programming language. It is usually built upon objects and actions, and used in turn to build routines.

Subprogram: A subroutine. See below.

Subroutine: A self-contained portion of code that performs a calculation that may depend on parameters given in invoking the function.

Variable: An identifier for data that may change in the course of execution of a program.

INTRODUCTION

The description of the structure and continuing growth of a new, rapidly growing science, technology, and industry such as computer usage is difficult within an encyclopedia's pages. These three elements interact within an area that is oriented to

1. intellectual effort,
2. information handling over wide geographic areas,
3. computation, and
4. equipment design and sale.

The reader, like the users of such machines, faces a rush of technological and economic details that continuously changes. A static description here will surely be altered continuously in the future. This article will, however, attempt to emphasize those elements which will remain invariant or change slowly as time progresses.

Classically, electronic computers may be classified as analog, using continuous voltages to represent (usually numerically encoded) data, and digital, in which analog pulses are used to represent bits (binary digits). Each bit can be assigned alternative values of 0 or 1 (absence or presence of a pulse). A string of bits can be used to represent many different informational elements by encoding such elements into so-called data structures. The basic element in such a data structure is usually an 8-bit byte or a 32-bit word.

These can be used to represent integers and floating-point approximations to real numbers. In addition, strings of bytes or words can be used to represent alphabetic and other symbolic characters, as well as pictures. With further interconnection into sets of strings, one can represent sentences, equations, and the internal graphical structure of pictures as well. Video images can be represented by digital numerical pixels, or picture elements. Much of computer science involves theory and practice of manipulation and transformation of such elements.

In this discussion, we will concentrate on electronic stored-program digital computers, that class which has gained dominance in modern society. Through success in a competitive market place of vendors, programmers, and users, along with strong support from governmental organizations, digital computers as described herein are at present dominant in their range of applications. Several possible replacement technologies will be mentioned only as a possible prediction of future directions of both research, development, and production.

Digital computers are complex switching devices, often generically labeled hardware, operating upon

1. data, furnished from outside the computers, by either humans or other machines, and
2. programs, labeled software, created and furnished, up until now, outside the computers, almost completely by human programmers.

Data input into computers must be collected by hand or by machine, and communicated on paper or by electronics. Data collection and assemblage must be considered as outside the range of this discussion. Data output is on paper, on cathode-ray tube or alternative electronic presentation devices, or by audio sounds or video, television-like graphical images.

Programming is now, in most cases, a labor-intensive human-performed operation. The process is marked by possible errors in the finished product. In addition, one needs continuing so-called maintenance of the created sequences of instructions over time, since the program itself may attempt to solve a real-world changing problem.

Programming in the most common case consists of the generation of a series of control operations. These, intermixed with data transformation operations, direct the hardware through a complex path. The end result of the process is transformation of the input data to produce output. The output data are required to satisfy some specified goal—to yield the solution of the problem.

In this survey a top-down approach will be presented, which emphasizes the fundamental structure of the elaborate computational system that has been developed.

1. PARADIGMS FOR COMPUTER USAGE

Because of the interposition of elaborate programs between the user and the computer itself, many users interact using paradigms in which the computer is disguised as a special purpose device, or machine. Among the external interfaces that have been set up by which users may interact with computers are the following:

1. The classical file cabinet, with files which can be viewed by "popping them up" on a cathode-ray tube (CRT) screen. Various "windows" operating systems allow the user to point at or name the wanted files and act upon them, opening and closing windows into different sets of text and data.
2. The classical matrix-like spread sheet, in which the user can name or point at entries, describe them in terms of equations, enter parameters, and operate on rows, columns, individual elements, or the entire matrix, with the computer automatically updating the entries.
3. The classical drafting procedure, in which the CRT face acts like the drawing board, and the user operates on various lines and surfaces with various pseudodrawing tools, including simulated pens, paint brushes, erasers, etc., actually consisting of electronically interacting artifacts. Such devices can be used to animate synthetic pictures in time.
4. The classical video screen, with operations to merge, delete, overwrite, recolor, etc., frames from external sources.
5. The classical notebook, with pen-like devices being used to point to and write onto an interactive representation, which changes and operates the computer inside a notebook-sized container.
6. The classical library card catalog, where the user can search for the desired information, which is presented on the CRT screen. Such information systems (with or without the actual card image) are called databases. As yet the card paradigm is incomplete, in that more often special languages are used to search out the information.
7. The classical typewriter, extended to the word-processor and desktop print shop, where copy is edited on the CRT face and then output using various sized type fonts intermixed with drawings and photograph, on laser printers.
8. The classical teletype system, extended into electronic mail or e-mail, such that users with keyboards can mail text or other information, including fax-like material, to other computer users on a worldwide net.
9. The classical bulletin board in which users, using e-mail, can post documents of their own choosing in a formal or informal exchange of information throughout a group.
10. Cooperative exchange of equipment, in which one user is able, by means of network interconnection of computers, to use programs and equipment located elsewhere geographically or administratively.

Still generally unavailable are widespread voice-mail integration of the telephone network paradigm into these systems, or video conferencing. However, as technology provides wider communications bandwidths, these appear to be coming. So-called video-tex systems, mainly in France and elsewhere overseas, have provided rudimentary picture-information network systems, like libraries or information desks. It has thus become apparent that almost any human information behavior, network, or system is a possible paradigmatic model for computer application.

Many of these paradigms have made it easy, as time went on, for nonusers of computers to learn to solve a restricted but important class of their own problems. However, it is still very difficult, in many cases, to move spread sheets onto video screens, images onto e-mail, etc., pictures and graphs into reports. This interconnection of the paradigmatic systems remains a partially achieved task.

Each time a paradigm becomes useful and important, it may need to be connected to previous such structures, and the sets of these interfaces grow markedly, often geometrically. Behind these user–interface paradigms, of course, flows a history that deals with actual equipment and the complicated programs that run upon it. As these change, the implementation of the paradigms for users must also, in many cases, be reworked.

2. HISTORY OF COMPUTER DEVELOPMENT

Historically, computer equipment arose from the vacuum tube technology of World War II radar. At that time fabrication was both expensive and unreliable. Assembly of individual discrete parts into large one-of-a-kind systems required detailed handwork (such as wiring) by human beings, which raised costs and produced many fabrication errors. These became known as hardware "bugs"; the term was carried over into software or programming.

The first electronic digital computer to be publicly operational was the Electronic Numerical Integrator and Calculator (ENIAC) (shown in Fig. 1), at the University of Pennsylvania in 1946. Other early systems were soon operational in laboratories of U.S. security agencies, the Atomic Energy Commission, and the National Bureau of Standards. Research projects were started in many British, Continental, and Soviet governmental laboratories, and in other universities in the U. S., Canada, Great Britain, and elsewhere. By the mid-1950s commercial equipments, pioneered by such firms as Univac, IBM, NCR, and others in the U.S., and Ferranti, ICL, Bull, Siemens, and others on the Continent, began to make their appearance in extensions of problem solutions previously attempted with classical punched-card equipment.

Costs of these electronic systems began to decrease and reliability to improve in the 1960s. The use of discrete transistors as the switching devices still required them to be interconnected by hand labor at high cost. Only after the labor-intensive circuitry interconnection methods for such devices were replaced by printed circuits and circuit boards produced by machine operations did the cost of digital computer hardware begin to fall.

Mass production of computers came only after 1970 with the invention and development of the integrated circuit (IC). This combined automated production of transistors and wiring on the same silicon base (or substrate). Using photolithographic-like technology, firms such as Texas Instruments, Intel, Motorola, and their Japanese competitors NEC, Toshiba, and others began to produce small versions of centralized computers.

These so-called microprocessors were produced using a different kind of high technology assembly line, in which solid-state physics and chemistry replaced mechanics as the underlying science guiding design and fabrication. This mass production of the central kernel of the digital computer had been paralleled by mass reproduction of software and data input, using, first, punched cards, then magnetic tape and the portable "floppy diskette" of magnetic material. The remaining economic bottleneck to truly efficient mass production and distribution remained in the design and fabrication start-up costs for both equipment and programs.

Design costs for integrated circuits began to drop with the development of computer-aided design (CAD) tools for integrated circuits. As quantities of an individual IC unit, or chip, began to increase, fabrication costs came down. Analogous design techniques for programs, called computer-aided software engineering (CASE), have not yet proved as successful. With both techniques, beginning about 1980, a mass market for both dealer and direct-mail sale of desktop computers began.

Continuing improvements were made in the distributed software. Programs are now sold using mass-published and mass-marketed copies, at relatively low costs with respect to the hardware, on small, inexpensive floppy diskettes. These fabrication and distribution advances now make individual computer interaction a potential for every technologically sophisticated worker in the modern

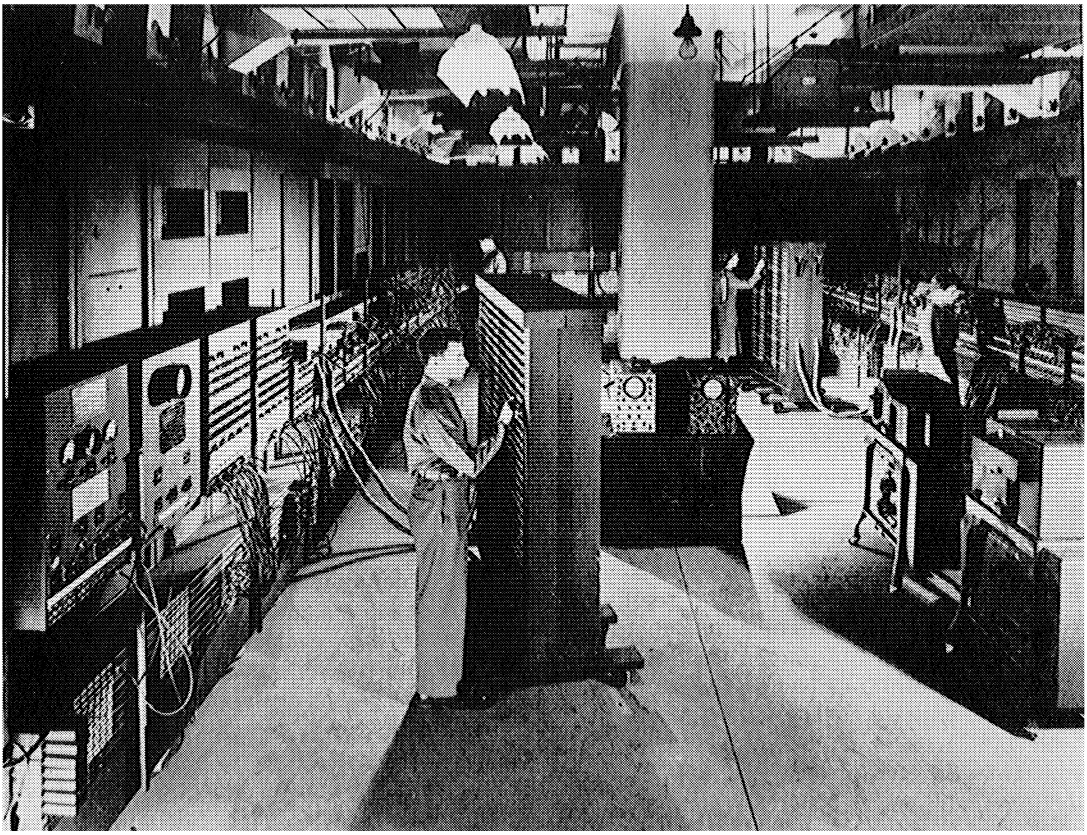

FIG. 1. The electronic numerical integrator and calculator (ENIAC), first designed and completed in 1946 at the Moore School of Electrical Engineering of the University of Pennsylvania, and used at the Ballistic Research Laboratories of the Aberdeen Proving Ground in the post-World War II era. (Courtesy of Moore School of Electrical Engineering, University of Pennsylvania.)

world, and for many for whom their use will be routinely integrated into their jobs.

2.1 General Structure of Computer Usage

Users should, it appears, view solution of problems of any sort in light of the entire computational system which has become economically available. Such problems may be computational or data processing, real-time control, or database searching. A useful model is to view the process of computation from the top down, or outside in. One starts with the problem and works inward towards program and computer, rather than starting with the detailed technology of the system and working outward.

Of primary importance is the problem, or class of problems, to be solved. Some type of applications program, a solution procedure, must be selected by the user. Such a program is the highest level performer in the hierarchy of program, operating system, and computer. The program (or programs) may have already been in operation, available for purchase, or may need to be written from the beginning. The program must interact with at least two other systems elements:

1. an operating system, or control program that performs the housekeeping for the applications program, on
2. a specific computer, or integrated system of computers, that accepts the language of the applications program, as integrated with the operating system program.

2.1.1 Operating System and Language Interactions. The operating system serves as a buffer between the applications program and the actual machine hardware, the computer itself. It manages the specific idiosyncracies of the input–output elements of the computer, and of the secondary mass storage devices such as magnetic disks. The applications program communicates with the operating system in a language which that system can interpret. In general, the applications program does not have to communicate directly with the hardware. For this reason, an operating system has the potential of offering a unique interface to many applications programs. Yet at the same time it may be tailored to control the hardware of many different computer versions.

Similarly, the language in which an applications program is written may be passed through a compiler–translator which outputs machine code for a particular machine. Different versions of this compiler–translator may produce resulting machine codes that are compatible with different machine hardware. Both operating systems and compiler–translators offer the possibility for the introduction of standardization, in which the programming languages, operating systems languages, or actual computer hardware is defined in a standard fashion. This allows ease of use, design, and manufacture in the interaction between these various elements.

The potential user, having decided on an applications program to solve the proposed problem, must decide on an operating system to accept the applications program, and a computer itself to accept the operating system. In many cases, the latter two are already decided upon as a result of previous analyses and decisions. This may restrict the available applications programs for solution purposes.

In some cases, if no solutions program exists as yet, or none can be obtained or modified to suit the need, someone—user or applications programmer—must write a program to interact with the operating system and at the same time solve the problem. In today's complicated computational systems, a professional programmer will most often be needed here, although for certain problems, so-called higher-level languages or graphical interfaces may allow problem-oriented users to create programs.

2.2 Changes in System Technology Simplifying Usage

In the early 1970s, computers were mainly used through the good offices of professional programmers, who wrote programs under the guidance of noncomputer specialists, fed in data, and monitored and produced the results. Three technological advances changed this situation: time sharing, integrated circuits and cheaper memory systems, and interactive graphical computing.

1. "Time sharing" was developed as a method by which many terminals (CRTs with circuitry) were connected to a large central main-frame computer, and shared its machine cycles among them. These terminals were originally mechanical teletypes, later electronic displays with keyboards. The central computer responded to individual users at these terminals so that in appearance, at least, each user seemed to have control of the central machine. The latter was actually sharing its operation sequences among the many terminals. This change allowed (particularly important) interactive usage of central machines from keyboards at remote sites. Such interactive time sharing included both computing and programming from the terminals. This sped up a previously much slower cycle based on punched cards, not keyboard strokes, as input. Time sharing also required design and development of networks connected between terminals and computers. Terminals themselves soon began to contain microprocessors, and thus became smaller local computers. The original time-sharing networks became computer-to-computer networks, expanding to many-computer interconnections called local area networks (LANs).
2. The development of the integrated circuit described above, along with the parallel development of computer-aided design, began to produce small digital computers. Such personal computers (PCs) based on these microprocessors became available for a few thousand dollars. Speeds continued to increase with decrease in size of the integrated microcircuits. Costs and size of the resulting computers decreased. The combined functions of the resulting computers also increased markedly. Low-cost, small-

size computers (see Fig. 2) began to appear not only in homes but also in small and large businesses. These—combined into networks—began to replace or extend the original far more costly main frames, as the physically large and more expensive original designs were called. By 1991, microprocessor chips with half a million to a million transistors were being produced in large quantities. These were sold at lower and lower costs, with former large-size circuitry and interconnections moving onto the chips themselves. At the same time, the cost of computer memory, mainly dynamic random access memory (DRAM), was coming down because of decreased transistor and wiring sizes on the IC chips. The result was the production and sale of large numbers of these cheaper microcomputers, which could be used in the same way as the time-sharing terminal, but without the need for the central main-frame computer. The sharp distinction between large main-frame computer and microcomputer began to blur with the expansion of personal computer performance and the development of so-called "work stations" with power equivalent to that of previous large computers. It is possible as of 1992 to obtain a computer that can comfortably be held on one's lap, yet performs at levels comparable to those of desktop computers (see Fig. 3).

3. Interactive graphical computing was bolstered by addition of electronic screen-pointing devices for the cathode-ray tube terminal. The "mouse," first developed by Xerox, was commercialized successfully by the firm Apple Computer. Its availability allowed the Macintosh computer to remain a firm competitor of IBM's ubiquitous PC as both began to enter the offices of major businesses internationally. Only after so-called windowing systems began to appear on the work stations and PC systems (about 1990) did they begin to compete in effective nonprogrammer user interaction. Hardware was thus combined with elaborate software, to produce what became known as graphical user interfaces (GUIs) (Sec. 4.3.3.2). These began to replace previous programmer-oriented, rather than user-oriented, interactive interfaces. Newer systems thus place the emphasis on making the interaction between user and computer less complex and more "user friendly." The paradigms for users mentioned above have sped up the so-called learning curve on the part of novice and nonprofessional programmer users. For the first time the computer user rather than professional programmer is more nearly in control.

2.2.1 Changes in Software Technology. Technology in software design and "construction" has lagged behind that of hardware. This is probably because the problems involved in such creation are more difficult and have often been ignored or passed on to the pro-

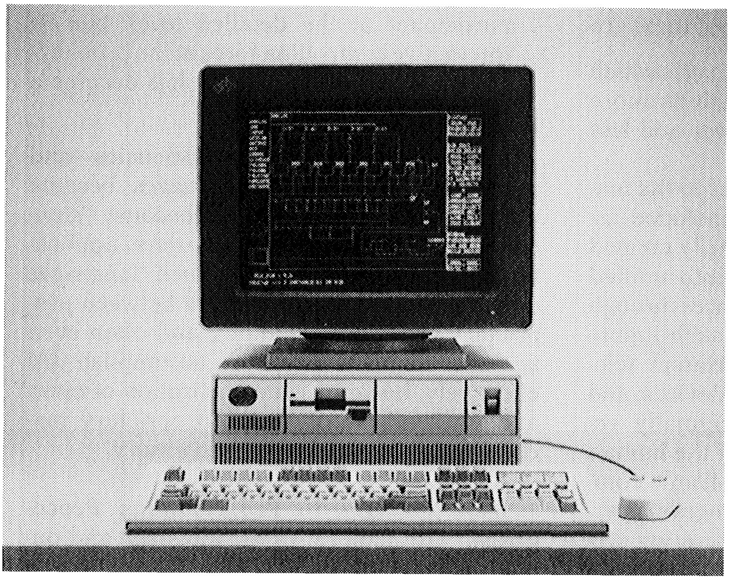

FIG. 2. A personal computer, rated about 100 times as fast as the original microprocessor-based computers, containing up to 8 megabytes of primary storage, a hard disk drive with up to 200 megabytes of secondary storage, and a powerful graphical display and high-resolution laser printer. (Courtesy of IBM Corporation.)

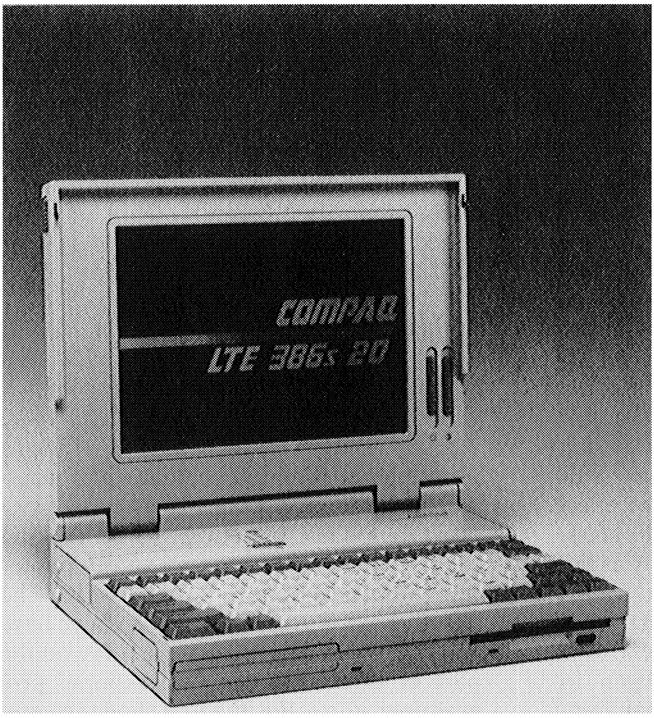

FIG. 3. A laptop computer, weighing about 6 lb, and containing up to 8 megabytes of storage and a $3\frac{1}{2}$-in. floppy diskette drive. Such computers perform at speeds and with programs comparable to desktop computers, which are also microprocessor oriented. (Courtesy of Compaq Computer Corporation.)

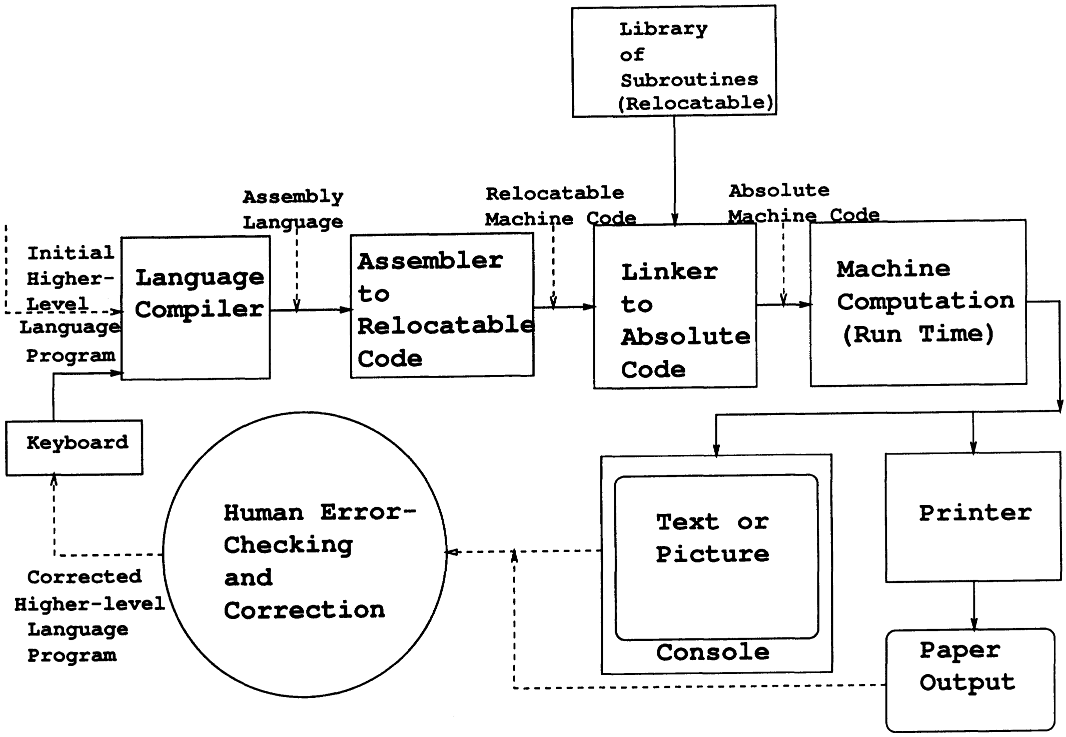
gramming creators by the hardware designers. Until now, there has been little computer-aided design for the generation of software. Here again handcrafting of program sequences has most often been the rule. The classical procedure is diagrammed in Fig. 4.

Many software tools, however, are now in use to aid applications programmers in creating and running their problem solution program. Among the more important of these are

1. applications programming languages which made the sequence of instructions more nearly that of the problem solver and less that of the machine itself;
2. translators from such languages to the machine language itself, which included assemblers that assemble previously created and tested sequences (code) into unified programs, and automatic interfaces through the operating system (OS) to such input–output devices as terminals, printers, telephone lines, and mass storage devices; and
3. operating systems, which originally replaced the behavior patterns of the human operators of the original main-frame computers by automatic control programs performing equivalently. Later operating systems changed many decision-making procedures from the human programmer to the system itself at run time. They also provided standard interfaces that applications programmers could use to guarantee correct performance. Thus the OS began to perform more and more "housekeeping" tasks for the applications program and programmer. The computer operator more and more became an onlooker rather than participant at the detailed level, but an interactive controlling force at the problem-solving level, made at what has become a problem-solving console.

These changes led to new efficiencies—and constraints. As certain languages became widely used, they began to become "standards" for a growing group of users. Applications programs written in such languages could be passed back and forth between proprietary hardware machines, and often even across machine families. To accomplish this effectively, however, standardization of operating systems beyond such proprietary machine families also became necessary.

2.2.2 Changes in Programming Procedures. In addition to the language and operational "utilities" described above, certain



Library of Subroutines (Relocatable)

fundamental strategies for producing computer programs more nearly automatically began to arise. Some of these were highly complex, such as the tactics of artificial intelligence (*q.v.*) and expert systems. These proposed to copy the behavior of human mental processes to aid in solving real-life problems. In certain areas, such as governmental intelligence and certain medical diagnostics, claims were made that such programs produced results beyond the behavior of human experts.

The concept of "objects," as developed with object-oriented programming, created classes of programs and data structures that passed along historical traits by a process of "inheritance," and abstracted out many programming details so that programs might be used over a broad range of analogous applications. This type of programming, combined with special graphical user interfaces, appeared to produce an interactive design process that benefitted from rapid interaction between programmer and programming system.

More immediately applicable computer-aided design procedures for programs have been collected under the title of computer-aided software engineering (CASE). Here the new programming processes of the graphical user interfaces, operating systems, and interactive programming are combined to aid in the generation of alternative versions of certain standard applications programs. CASE has most often been applied to replace the generation of simple, but nevertheless expensive, programs in commercial and data processing applications, previously produced by hand coding. The results are intended to be user-friendly programs. The generated programs themselves interact with nonprogrammer users to create specialized data handlers and transformers.

The resulting programming process is now a mixture of both labor-intensive human analysis and design, combined with machine aids that attempt to guarantee ease of maintenance of the resulting code. Some systems keep a complete record of the historical changes in large programs, combined with histories of certain tests and their results. As software generation has become a more nearly engineering process (as opposed to art form), the introduction of engineering design and test procedures, similar to those of integrated circuit hardware design, increases.

Software costs continue to grow as a major economic factor in the use of computers. Until adaptive program generation techniques begin to produce correct programs automatically, human programming will remain a major constraint on computer utilization.

3. THE CLASSICAL SEQUENTIAL COMPUTER PARADIGM

This section describes the original stored-program computer and gives both abstract and concrete descriptions of how it has been extended with memory and input–output, becoming the central element in local area networks, client server systems, etc. Later, how it has been replicated into parallel computer systems will be discussed.

The simplest model for a digital computer, now only an approximation to the smallest portions of very elaborate systems, is that of the stored-program digital computer. Often credited to Burks, Goldstine, and von Neumann—who published first—it was first proposed by the creators of the ENIAC, Eckert and Mauchly, at the University of Pennsylvania in the mid-1940s. It is useful to compare these basic ideas with the structure of the most popular present design, the IBM Personal Computer.

Parts of such present-day popular microcomputers copy the separated-memory model of the "Harvard machine" of the 1940s, with separate program storage [now in read-only memory (ROM) in the IBM-PC basic input-output system (BIOS)] and separate data storage (in the PC, always in DRAM).

Most of the systems today, however, store other program instructions and data intermixed in the same storage medium, usually DRAM, following the model of the Pennsylvania designers and von Neumann. In the discussion that follows, the classical model is slightly modified to adapt to changes in structure and perception since it was originally proposed. The structure of such a computer can be viewed, as with most such artifacts, by means of both a behavioral and an architectural model.

3.1 The Control and Data Units

The behavioral model provides an idealized, abstract description of how a single digital computer behaves, described in terms of two units, each formally so-called finite-state machines—"FSMs." The behavioral units are pictured in Fig. 5.

Two separate units, control and data, act in a time-interleaved fashion in this model. Each unit has inputs, outputs, and internal states, drawn in each case from a finite set of alternatives. Passage of information between the two units, as described in Fig. 5, is performed in a "ping-pong" fashion, starting with original initial address and data states inserted from outside.

First the control unit uses its initial starting address to generate or retrieve an instruction, which becomes the control unit output. This becomes the data unit input, and is then performed by the data unit, transforming the internal data in the data unit. At the same time, an output is sent back from the data unit to the control unit. This output becomes the control unit input. The control unit uses this input to choose a new address, and the cycle is repeated, beginning at the first word of this paragraph.

3.1.1 Data Unit. In more detail, the data unit holds the data state (consisting of many bits representing numerical and linguistic or structural information). It possesses arithmetic and information-transforming operations which change the data states. The data state is transformed at each step or cycle of machine operation, as a function of the input data operation coming from the control unit. Its outputs are test results sent back to the control unit as the result of test operation inputs.

3.1.2 Control Unit. Outputs from the control unit are operations sent to the data unit, which perform specific transformations on the data states, or test them (in present microcomputers, usually as "flags") for properties such as sign, overflow, etc., generating outputs which are sent back to the control unit, usually of "true" or "false" nature.

a_0, t_0
i_n

FIG. 5. A behavioral diagram of the classical sequential computer, described in the text. A data unit transfers data upon input of instructions from the control unit, which changes its address as the result of test information from the data unit, sending instructions on as a function of the address. The latter is the program.

The control unit has its own internal state, usually called the address state, which changes at each cycle of the joint system. Ordinarily, the succeeding address is obtained in integer succession, with addresses represented as integers. However, results of test operations on data change addresses out of the regular integer succession sequence. It is the latter result which allows "transfer of control" and "loop control" between instructions in the control unit.

Some operations sent to the data unit are more complicated, such as test operations which also transform data states (such transformations are often termed "side effects" for operations or programs that are not logically clean).

3.1.3 Initial Conditions. The user of such a system (which may be a human, or another program such as the operating system) must furnish

1. the initial address state (which is where the program is to be started) in the control unit,
2. the initial data state (which generally consists of all of the initial numbers, integers, and other parameters which specify the exact problem to be solved),
3. the next-address function, which takes data outputs and the previous address, and decides on the new or next address. This function, in the mathematical sense, must be supplied as a part of the computer program from outside this system, and
4. the next-data function, which takes control outputs (operations to be performed) and the present data state, and generates a new data state. This function is hardware, wired into the system and generally not changeable from outside.

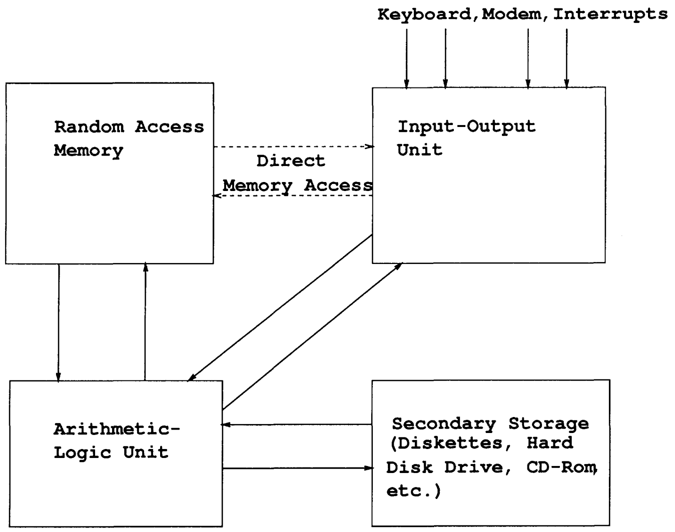
3.1.4 Continuing Operation. Once these four elements have been set (either at hardware design time or program and data entry time), starting the computer initiates the cycle of successive (address, data) changes until a "halt" instruction is reached, which leaves the control unit in an address with no output instruction. In actual systems, there generally are no halt instructions. Once one program terminates, it supplies the initial address and data to another program (which might be some other program controlling it, for example).

3.2 A Corresponding Structural Model

Corresponding to the behavioral description given above, which only describes elements being manipulated as abstract, coagulated units, one can produce a structural model, which is usually what the actual hardware designer works from. One such model, with four units interconnected in a more elaborate fashion, is given in Fig. 6. Parts of these units may belong to one or the other of the control and data units above. Engineering and hardware realities dictate a more elaborate representation.

The four units of the present usual hardware configuration are usually connected by one (or sometimes more than one) common electronic highway or "bus." Some systems have separate instruction and data buses; others have special buses to match different speeds of information transfers of the units that follow:

1. Memory or storage unit: In "stored-program machines" the address-instruction function (or program) in the control unit is stored as instructions in positions given by machine addresses (usually implemented in the integrated-circuit DRAM). In addition, data states are stored in addressable positions, usually as short (8-, 16-, or 32-bit) sequences, as are the instructions.
2. Control unit: In this, the control or address state is represented as a changeable stored integer, along with the hardware next-address function. This latter function changes addresses depending upon test results of flags, or individual bits developed as the result of test instructions.
3. Arithmetic–logical unit (ALU): In this unit, data states, with changes occurring in words in the memory, are transformed according to the definition of the arithmetic or other data operations, wired in and defined by the machine's designers. Key data information is generally stored in accumulators or registers (analogous to the accumulators on the original desk calculators) and transformed by operations on one or more of these, with results fed back to the same or a different accumulator.
4. Input unit: This unit brings in new data from outside sources such as keyboards, telephone lines through modems, analog-to-digital converters bringing in audio and video information, and floppy diskettes and hard disks with programs and data. These are stored in registers or memory to change the computer data state or instruction program.
5. Output unit: This unit passes information, including data and control commands (instructions), to effector output devices such as printers, cathode-ray tube and video displays, digital-to-analog converters, telephone lines, and the floppy diskettes and hard disks.



Keyboard, Modem, Interrupts

Arithmetic-Logic Unit
Secondary Storage (Diskettes, Hard Disk Drive, CD-Rom, etc.)

FIG. 6. The classical four-unit structural model of a sequential computer, with arithmetic-logic unit, storage unit, and input and output units to communicate with the outside world.

One can also consider the floppy diskettes and hard disks, along with compact optical disks and magnetic tape units, as representing a unit:

1(a) Secondary storage unit or memory, in which a mechanical device backs up the initial electronic random access memory (RAM).

3.3 Methods of Speeding Up Performance

Hardware designers, in efforts to speed up performance often slowed by mechanical or lower-speed electronic information transfers, use buffering techniques and parallel memory transfer as expediters. Most common is the so-called "cache" memory, a smaller, more expensive high-speed memory that holds most-often or most-recently used instructions and data. In many cases, sophisticated compilers and assemblers allow these artifacts to be "transparent" to the user-programmer at some level, although quite complicated algorithms may be necessary to achieve best performance.

3.3.1 Use of Static Memory. At the present time, the memory or storage units are most often DRAM. These are mass-produced integrated circuits whose time of information access has continually decreased during the past ten years. At the same time, the number of memory units (bytes or words) per chip has moved upwards the megabyte range. With increase in the density of the storage transistors on the chip, costs have come down. These units are called "dynamic" because they do not hold their information without constant refreshing—reading and writing back the storage contents. Alternative, higher speed but higher priced, storage elements are the static RAM, which do not need this refreshing process. Other memories (as used in the PC BIOS) are used with permanent program or data storage, ROM. These contain information (data or instructions) stored at fabrication time, or later changed only by substitution of new chips.

3.3.2 Combined Control and Arithmetic-Logic Unit. The control unit and ALU have from the time of the first microprocessors been combined on a single integrated circuit chip, or silicon element. Transistors are used to perform the switching functions necessary to change addresses and data. More recently, as more transistors became available on a single chip, further input and output units of increasing complexity have been added to the central structures. All of these units contain smaller portions of their own memory, usually fabricated as high-speed local static RAM.

The overall speed of both memory and the other units is dependent on the speed of action of individual transistors. This is usually described in terms of a "clock" or high-speed counter, which synchronizes storage and shifting of pulses between different elements on the chip. Present commercial microprocessor clock rates range from 20 to 100 MHz, or millions of cycles per second. This means that the smallest time duration for local information transfer might be in the neighborhood of 10^{-8} s. (Actual arithmetic operations, which require more complex pulse manipulation, would be longer in duration.)

4. ACTUAL IMPLEMENTATION OF HARDWARE CONFIGURATION

The model for actual hardware design is not of the single sequential computer, but, as on the integrated circuit (IC) chip, of a set of parallel subsystems made up of transistors mounted on a common substrate. On the chip, the silicon substrate is the physical common element that allows electronic interaction by transistor switching. The parallel subsystems interconnected on this substrate can interact both synchronously and asynchronously.

A synchronous system is locked into a common clock, which coordinates the timing of the many subsystems in the overall systems. Common actions—moving or complementing pulses—are performed at (more or less) the same time when a clock pulse, propagated all over, triggers local transistor switching.

Most simple ICs are controlled synchronously; the upper physical size of a synchronous system becomes dependent on the maximum delay in clock pulse propagation from one point of the chip to another (called "clock skew"). An asynchronous system is one in which a local action may have to wait on the completion of a more remote operation elsewhere in the system. Such systems contain inherent delays, obviously, as well as possible blocking conditions (two subsystems waiting on each other to complete each one's present task, for example). There exist some asynchronous circuits at the IC level (the classical "flip-flop" circuit is an example), but most asynchronous interaction comes at higher levels, between chips, computers, independent memory units, etc.

4.1 A Typical PC Architecture

A typical computer of the PC variety will have a synchronous, clock-controlled microprocessor as its central processing unit (CPU). The CPU, however, will change its control asynchronously upon being interrupted by such input–output units as keyboard, hard-disk controller, and telephone modulator–demodulator (modem). In addition, if other so-called coprocessors are present (such as a high-speed floating-point arithmetic unit), the microprocessor will asynchronously pass information back and forth at arbitrary, irregular intervals dependent only on the size of different parameters and corresponding calculations. Sometimes this "coprocessing" technique moves information so as to by-pass the CPU, such as in the direct memory access (DMA) process which captures a bus (hardware highway) for a time, in order to move information back and forth between storage and input–output.

4.2 Standard Microprocessor Families

Large-scale main frames and minicomputers more often have had structures which were later copied in microprocessors, and so it is useful to look at microprocessors as the most prominent examples (at least in manufactured quantity) of single processors. In practice, microprocessors have over time come to be fabricated in large quantities. In this process, the number of different hardware architectures has come to be narrowed down to families, usually created by one manufacturer, with upward compatibility of programs. Original systems, such as the Intel 8080, were later expanded into more complicated 8086, and then 80186, 80286, 80386, and 80486 (Fig. 7) systems, over a period of about ten years. A comparable family developed by Motorola started with a very simple 6800 microprocessor and expanded upward through the 68000 series. There are other families for less standard purposes (e.g., digital signal processing, by Texas Instruments), but quantity occurrence in the marketplace has often been restricted to a few families.

4.2.1 Changes Within a Family. Successive numbered versions of such a processor family usually consist of chips in which added architectural features are adjoined at each stage. In addition, basic clock rates increase as transistor rectangle size decreases with improved fabrication technology. "Upward compatibility" of programs attempts to guarantee that programs written for previous versions in the family will perform on later versions, thus allowing older programs to be used with newer processors. Through the use of interfacing software such as operating systems and compilers, this is often accomplished.

Among the architectural features which vary are those which improve speed of computation and decrease cost of fabrication. The central limiting factor in such a process is often the bus or joint information communication path on the chip (see BUS SYSTEMS AND COMPUTER INTERFACES). Such a bus appears abstractly not only in hardware on a chip, but at a higher circuit-board level, and abstractly in the software operating system as well.

4.3 Hardware and Software Buses

Abstractly, the common highway or bus of the microprocessor chip, from which subsystems are connected asynchronously, has a parallel in the common interconnection structure of the software operating systems. Just as subcircuits are designed independently and then connected on a chip, subprograms (often called subroutines) are designed independently with standard behaviors, and then interconnected to form a working program. Such programs can be "utility" programs, used to perform housekeeping tasks for the overall computer system, or parts or wholes of application programs created to solve specific problems.

The standard hardware bus will have a set of wires, divided into subsets transmitting data, instructions, and control information back and forth between the asynchronous (and sometimes synchronized) subunits. The addition of a new electronic subunit consists of attaching its inputs and outputs to the appropriate data, instruction, and control wires of the bus, so that those common bus signals can be manipulated by the new subunit. Thus, a special memory, input, or output system can be mounted on a printed circuit board and plugged into the bus to expand the capability of the original system. Obviously, along with the new circuitry, in most cases appropriate changes and additions to the central microprocessor program instructions will also be necessary in order to synchronize with the control signals to the newly added unit.

4.3.1 The Central Hardware "Motherboard". Those parts of the computer hardware which are fixed at fabrication time (e.g., of the standard PC) are mounted on what is called a motherboard. This contains wired connections between sockets into which the IC chips are to be inserted. These standard chip sockets are usually mounted on a printed circuit board, along with a series of open sockets connected to the bus. Such sockets on board or bus may be filled at manufacturing time, or later by the vendor or actual user. The standard chip sockets allow the possible potential substitution, e.g., of a later microprocessor in a family series for an earlier slower version. This is a substitution at the chip level. The bus sockets, on the other hand, allow the interconnection of extra boards, fitted with appropriate pins, into the bus. Such extra boards, often from a different manufacturer than that of the original motherboard or of the entire system itself, allow an extension of the memory, control, or operating capability of the original motherboard configuration.

Thus, the flexibility of the motherboard with its sockets along the standard bus allows many different designers and fabricators to add new or different subsystems to the original system, provided they follow standard socket and bus specifications.

These generally have been set up with standard signal, timing, and electrical characteristics, by specific manufacturers or groups of manufacturers, or by IEEE or other standards committees. Such buses, unless accepted widely, tend to again become proprietary in nature, locking in users for a period of time to a restricted set of sources of hardware modifications and extensions. The hardware bus is thus the standard interface by which disparate subsystems can interact.

With these ideas of flexible socketing, memory and microprocessors can be extended or replaced, at least within the electrical and physical limits of the bus system itself. Many of the newer paradigms for computer users, including audio, video, and telephone interaction, have been achieved by development of special-purpose boards able to be plugged into available sockets on a bus. Sequential and parallel data transmission, and digital-to-analog converters (as well as the inverse a-to-d devices), were first added to original personal computer configurations by special boards. Powerful graphics systems, themselves often containing microprocessors, can be added into standard buses, provided accompanying programs are made available. Later, many such functions have been moved down to the central microprocessor ICs themselves, since these have been growing continuously in available functionality.

4.3.2 Standard Buses. Present standard buses in the PC world include ISA (for Industry Standard Architecture; used in the original PC), EISA, an extension, and the Micro Standard Architecture of IBM's PS-2 newer configuration. Newer standards generally have a wider, faster bus to fit the later-developed microprocessors and memory that are to be combined on the motherboard configuration.

Other standard buses used in larger, faster work stations (which have grown out of proprietary buses), such as Multibus, VME bus, etc., were originally designed around a particular microprocessor family, but later in some cases were able to be used with other equipment. The larger minicomputers and mainframe computers also have their standard buses, to allow "third party" vendors to design and furnish extensions to the original architecture.

4.3.3 Operating Systems as Software Buses and Interactive Interfaces. A similar commercial-industrial method of furnishing software extensions to computer control systems uses the operating system as a "software bus," which allows the "socketing" of new programs and data structures into the overall computer software structure. Corresponding to the wires of the hardware bus are parameters in the programs which are to be "plugged in" to the operating system's data storage. Standard transfer of control procedures correspond to the control wires of the hardware bus. Since CPUs most often contain only one processor at a time, classical operating systems have asynchronous-like features only when multiprogramming (performance of two programs on the same single processor) is being carried out.

4.3.3.1 Combined Hardware and Software Extensions. Standard operating system definitions allow separate hardware producers or vendors to specify extensions to the software. The results are intended to operate correctly, if they correspond to the system constraints. Among the best known of operating systems was the original OS-360 for the IBM-360 series, which allowed many applications to be successfully integrated into this IBM main-frame series of computers. For the PC systems, Microsoft's disk operating system became such a standard that all application programs for PCs, for many years, have used the MS-DOS rules for interaction with that operating system. More recently, the Windows program for the same computer family has belatedly introduced a GUI standard. The power of the Apple Macintosh computers was in the existence of a combined GUI and operating system many years earlier, using the original "mouse" screen-pointing concept pioneered by Xerox, and now available on Windows.

Broader standards for windowing systems, e.g., X-Windows, are appearing as GUIs for faster work-station systems made by Sun, Hewlett-Packard, and others. These systems, like many recent computers now being marketed, have as their common extended software "bus-like" structure the UNIX system. This operating system, originally developed at Bell Laboratories, is becoming, more and more, the OS of choice for hardware manufacturers, applications program vendors, and users. Its combination with a successful common standard GUI may become the future overall standard for programs generated by different originators.

UNIX was originally designed for word processing and text manipulation at Bell Laboratories, but its use has been markedly extended over about 20 years. It contains the software equivalent of many of the hardware techniques implanted on chips or motherboards, including software coprocessors, splitting of processes into parallel tasks, and complete control of files, following the file-cabinet paradigm. It works with many interacting terminals dealing with a central system, and allows mutual interactive operation on common files, under appropriate controls. Only recently have memory prices decreased enough so that UNIX systems appeared economic on PC platforms.

4.3.3.2 Graphic User Interfaces. GUIs like the Macintosh clipboard–file-cabinet paradigm extend user interaction to graphical presentations which allow the mouse pointer to manipulate files by pointing to "icons" or "buttons" on the screen (Fig. 8), rather than requiring lengthy key-stroke sequences as with UNIX or the PC-oriented DOS. Microsoft's windows 3.0 extends the Macintosh behavior by directly linking various programs through

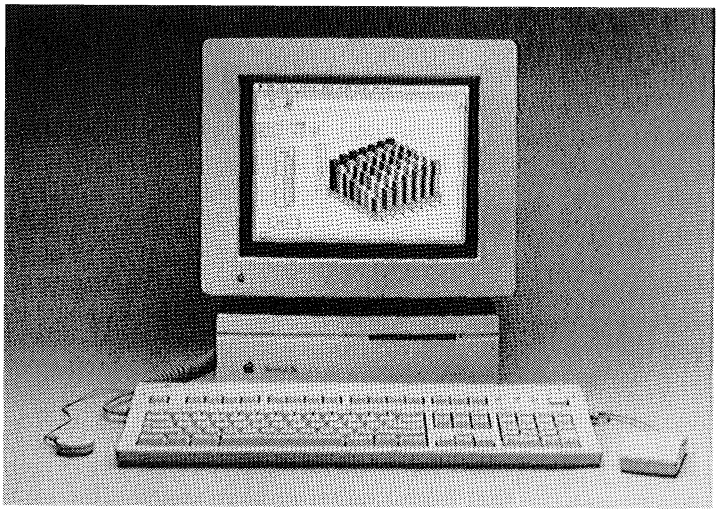

FIG. 8. A graphical user interface, in use with a "mouse" to point to icons, "buttons," and specific windows, text, and pictures on the screen. This point-and-click process bypasses much of earlier character-oriented interfaces on microprocessor operating systems. (Courtesy of Apple Corporation.)

dynamic data exchange, which will cause a chart from a spread sheet, embedded in a word-processing program, to change as individual cells in the spread sheet are changed. This is an example of computational paradigms being interconnected.

4.3.4 Asynchronous Hardware–Software Interaction. The asynchronous behavior of hardware systems obviously causes a need for appropriate response by programs. Two methods of having CPUs such as microprocessors (and much larger machines) respond to the real-time (often mechanical) behavior of the outside system are as follows:

1. "Polling": The CPU synchronously, at regular intervals, looks at electronic control signals from other units, and responds by changing its internal software control to respond to that unit with highest priority to be serviced. This of course places a burden on the CPU, which must spend a portion of its time in checking on its environment. (This is indeed analogous to a "poll" of a population to learn each individual's situation.)
2. "Interrupt processing": The CPU only responds when interrupted by an external unit (analogous to a telephone ring), and then transfers its internal control to software which responds to the particular situation. This system is much faster and much more efficient, but also requires more complex software and computer operation capability on the part of the ALU and peripherals.

This programming behavior is, of course, very similar to the behavior of interconnecting hardware devices interacting in a "master-slave" relationship or requiring a "handshake" procedure to guarantee that both subsystems have the same common control information. Many of the tactics of circuits have found their way into programs, and conversely.

4.4 From Integrated Circuit to Area Network

4.4.1 The Integrated-Circuit Chip as a Similar System. Because integrated-circuit chips need efficiency both in space and speed, the structure of a chip follows many of the characteristics of the larger systems, particularly since entire microcomputers are now being moved onto single chips. Individual chip configurations are, in general, synchronous with respect to the fundamental clock cycle frequency, which times basic transfers between transistor–capacitor storage elements.

Larger subsystems on many chips act relatively independently and asynchronously, waiting on completion of actions by other subsystems before starting on a local task. Such interactions often contain feedback that corresponds to rudimentary hand shaking. This is the more elaborate interaction between higher-level subsystems to guarantee that mutual tasks can be continued because local subgoals have been reached.

Communication on a two-dimensional planar chip is of course constrained by that planarity, somewhat relaxed by the availability of multiple levels of wire crossing.Thus, not every subsystem can easily connect directly to every other, and the concept of bus is forced upon the designer, as a standard pathway with standard interfaces that allow independent subdesign.

4.4.2 Design of Integrated Circuits.

IC chips were originally designed by "hand," with drawings made of the many levels of silicon and metallic compounds that were to be superimposed. The entry of programming technology, particularly in the case of graphics, began a continuing development of "silicon compilers" (see COMPUTER-AIDED DESIGN IN ELECTRONICS). These latter were oriented towards linguistic or GUI descriptions of the circuits, which were to be translated into the final sequences of rectangles to be deposited on the silicon substrate. The most sophisticated of such programming systems were aimed at creating application-specific integrated circuits (ASICs). Among the many applications that have been moved from software onto hardware circuit boards and finally onto ASIC chips are graphics, telephone modems, spelling checkers, games, disk controllers, and many other key "bottleneck" processors where lower cost or higher speed is absolutely necessary to make such behavior economically feasible. These similarities in structure, creation, and economics of various levels of computer software and hardware emphasize the abstract (although certainly not concrete) similarities of these varied forms of information storage and manipulation.

4.4.3 A Higher Level of Area Networks.

Once low-cost computers began to appear on many desks, it became apparent that their interconnection had the potential for mutual information processing and control among many users. Microcomputers and work stations are limited to the number of common interactive users that they can accept; they cannot carry out such interactions and at the same time perform requisite calculations. From this need and opportunity came the LAN concept (Fig. 9), which allows machines to call on storage, programs, and even program performance from and by other machines. The development of such commercial standards as that of Ethernet and corresponding packet-switching networks first produced LANs, and then began their interconnection into wide-area networks.

At present, LANs are usually configured out of a collection of PCs or work stations, acting asynchronously except for bus message communication, which is synchronized to a standard cyclical system. This means that LAN designs are constrained, like the structure of chips, as well as the structure of PC interrupt processing, to those design tactics that guarantee the absence of deadlocks and other fatal interactions. One can thus note that from smaller to large systems, the same rules of synchronous and asynchronous interaction apply:

1. individual transistor circuits;
2. interactive subsystems on a chip;
3. chip sets in a cooperating system, such as on a PC motherboard;
4. interactive multiprocessing systems;
5. common-bus parallel machines;
6. many-processor locally connected massively parallel machines; and
7. LANs.

It is this potentially recursive, replicative nature of the hardware and software artifacts that have been created that allows individual humans the possibility of understanding their behavior. At some near future stage, however, it may be only through embedded computer descriptions within themselves that humans will be able to maintain enough knowledge to make satisfactory use of such systems.

4.5 The Philosophy of Interchangeable Parts

The sometimes chaotic growth of all these various combined hardware and software systems illustrates a growing organization of their structure. Under the constraints of technology and the economic-sociological environment of the marketplace, a process classically

FIG. 9. Diagram of a local-area network (LAN), showing the asynchronous interaction between semi-independent processors which nevertheless may call on each other for data, program, or actual execution of program and data in combination at a remote site. (Courtesy of GRASP Laboratory, Dept. of Computer Science, University of Pennsylvania.)

akin to the "interchangeable parts" systems of 19th century New England has been developing.Standards are beginning to guarantee that individual subpieces of the overall system are replaceable, sometimes by software, sometimes by hardware. As long as the interfaces are well-defined as to interconnection syntax and behavioral semantics, individual designer groups can work on improving subsystems without interfering with the remainder of the system.

The evolution of computer systems thus can be viewed as a continued design process, making use of improvements and changes in technology as increased physical information is discovered, obeying flexible but locally fixed laws of interconnection.

5. THE LOGICAL EQUIVALENCE OF SOFTWARE AND HARDWARE

Through the systems optimization, or at least improvement, process that goes on alternatively with new hardware and software design, runs a common thread. It may be stated as a somewhat constrained principle: Computer software and computer circuitry are logically equivalent; at any time an example of one may be replaced by an equivalently behaving example of the other.

This is certainly true in that any circuit can be simulated by a program. Such simulators have become increasingly important in the CAD process for circuits, where simulators are used to test integrated circuit behavior. The hardware design language VHDL (a very high-level hardware description language) is an example of a language for creating such programs which simulate hardware. In the other direction, only programs that, intuitively speaking, do not modify themselves can be replaced by circuitry, since at present circuitry is not able to modify itself.

With the coming of low-cost, high-speed ASICs, these units are designed rapidly through CAD procedures. Portions of operating systems and application programs are beginning to be replaced by individual chips or subportions of larger systems on a chip. This process seems to indicate that the flow of innovation in digital computers will move from application and utility programs, able to be easily modified and improved. Such programs, relatively expensive to create, use, and maintain, will be transformed to chips, chip sets, and portions of larger microprocessor systems. These hardware systems will run much faster than the original programs. Primitive examples, mentioned elsewhere, include many cases where microprocessor programs were later reimplemented as peripheral processors in hardware.

Replication of design and fabrication costs is a chief factor contributing to overall systems cost. Such movement from software to hardware will probably prove most effective in applications in parallel to produce hardware parallel processes. The chief immediate application of such replication in this fashion, of course, is in the development of parallel processors consisting of many interconnected microprocessors (or microprocessor-like subsystems) performing the same or different operations at the same time. Such hardware will be described further below.

6. MODERN TECHNOLOGY

6.1 Applications Programs

The structure of applications programs has evolved towards a concept of "user friendly." A definition of this term might initially be that the program does not require from the user any specific knowledge of programming skills or operating system or computer structure. In addition, the program, through its GUI, should guide the user through the computational process by asking questions. For example, it can request responses by simple user actions (motions of the pointer-mouse, single "hot-key" keyboard responses). These replace the elaborate and arcane sequences of keystrokes originally required in many of the first applications programs, tailored to the programming technology of that time. At its most straightforward, the interactive program might offer to the user an elaborate version of "20 questions" in which the program is the questioner, working to discover the true desire of the user.

Such programs may be centered around a single (or more than one) paradigm or conceptual programming structure. The GUI, which likens the terminal screen to a notebook or blackboard, is one such presentation. The spread sheet, a matrix-like representation in which the user enters numbers and/or letter sequences to be processed by standard actions (preprogrammed or under user-control) is another. Standard word-processing programs offer a visual structure not unlike the pages of a manuscript. The more a user can call on previous experience, the easier use of such a system can be.

Many applications programs (like some operating system interfaces) offer menus, either in printed characters or in pictures on a graphical user interface. These constrain and simplify the choices that a user has when interacting. The system may offer the ability to browse through the menus, or additionally, through the text, pictures, or data that are being processed—or the program itself. The system should offer complete information and preventive editing so that incorrect or out-of-range data does not cause the program to "crash" (end up with insufficient information to recover automatically or manually, or to continue).

Applications programs for more complicated problems may require even more complicated interfaces. These should produce graphical results posed at high speed for the user to assimilate and respond to. Computer user and system thus become a pair of joint co-processors working interactively to solve a specific problem or class of problems. This process can of course be extended to many computers and many machines, provided an understanding of the needed interactions can be placed into the hardware and software.

6.2 RISC vs CISC

The advent of CAD for computers themselves, in the form of silicon compilers and layout programs, has produced basic changes. These are changing the output of the silicon chip assembly lines in such fabrication firms as Intel, Motorola, Texas Instruments, AMD, and National Semiconductors in the United States, and Siemens, NEC, Toshiba, and others overseas.

Because of the increased ease of designing and fabricating logical structures, a new overall systems approach including both hardware and software is now being undertaken. Most indicative of this process is the development of new reduced instruction-set computer (RISC) devices. System architects analyze the entire system structure consisting of software (program, compiler, operating system) and hardware (central microprocessor and peripheral chip set). The resulting optimization, originally carried out by researchers at Stanford University, the University of California at Berkeley, and IBM, among others, produced a different design from that of the classical main-frame computer and microprocessor—a class usually called complex instruction-(CISC) (for example, the Intel 80486 shown in Fig. 7). (It is the instructions themselves that are reduced or complex, not the set.)

In such RISC machines, much of the behavior of a complex instruction in a classical CISC machine is generated by the RISC machine's compiler at compile time, rather than by the hardware designer far earlier at the instruction design time itself. The combination of an optimized compilation sequence of simplified instructions is claimed (and often verified in actual hardware designs) to be much faster than a possible shorter sequence of the more complicated complex instructions. The inclusion of pipelined instruction operation and storage caches yields an advantage, in many cases, to simplified RISC instructions as compared to their CISC complex counterparts. Since the cost of memory has decreased with integrated circuit costs, a larger program instruction memory is now available, and thus brings down overall RISC cost.

One major efficiency of RISC designs (which may be possible to introduce into more classical designs such as the Intel 80x86—x = null, 1,2,...)—is the introduction of parallel performance inside individual operations themselves, so that additions and multiplications, e.g., can be performed simultaneously on different pairs of operands. As the cost of memory decreases, compilers can use more storage for instructions, translating and unwinding loops so that the product (memory access/instruction) times (number of instructions) continues to decrease.

Although RISC designs have been used in some main-frame and/or minicomputers, their most publicized appearance has been in microprocessors, which have become more powerful as their speeds encroach upon those of past minicomputers. RISC designs are competing markedly with the more classical Intel and Motorola CISC chips, both for performance and in the market place as parts of so-called work stations. The Intel 80x86 family, e.g., has served as the central processor in the family of IBM PCs and their clones (duplicate copies). Partially because of its speeds, this chip sequence in time has come to constitute an estimated 80% of the microprocessor sales market for personal computers, as the clock frequency, directly related to the overall performance rate, has increased to about 50 MHz (early 1992).

On the other hand, comparisons of performance of a recent RISC-based Hewlett-Packard work station, using the manufacturer's own RISC chip, generate claims of speeds "up to ten times faster" than the most recent, highest-speed Intel CISC microprocessor, the

80486. Machines based on this and similar RISC designs, by HP, MIPS, Sun, and IBM, and even by Intel and Motorola, have produced work stations fundamentally different from the PC architecture of the 80*x*86 family, and much faster. Part of the difference is masked by differing compiler technologies, and by different operating systems, as previously discussed.

Even so, the coming of these new architectures seems to presage further overall system optimizations that may change the software–hardware combination more markedly than before.

The future of mass-produced and -marketed machines (almost everything, in the near future, but the largest computers) will therefore depend on conditions of production and marketing among the large international companies that now increasingly dominate integrated hardware–software systems, as well as the larger number of entrepreneurial smaller organizations that appear to effect distribution.

Just as important, perhaps, will be subsequent software–hardware optimizations that may produce further marked efficiencies, not predictable before the integrated-circuit design and fabrication revolution. These may produce classes of designs as yet untried and perhaps not yet thought of.

6.3 Artificial Intelligence

Beginning in the mid-1950s, researchers began using the term "artificial intelligence" (*q.v.*) to describe potential computers that would behave like intelligent beings—e.g., humans. Competition for research funds has moved emphasis back and forth in this area between mechanical translation, game playing, so-called planning, and later "expert systems." Portions of work in image-processing analysis appeared to fall into this area.

6.3.1 Division of Artificial Intelligence into Problem Solving and Learning. Early efforts seemed to divide the area of study into applications to problem solving on the one hand, and efforts to create learning systems on the other. One of the key methods, now appearing in some commercial and governmental applications, was the attempt to copy a human expert's capabilities into a corresponding computer program running on a machine.

Applications have included copying of such human activities as geologic exploration techniques, testing and tasting of soup, recognition and discovery of terrorists and their activities, medical diagnosis, and a host of other less exotic human behaviors. Special programming procedures, built around a list processing language (LISP) or PROLOG (a logic programming language), bypassed some of the difficulties of the more classical machine-oriented and numerically oriented languages. This was in an attempt to move computer behavior much further into the logical area. So-called knowledge engineers produced "protocols" of medical experts' diagnosis investigations, in order to translate them into computer programs that would produce a similar behavior.

Most of these systems, independent of language, were based on a (condition, action) paradigm, in which the presence of a particular condition in the case at hand (whether medical, geological, or whatever) caused the computer to produce a corresponding information-processing action, whether inside its memory, or output to the observer for possible outside action. The priority of which conditions to give immediate action to, whether to perform them in parallel, etc., in some ways copied the structure of certain computers themselves.

The computer-expert system and the external user were once again a co-processing system, each responding to the other's input by changing state and yielding output. The design of a controlled interactive sequence of (condition, action) pairs thus became a first approximation at generating an intelligent computer program, whose instructions were made up of these individual responses.

Although the knowledge engineer might be considered to be learning from the expert whose protocols he recorded, the need for systems that modify themselves to produce better performance is still there. Such "adaptive systems" have been developed to aid various control systems for aircraft and factories to improve their performance, but these in general have depended upon classical statistical techniques—after all, a type of learning to predict behavior.

A new engineering-oriented theory, the "fuzzy sets" of Zadeh, attempts to introduce enough vagueness into the measurement of the external world that the computer can produce results that might be considered qualitative rather than quantitative. Results from such systems appear to remain experimental.

6.3.2 Neural Nets. The most sophisticated proposed technique for fine-grained intellectual behavior is based on an attempt to copy brain behavior at some detailed level. Both programs and hardware have been designed to copy individual neuron action, with self-adaptation through feedback to the artificial "synapse-like" input elements in individual units. Actual neural net machines, with variable control, have been designed and constructed using special ICs (see NEURAL NETWORKS). Compiler–assemblers are to interconnect substructures both initially, and perhaps later dynamically. Neural net programs so far have been successful in certain classes of simple tasks, but their competitiveness in practice still remains to be seen. They do offer a potential common method of applying learning techniques which otherwise appear markedly different in different problems to be attacked.

The most impressive examples of human-like behavior have perhaps been with chess-playing machines, which in certain cases have been able to defeat very competent human players. However, neither learning nor complex logical expert systems are deeply involved with such machines. Instead, they make use of the brute power of massive integrated circuit techniques to search widely and deeply within the tree of possible moves available to the machine and its opponent. A simple but powerful intellectual heuristic technique is able to limit this search by ignoring certain branches in which it would be of no value to continue the search. For the moment, the expert behavior of human chess masters does not appear to have been captured.

6.4 Creation and Standardization of Languages

A major factor in the development and usage of computers has been the creation of a mass of computer languages (see COMPUTER PROGRAMMING LANGUAGES) to specify the behavior of a specific machine or class of machines.

Two basic techniques of responding to computer languages, which are usually input through a programmer's interface, involve the level of the system which responds to the language:

1. Compilation-translation: This term describes the replacement of external language strings, understandable by the human programmer, by equivalently behaving computer language strings immediately interpretable as programmed instructions by the target computer. Such compilers are one-time performers, which do their translation job, and then retire from the system and leave the computer to interact with its own language translated strings.
2. Interpretation: This term describes a process in which a program (interpreter) stored permanently inside the computer continuously intercepts, interprets, and acts upon the external language strings, dynamically, responding element by element to the external language.

Obviously interpreters are more powerful than compilers, since they include the compiler capability, and are always resident, and thus contain the potential of changing the linguistic program strings with time—adaptively. Correspondingly, compiler-translators, because they look at the external language only once, yield a much faster overall system performance.

The classical example of a language that is compiled is FORTRAN, created by IBM programmers in the early 1960s. This is a formula translator that translates numerical formulas, appropriately modified at the programming input stage, into the languages of various target machines. FORTRAN has proved both effective and long-lasting; it is still being used as a standard language for certain classes of numerical analysis problems even with massively parallel computer systems, in a modified form to include control of the synchrony and asynchrony of individual computers performing concurrently.

An alternative example of an interpretive language is that of BASIC, first created at Dartmouth University at about the same time. BASIC proved particularly useful for interactive computing, which arose at the same time, because the need for recall of a compiler was obviated. It was adopted, because of its relative simplicity in usage (first designed for students), as the original programming language for the IBM PC, embedded in its ROM as a fundamental artifact purchased with the machine. Because of its interpretative slowness, however, BASIC does not compete in large problems, and does not appear as a widespread language of use, except in certain special cases.

Languages evolve as a function of classes of problems being solved, and classes of users or programmers. LISP and PROLOG, oriented towards functional and logical descriptions of problem solution techniques, came out of mathematical studies almost completely independent of computers. On the other hand, the language C, developed at Bell Laboratories, was conceived as a human-oriented programming language nevertheless allowing close interaction with actual machine instructions. Many important non-numerical applications, such as operating systems and utility programs for newer machines, are written in C. A sample is shown in Fig. 10.

An important step forward in computer language structure was the development of command languages (in classical computer command form) that were recursive in the formal mathematical recursive-function behavior that allows functions to call on themselves. From LISP, which had this characteristic, came the algorithmic language (ALGOL) languages, which for the first time had well-studied plans for such recursive behavioral implementation.

A family of computers, first created by Burroughs, and later adapted by microprocessor designers, used a so-called "push-down stack" to store data and addresses automatically on a "last-in, first-out" basis. Without these continually developed hardware capabilities, programs that call on other programs and each other recursively would be much more costly to implement. The extension of this initial structure to more elaborate register "context switching" is purported to produce much of the power of the new RISC architectures.

University users, in attempting to codify the fundamental structure of the more pragmatic commercial languages and simplify the ALGOL complexity, invented other languages such as PASCAL and MODULA, with which many students wrote their first programs.

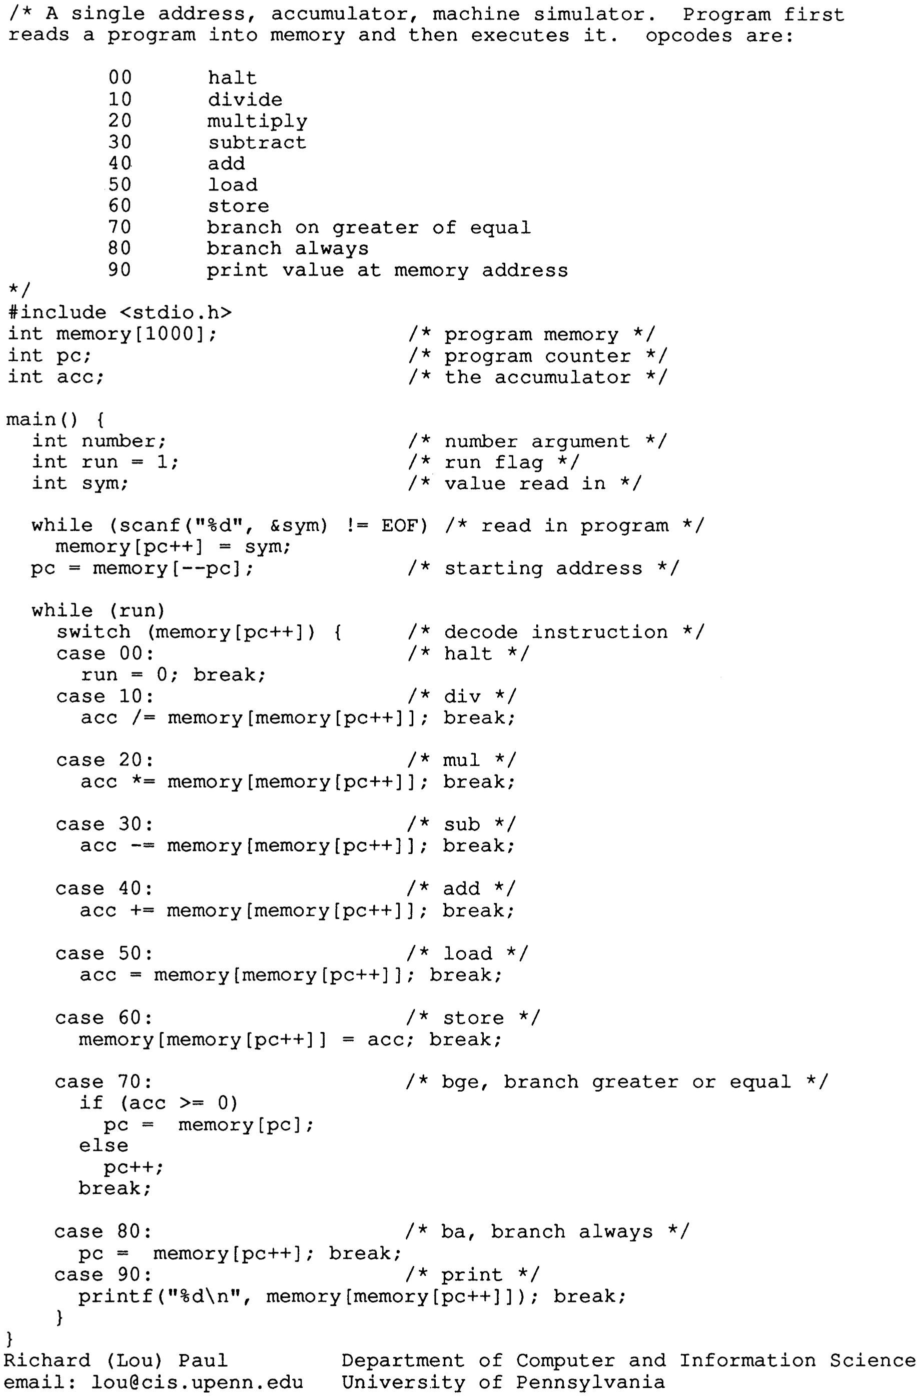
The U.S. Government, a large user of programs and programmers, demanded standardization of its data processing procedures and produced (with other outside organizations) a common business oriented language (COBOL). The Department of Defense went further to produce an extremely complex language, ADA (named after an English woman regarded as the first computer programmer). This has elaborate certification procedures to guarantee that the results of translation, compilation, and performance would be the same for any machine on which it was to be run. Complex language such as COBOL and ADA combine behavior of both translators and interpreters. They perform certain transformations initially, and then the system interacts dynamically from time to time at run time.

Similar languages, such as VHDL for integrated circuit and chip description, were formally codified and have become part of the design process for microprocessors, ASICs, and other assorted hardware boards and systems.

In fact, one can view this expansion of languages as describing a second level of paradigm, in which the computer is viewed as an instrument to which a programmer communicates, talking about how to solve a restricted class of problems, but in many cases using a very complicated set of nouns (data structures) and verbs (commands).

While higher-level languages have offered tremendous power to the programmer in developing more elaborate data structures and transformations, they have not solved the problem of guaranteeing correctness of the program to produce a specific result. This is the goal of the logic languages (of which PROLOG is a somewhat modified offshoot) which attempt to describe the goals desired and from them produce commands to achieve those goals. Most such languages have achieved only research performance, although Japanese commercial plans indicate use of PROLOG.

The world of computer languages is Darwinian-like in its evolutionary behavior. The power and number of users, as well as investment in previous programs in a language, may guarantee its survival. IBM's imprimatur produced FORTRAN's longevity, but failed to preserve a more elaborate in-house language, PL-1, in the external world. LISP, a powerful and classical artificial intelligence language, failed to produce a much-wanted hardware interpretive commercial machine to run LISP



```
/* A single address, accumulator, machine simulator.  Program first
reads a program into memory and then executes it.  opcodes are:

        00      halt
        10      divide
        20      multiply
        30      subtract
        40      add
        50      load
        60      store
        70      branch on greater of equal
        80      branch always
        90      print value at memory address
*/
#include <stdio.h>
int memory[1000];               /* program memory */
int pc;                         /* program counter */
int acc;                        /* the accumulator */

main() {
  int number;                   /* number argument */
  int run = 1;                  /* run flag */
  int sym;                      /* value read in */

  while (scanf("%d", &sym) != EOF) /* read in program */
    memory[pc++] = sym;
  pc = memory[--pc];            /* starting address */

  while (run)
    switch (memory[pc++]) {     /* decode instruction */
    case 00:                    /* halt */
      run = 0; break;
    case 10:                    /* div */
      acc /= memory[memory[pc++]]; break;

    case 20:                    /* mul */
      acc *= memory[memory[pc++]]; break;

    case 30:                    /* sub */
      acc -= memory[memory[pc++]]; break;

    case 40:                    /* add */
      acc += memory[memory[pc++]]; break;

    case 50:                    /* load */
      acc = memory[memory[pc++]]; break;

    case 60:                    /* store */
      memory[memory[pc++]] = acc; break;

    case 70:                    /* bge, branch greater or equal */
      if (acc >= 0)
        pc =  memory[pc];
      else
        pc++;
      break;

    case 80:                    /* ba, branch always */
      pc =  memory[pc++]; break;
    case 90:                    /* print */
      printf("%d\n", memory[memory[pc++]]); break;
    }
}

FIG. 10. A program written in C, one of the most prevalent languages at present in use by programmers developing applications programs for commercial marketing. (Courtesy of Professor Richard Paul, University of Pennsylvania.)

programs directly. (This would have speeded up productivity many times using this language. Nevertheless, users apparently could not support the costs of the equipment involved.) A very powerful language, APL, once supported by IBM and popular in Canada, the land of its creator, has almost disappeared despite its power in certain classes of vector computations.

The disappearance of such once-popular languages, like APL and PL-1, and the rise of the use of C, demonstrate how the constraints of technology, programmer acceptance, compiler complexity, and user demand on the part of government and industry produce survival of the "fittest" languages only in terms of very complex, far from only technical, measures of effectiveness.

The rise of C as a programming language, similar to, but less sophisticated theoretically and technically than, university-oriented PASCAL, shows the technical and market forces at work in language adoption and usage. The language C is closer to machine language than almost any other higher-level language, and contains operators that approximate many machine operations in the standard CISC microprocessors. Its close association with UNIX at Bell Laboratories and University of California, Berkeley, also gave a wide impetus to its usage. Moreover, it is a programmer's language, not forced upon its users by educational curricula.

Specialized languages include those for such user paradigms as the database search process. Designers here created so-called "fourth generation languages," such as SQL, successful in this area, but not extended more widely. The interest of the Japanese in interacting with potential European users of Japanese computers has boosted the potential of PROLOG, originally created and nurtured in France and England. Japanese "fifth generation computers," supported in development by their Ministry of International Trade, may use this logic language based on nonimperative structures similar to declarative sentences. On the other hand, the most powerful new Japanese supercomputers may competitively use FORTRAN, because of the nature of available programs.

A powerful, potentially useful class of languages are those first based on SMALLTALK, another product of the Xerox Park Research Center (which also developed the "mouse" and portions of the IC design systems). SMALLTALK is labeled an object-oriented language, in which the objects are generalized data structures and operations on each class of object are associated with that class. Object classes have a hierarchical hereditary structure in which descendants have the same characteristics as their predecessors, but with potentially more detailed structure and corresponding operations.

Object-oriented languages apparently owe their initial concepts, among others, to mathematical category theory, in which structures are essentially viewed in terms of pointing arrows describing abstract interactions. Despite what might be considered an arcane beginning, pragmatic object-oriented languages such as SMALLTALK and C++, a C derivative extension, are beginning to be used with claims of markedly increased programmer productivity. The abstract view of elements, as opposed to the details of the more classical languages, offers an alternative top-down view.

In the university research community, so-called "typed languages," again corresponding to mathematical structures in abstract algebra, allow powerful but correct manipulation of complex data structures. Such languages have not yet gained a foothold in any commercial or production sense.

Certain small groups of users, such as astronomers, have adapted special languages that prove easy to use and exchange (in this case FORTH, a "growing machine" language, which provides semantic clarity and abbreviational simplicity by sequences of Polish suffix operators, using interpreters).

Throughout this Babel-like set of language developments runs the pragmatic thread of appealing jointly to a body of users on one hand and to a specific computer architecture on the other. Nevertheless, up until very recently, the desire for control of the result by the user population has generally kept resulting programs, in almost any language, highly labor intensive in generation.

Clashes between esthetic formal theory and pragmatic user acceptance generally have found the latter winning out. The coming of the GUI, with its amplification of user performance, has begun to produce acceptance of automatic programming generation, triggered from such graphical interactive interfaces, by nonprogrammer users who wish to produce programs.

The clash here becomes one between the classical programmer, who desired freedom to create at will, on the one hand, and the more casual problem solver, who is willing to accept constraints on what can be communicated in return for more speed and power in producing results. Cheaper computation would appear to increase the potential for more constraints and less creative freedom. Among such constraint systems now are syntax-directed compilers, which only allow correct language strings to be typed. Also there are strong restrictions, in many newer systems, on what commands are allowed, and on use of replication features that manipulate previously written code, just as hardware designers use previously designed subsystems.

In general, this process of automatic generation of computer programs, still unsuccessful, illustrates the paradox that relates the two philosophical extremes: freedom and constraint. Machine languages offer almost absolute freedom to the programmer (with the sometimes crude constraints of the actual hardware). Only very crude syntax is required. As languages become higher level, stricter syntax is required, but semantics becomes more widely defined. The user is constrained as to what program primitives can be used. But these can be used, hopefully error-free, freely, and at very low cost. Just how the Darwinian process of language evolution will proceed in this situation is still to be seen.

6.5 Creation and Standardization of Operating Systems

It has been noted above that the operating system is abstractly the equivalent of the hardware bus inside various computer families, such as that of the PC. Its construction allows addition of subroutines and applications programs into slot-like positions, in a standard process, so that the set of programmed operations can be extended in a growing fashion.

The origin of the operating system, perhaps first developed on the Digital Equipment Corporation's model PDP-8, was the result of applying a classical expert system technique. One observes the sequence of interaction protocols of an operator seated at the console. These sequences, translated into a program, allowed replacement of the expert, in this case the operator, by a computer program that performed the same actions much more quickly and effectively.

The development of the operating system OS-360, for IBM's family of similarly named machines, powerfully demonstrated the potential of the operating system as the integrating factor for a family of computers. Its use continued over many users, and down through tens of years of time. The OS-360 system, however, did not have the interactive power that would allow humans to program and solve problems easily on line.

The development of the operating system Multics by the government-sponsored Project MAC at Bell Labs and MIT first proved the large-scale potential of interactive computing. Honeywell and General Electric used this design to produce the first commercially successful time-sharing operating system. The specialization of Multics to UNIX by workers at Bell Laboratories produced a system originally emphasizing processing of strings using terminals connected to a minicomputer. Over almost 20 years the efforts of the telephone company, AT&T, as well as other firms and universities, such as University of California, Berkeley, produced adaptations that showed success.

UNIX is now expanded to a broader range of equipment, including larger machines as well. Despite its requirements for large amounts of storage, improvement in hardware performance has moved it closer to becoming a possible standard for even personal computers. Since many work stations and larger computers now also use UNIX, this will allow passage of programs and data back and forth electronically between computers from different vendors. Users of one computer can perform portions of their programs on more powerful computers in the same network, with data from elsewhere in a network file system. Such capabilities require interactive network utility programs tailored to fit the cooperating operating systems at both ends.

The development of similar small operating systems on microprocessors, often restricted UNIX-like versions, culminated with Microsoft's disk operating system (DOS) on the IBM PC. This became a de facto standard for those operating systems running on that common de facto standard personal computer, the IBM PC.

The embedding of operating systems in graphical interfaces was first developed by Xerox and commercialized by Apple with the Macintosh. The Macintosh used the paradigm of the desk top, the clipboard, and the file cabinet. The transporting of this technology to the PCs by Microsoft recently produced a powerful, popular GUI, Microsoft's Windows 3.0, as an extension or replacement of that vendor's ubiquitous MS-DOS.

Other technological attempts to improve operating systems include placement of operating systems on ROMs or IC chips. The BIOS on the PC is one such example. Special operating systems have also been developed for real-time systems controlling man-made artifacts, such as aircraft, rockets, automobiles, and factory systems.

At a certain level, the operating system may be viewed as replacing the hardware computer itself as a machine paradigm, with its own operations, data structures, and interfaces. Portions of it may obviously move into the hardware itself. Probably more of the applications programs operations will become codified within the operating system, in a classical process of movement from human information and behavior into automated instructions in the machine.

7. SEQUENTIAL VS PARALLEL PROCESSING

With the coming of low-cost microprocessors, fabricated using VLSI technology, construction of massively parallel-processing systems became possible (see PARALLEL COMPUTING). These consist of large numbers of simpler subprocessors. Originally, parallel systems contained few subprocessors and were very expensive. With new technology, designs have grown in size from tens to thousands of subprocessors, connected in arrays that attempt to pass information and control from element to element in as efficient a fashion as possible.

Such systems require elaborate extensions of previous sequential-programming technology, its algorithms, routines, and languages. An entirely new set of control instructions, many borrowed from parallel hardware design procedures, had to be added to classical languages such as FORTRAN. Alternatively, new languages had to be developed. Investigations into which classical sequential algorithms could be easily and efficiently extended into parallel computation have been necessary. For those problems where this extension technique would not work, entirely new parallel algorithms were needed to make use of the new experimental parallel programming structures.

7.1 Classes of Parallel Equipment

In general, an individual subprocessor in an array is some type of sequential processor. Since each individual subprocessor in an array has both program and data, it is straightforward to classify parallel processing systems according to program (instruction) and data. If all of the basic subprocessors scan the identical program stream (and the same instruction) at once, the system is termed single instruction (SI). Otherwise, if different subprocessor control units scan and interpret different instructions, the term multiple instruction (MI) is used. If all of the data units act upon the same data element, the system is called a single-data (SD) parallel system. Otherwise, with different data being processed in different subprocessors, the label is multiple data (MD).

Thus, to a first approximation, such systems may be classified into four obvious categories: SISD, SIMD, MISD, and MIMD.

SISD machines are classical von Neumann–Eckert–Mauchly digital computers such as the first stored-program computers of the early 1950s. Recently, designers have come up with possible extensions to produce very long instruction word (VLIW) instruction processing. Such processing is now making its way into RISC microprocessor, as well as into single high-performance processor, design. VLIW instructions perform different operations, such as multiplication and addition (included in one instruction), in parallel on local data sets which are made independent of one another through pipelining, vectorizing, or other tactics.

SIMD computers most often operate on vectors of many individual data elements, with the same instruction in parallel. Such architectures very early became important in large numerical calculations able to be expressed in vector-like form. Searches of many databases in parallel, for the same information, also falls into this category. Such problems replace sequential many-input calculations, repeated in time, by the same calculation sequence performed by duplicate processors over space. With these, there are local problems whenever programs produce different conditional transfers for different data inputs. This obviously no longer permits easy use of the same instruction simultaneously in every subprocessor.

7.1.1 MISD and MIMD Systems. MISD systems involve solving many problems with one data stream. A computer with multiple searches on a single data-base stream is an example of such a processor type. Another technique is the use of pipelining, which takes sequential instructions and performs them concurrently on successive iterates in a sequential data stream. The most sophisticated of such systems might well be termed MIMD systems, as described below.

Most important in the future will probably be MIMD systems, which can support multiple instruction streams by pipelining and parallel processing. In the latter case, the interconnection structure by which information, both instructions and data, is passed between processors becomes important, and can be used for further classification. MIMD systems can, e.g., use a bus, or common information channel, to pass information at lower cost but lower overall speed. Most lower-cost recent commercial systems, such as the Sequent and Encore computers, originally used standard microprocessors as the processors connected with common memory, along a bus.

More complicated MIMD systems, such as *n*Cube, and the Hypercube and later versions from Intel, connect each memory-equipped processor to its *n* nearest neighbors, to form an abstract logical hypercube (see Fig. 11). Messages are sent between the node subprocessors in the hypercube to synchronize the concurrent computations.

Hierarchical direct connections include such geometrical forms as trees, pyramids, and prisms. Crossbar machines (in which every processor is connected to every other), are overly expensive, so far, except for small systems. Marked changes in cost of such communication between subprocessors would be necessary before complete crossbar systems became commercially viable.

A most important characteristic of a parallel processing system is its granularity, defined in terms of the size of unit of work allocated to individual processors. Until recently, the most powerful systems were termed "coarse-grained," such as Cray, IBM, and previous ETA systems, with four to ten very high-speed processors, each individually constructed, generally not using VLSI fabrication. Such systems have computing power ranging up to thousands of megaflops. ("Flops" stands for "floating-point operations per sec-

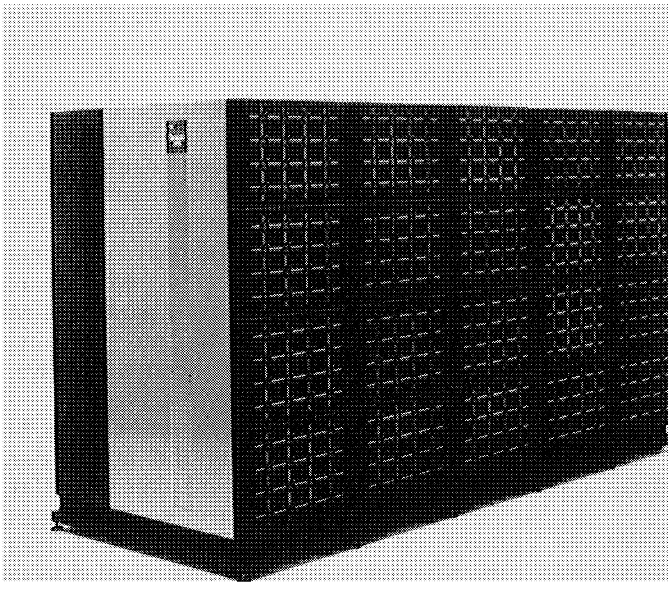

FIG. 11. A multiple-microprocessor parallel machine with potential for more than 1000 individual separate processing units connected to "nearest neighbors" in a cube-like "hypercube" array. (Courtesy of Intel Corporation.)

ond;" mega and giga are the standard prefixes for 10^6 and 10^9.)

The relative cost performance of such coarse-grained processors, compared with alternatives using many-times replicated VLSI microprocessors, appears to be decreasing through multifabrication economies of scale. These "supercomputers," therefore, may tend to be replaced by the massively parallel newer designs.

7.1.2 Cost of New Large Systems. Current 1991 prices for Cray's smallest to largest computers range from $300,000 to $30 million, according to published reports. The largest of these, the Y-MP C-90, is announced as having a central processing unit that can perform at the rate of one gigaflops. For the top price unit, there will be 16 such processors, each program-compatible with previous systems.

New examples of massively parallel designs have been announced recently. An Intel announcement of a new massively parallel processor (Paragon XP/S) with up to 4000 internal processors, gives a range in cost from $2 to $55 million. This system uses standard Intel 860XP RISC-like processors in each node, and is claimed to generate 5 to 300 gigaflops. Such parallel systems with so many internal subprocessors would tend to fall into the medium-grained category, based on the necessary detailed work each subprocessor might do. An Alliant Computer announcement gives price ranges of $2.5 million for a 100-processor system to $16 million for an 800-processor system.

Among other medium-grained commercial systems would be those using tens of Intel 80*x*86 or competitive RISC processors connected along a bus (Sequent, Encore, and other less powerful commercial versions). So-called fine-grained systems were built around simpler and cheaper basic units. The Connection Machine, built in hypercube interconnection with a special chip as subprocessor, is an SIMD machine which replicates the same computation in every one of its thousands of elements.

7.2 Relative Serial and Parallel Efficiencies

Simulation and direct experimentation on existing equipments is being used to test classes of problems according to a criterion of "efficiency": the ratio of actual performance of processors, interacting in an inefficient manner due to delays in waiting for the results of other computations, to that performance possible with perfect undelayed response from all other processors at the same time. [A sequential machine, which does not wait for outside results, has an efficiency of 1, for one processor. An n-element parallel processor with perfect efficiency of 1 would have an efficiency ratio of $n \times (n\text{-machine parallel eff.}) / (\text{sequential eff.})$, with a maximum value of n.]

Certain types of near-linear partial differential equations are solved on key MIMD machines with a very high efficiency, near 1, and efficiency ratio close to n. Nonlinear partial differential equations, on the other hand, which require more elaborate communication (therefore larger communication delays) when solved on parallel processors, have a much lower efficiency ratio.

7.2.1 Methods of Improving Performance. Methods of improving performance of such complex solution procedures in parallel include the attempted use of Monte Carlo (probabilistic) analyses, easily replicated in parallel. Recent conference reports on high-performance computing include examples of this and other new tactics. These develop parallelized solution processes, alternatives to sequential classical procedures that are not easily extended.

In any case, of course, even with low efficiency of usage of parallel architectures, any marked improvement means that solutions to otherwise impossible problems may be obtainable in a finite time. Most of the improvements in productivity in analysis and design of large physical and engineering systems will probably depend on improved usage of such massive architectural computer complexes. Two recent descriptions of experience at Sandia Laboratories and IBM Research make the claim that massively parallel MIMD architectures are becoming more commercially competitive and application effective.

7.2.2 Examples of Problem Solution Implementations. Among the applications whose efficiencies have been studied for MIMD shared and distributed memory architectures is the use of "farm parallelism," with many workers doing the same task, applied to the modeling of gas-phase reactive systems. The problem is broken into several elementary chemical reactions, each investigated separately and concurrently. Many classical events (so-called trajectories) are calculated concurrently. Experimental results on an IBM-3090 multiprocessor (6 subprocessors) and an *n*Cube 2 with 128 nodes were carried out for 4096 trajectories. Efficiencies of over 90% were obtained with several alternative grains of parallelism.

7.3 Areas in Which Parallel Computers Have Succeeded

Other numerical calculations recently described, where parallel computers improved performance, include Navier–Stokes equations (IBM-3090-VF, 6 processors); simulation of laminar–turbulent transition (Cray 2); structure of semiconductor strained superlattices (IBM-3090VF); 3D shallow-water models (Alliant FX/4, 4 processors); and Poisson problem using domain decomposition (IBM-3090VF, Alliant FX/80). Again, future effectiveness of such architectures will depend upon growth in effectiveness of the overall complex of programming languages, compilers, and operating systems, as applied to such parallel performance.

8. SPECIAL-PURPOSE EQUIPMENT STRUCTURES

Because of the increasing ease of design using silicon (or alternative technologies, of which gallium arsenide is the only remote future contender, at the present time), many special-purpose devices for replacement or extension of standard classical machines have been tried; some have been successful. Almost all retained the stored program.

Among past entries not able to be successful commercially were special-purpose database machines. Among those which have proved successful is the graphics image creation machine originally developed at Stanford University, and mapped into silicon by Silicon Graphics. This forms a powerful chip set that has enabled computer graphics presentations on work stations to be markedly sped up at a large decrease in price over previous techniques using the central processing unit.

8.1 Simplified Microprocessor Controllers and Coprocessors

Special simplified controllers have been developed for controlling portions of a microcomputer system. For example, a separate microprocessor, of simplified design, often controls the microcomputer keyboard or the hard-disk drive. Even more simplified special-purpose computers, often without stored programs, control interrupt processing, real-time processing, or analog-to-digital and digital-to-analog conversion outside of the central microprocessor.

The original microprocessors had too few transistors to carry out floating-point arithmetic operations. Therefore, arithmetic coprocessors, on a separate chip, accepted operational commands and data from the central microprocessor. This chip performed the actual multiplications and divisions for scientific and engineering applications programs that required high-speed arithmetic. Successful co-processors of this type were originally off-chip (such as the 80*x*87 floating-point processor for the Intel 80*x*86 series). With growing transistor count on chips, many of these original special-purpose co-processors have since been incorporated into the newer designs which allow for far more functions on the same chip.

8.1.1 Real-Time Applications. Special-purpose real-time microprocessor controllers, such as the Motorola 6802, have become integral parts of automotive systems, acting to control antilock brake systems and to monitor engine behavior. Other classes of specialized digital computers, mass produced in silicon, have found mass applications. Large areas of technology, previously based on analog electronic voltages, are now being manipulated with digital devices. For example, the telephone industry has spawned the digital signal processor, especially made to handle digitized audio signals. High-definition television (HDTV), which has competing analog and digital proposed systems, will probably end up almost completely digital in character, with digital computers as the central controlling and processing elements.

8.1.2 Future Control Devices. Such devices are example of mass-produced, low-cost, stored-program computers, interacting through sensors inputting signals from the outside world. Their output, through effectors, can be used to change and control the outside world. The ability to change their internal behavior, either from outside, or by means of their own program, through tactics of control theory, artificial intelligence, or other heuristic techniques, offers the capability of small, local devices, independently responding, where needed. Their applications to experiment in many areas are still ahead.

8.2 Digital Signal Processors

With its capabilities, an important section of digital computer usage, not ordinarily known to the standard user, is that of the digital signal processor (DSP). These specially designed digital computers are particularly oriented to handle streams of signals in such devices as cellular phones, private branch exchanges, central telephone exchanges, industrial controllers, telephone answering machines, motor controls, multimedia applications, and such internal digital computer mechanisms as hard-disk drives.

The DSPs themselves are now being produced by use of customized design procedures that allow inclusion of new and specialized logical functions on a central computer chip. An example is the Texas Instruments TMS320 series of chips, which allows customized inte gration of analog-to-digital and digital-to-analog converters on the central integrated circuit. Such input–output devices translate from classical audio and other signal levels into digital samples, and conversely.

Such combinations are now being fabricated in low-power CMOS technology, with 32-bit floating point arithmetic units included on the same chip. Unit prices are quoted at "$1/Mflops in 1992," with 27-Mflops units currently being shipped.

The integration of a standard central unit (here the DSP itself, oriented to handling streams of numbers very efficiently), with peripheral elements designed in at the silicon level, produces a chip specific to the application at hand. This is an example of the fundamental logical equivalence of software and hardware and of the continuing movement of functions, originally implemented as programs, into the design of the central silicon chips themselves.

Almost any electronic consumer product, from automotive brake and audio systems to modems and telefacsimile devices, will probably use something like a DSP as its central control element. Most users of standard commercial computers and networks will not directly interface with DSPs. Nevertheless, their existence offers the capability of extension of real-time networks into a broad range of data collection and control procedures, far beyond the standard artifacts most often thought of as computers. As applications arise, other analogous designs, still with stored programs, may extend the range of classical computer systems even further.

9. COMPUTER ECONOMICS IN 1991

9.1 Overall Economics of Computers

Early usage of digital computers entailed high cost of equipment and low productivity due to individual human programming. Financial support was originally economically centered on governmental or large corporation funding.

Moreover, within the United States and Western Europe, construction and distribution of the machines themselves was controlled by means of proprietary systems. These were specially designed so as to prevent easy passage of computer programs from one computer manufacturer's machine to that of another manufacturer. A commercial or scientific user, therefore, was locked into its manufacturer's equipment and programs. Most scientists or engineers involved with large calculations, until recently, at least, may have experienced this situation.

A similar proprietary situation began with the software, although it too generated a conflict: proprietary restrictions vs ease of circulation. On one side, computer programs are easily reproducible using computers themselves (like books with photocopying). On the other, their purchase has become surrounded with complex licensing procedures, copyrights, and other attempts by the vendors to restrict unauthorized reproduction. Just how exactly innovation will be encouraged or discouraged by such processes is still to be worked out, since proprietary families of programs obviously become tied into operating systems, for example.

9.2 Standards Organization

To allow crossover of programs from proprietary hardware or software family to other families, a standardization process began to be developed for hardware, languages, and operating systems. Such standardization mitigates against the restrictions of proprietary hardware, operating systems, and applications programs, all of which aid individual manufacturers in protecting their market share. There is thus a conflict between the forces of commercial hardware and software producers, and the users. The former want to control certain parts of the overall system, to optimize market share and profit. The users want some optimal method of producing the resulting computation at low overall cost in time and money. This clash provides the key continuing dialectic for computers today. Much of the ongoing changes, in particular the effort at standardization, are attempts at resolving this conflict.

9.2.1 International Economic Conflicts. Among the hardware devices that came to be fabricated in quantity, one became an international *cause cèlèbre* rivalling that over imported automobiles. DRAMs became a cheap but powerful method of storing programs and data during processing. Without them, the PC would have been impossible. In the United States, only the largest manufacturers such as IBM and AT&T were able to compete with their own in-house versions of these devices.

Overseas, this part of the computer technology market became economically dominated by Japanese integrated circuit manufacturers, often accused of "dumping" products below cost onto the American market. This alleged oligopoly and its future effect on production of U.S. computers (mirrored by alleged U.S. control of microprocessor production) became a prime "political football" in U.S.–Japanese economic relations. This economic conflict emphasizes the rapid rise of computers to a most important level in the international economy. The DRAM's marketing as a commodity product demonstrates the importance of the standardization process for hardware, here built around the concept of interchangeable electronic parts.

With standardization, the sociological structure of machine usage began to form around standardized technological artifacts: standard hardware, standard languages, standard operating systems, and standard graphical user interfaces. Behind these standards, the hardware and software being distributed began to be commodity products, sold on price and effectiveness, not the proprietary products sold on the historical necessity of the user not losing the investment in past hardware and software. Standardization began when U.S. and European governmental organizations, such as the Department of Defense (DOD), and industrial user or vendor consortia began to negotiate common standards. Among classically important ones were the ALGOL standards, the International Standards Organization agreements on the open systems interface, and the standards on the FORTRAN, COBOL, and ADA languages, the latter two required for U.S. governmental program procurement. Such standards increased the probability that hardware and software from different origins would nevertheless interact with each other successfully.

9.2.2 Hardware Becomes a Commodity Product. As a result of this effort, at the end of the 1980s, the economics of computer manufacture, marketing, and usage began to change markedly. Before, the use of proprietary hardware (the IBM series of IBM-360 and subsequent mainframes) or of proprietary operating systems (such as the VAX-VMS system of Digital Equipment Corporation) locked users into a continuing sequence of same-vendor equipments.

During the last years, much of the computer industry has been forced out of this pattern. A lead story in a September 1991 Wall Street Journal, entitled "Computers Become A Kind of Commodity, To Dismay of Makers," indicates the extent of this change. This report, as well as somewhat more technical reports in trade journals, lists the changes:

1. Customers, except for the buyers of the larger machines, are buying computers as if they were commodities, attempting to buy as cheaply as possible.
2. Profit margins have dropped; sales channels have been transformed away from retailers towards mail order distribution and mass purchasing. The result of decreased margins has forced virtually every computer manufacturer to try to "reinvent itself." Some manufacturers (e.g., Wang)

no longer sell their own computers, only software for another manufacturer. New alliances, such as that between once archrivals Apple and IBM, are springing up.

3. With the loss of proprietary computer system monopolies and the coming of "open systems," the sale of "clones" (or near-exact duplicates), such as for the IBM PC, brings new competition. New quasimonopolies, for the moment, have arisen in software (such as the Microsoft DOS PC operating system and its Windows derivative). In hardware, Intel, the maker of the system 8086 microprocessors and derivatives, may also be momentarily considered a quasimonopoly, despite the beginning fabrication of duplicates by competitors.
4. The coming of UNIX as a standard operating system offers a new level of open system and commodity product structure. UNIX has now become the standard operating system of computers at the work station level above the IBM PC and its clones. For much of the past, implementation of full-scale UNIX on PC-level machines was impossible because of RAM and hard-disk storage limitations, but recent pricing decreases offer storage capabilities that make UNIX competitive. However, the complexities of the system, without appropriate graphical interfaces such as the open-system X-Windows, do not make it a system for the casual user.

The result predicted is that the number of vertically integrated hardware vendors will decrease markedly, replaced by a smaller number of fabricators in the U.S. and overseas. Consulting and integration companies will become more important. Software companies, with proprietary programs, may replicate the past domination by proprietary hardware systems—until their products, too, become commodity products.

All this, of course, does not take into consideration very much what foreign (most likely Asian) competitors in both areas may do. It also assumes that computers will merge "gracefully" into all areas of modern industrial society, which is far from likely. Nevertheless, such critiques seem to indicate that, whereas the technological future of computers might be considered predictable, their place in the economy may shift drastically due to such technological changes themselves.

New paradigms for computer users that will be designed to hide the actual software–hardware structure will continue to be invented. The beginning capability for computer statistical, neural net, or other "learning" will begin to grow if small practical commercial attempts prove successful. The size of computers, decreasing from main frame to desktop to laptop to notebook size and below, makes new applications suddenly feasible. The interactive one-person, portable computer, connected by cellular phone networks to e-mail and giant database servers, appears almost within the present technological-economic range.

There thus appears to be a dichotomy in future usage: On the one hand, smaller and smaller physical computers will become more tailored to individual users, with these individual software–hardware systems adapting themselves to the needs and idiosyncracies of the individual human with whom they are in synergy. On the other hand, such devices (and others) will also serve as end organs of input–output to giant client-server network systems. These will provide knowledge, computational, and retrieval services for varied forms of information, with many alternative methods of presentation. Interaction with other humans on this network will be rapid and powerful. Problems of misuse of such systems are among the most important not yet posed.

9.3 Fundamental Changes in Scientific Economics

One major effect of the computer revolution on scientists and engineers has been the disappearance of many "wet laboratories." These classical laboratories, where experiments were carried out on the actual physical, chemical, or mechanical devices, have in many cases been replaced by digital computer computations to predict comparable behavior. Wherever the theory is trusted, stored-program computers, with programs to solve problems based on that theory, should often be able to produce predictable results far less expensively.

On the frontiers of a new field, experiments obviously are necessary before any theory can be created or verified. Nevertheless, many highly sophisticated experimental laboratories, such as wind tunnels, are no longer being duplicated in quantity. Predictive behavior of supersonic planes, in most cases, are the results of elaborate computer calculations. The software component of such classical organizations as Bell Laboratories has become an increasingly important financial factor. Originally, the experimental laboratories were often most expensive; they are still present, but economically may no longer dominate. After that the hardware costs of the computer equipment, so often first supported by the government in national laboratories, became a marked burden. Finally, in time sequence, the software development for such computer hardware has become increasingly expensive. The process of prediction and verification of experiment is thus intricately entwined, both technologically and economically, with use, design, and development of both hardware and software. In certain cases, the computer has become the experiment.

GLOSSARY

Adaptive System: A system which changes its behavior as a function of its input.

Analog: Method of representing information by continuously varying physical quantities.

Arithmetic–Logic Unit (ALU): A portion of a computer which performs arithmetic calculations and also makes logical decisions based on the arithmetic results.

Application-Specific Integrated Circuit (ASIC): Usually an IC designed especially for some specific problem solution, as opposed to general-purpose microprocessor ICs.

Basic Input–Output System (BIOS): That part of the operating system concerned with handling the details of input and output procedures; usually stored in ROM.

Bus: A (usually parallel) set of wires connecting many units together in a common pathway for data or instruction passage.

Cache: A small, high-speed storage unit between RAM and the CPU or microprocessor's register storage, that requires far less time to access, and thus allows the computer to run much faster.

Computer-Aided Software Engineering (CASE): An area of study and development of ways to produce effective programs semiautomatically or automatically.

Central Processing Unit (CPU): That part of a computer which interprets the program and carries out instructions.

Chip: A technical term for the usually rectangular piece of silicon substrate onto which integrated circuits are deposited and fabricated as a microelectronic device.

Complex Instruction-Set Computer (CISC): One in which individual operations carry out elaborate data processing. Such designs are alleged by RISC protagonists to be much less efficient, slower, and more costly.

Clone: A "duplicate copy," usually marketed, designed so as to duplicate the performance of the original design. For computers, most recent clones are copies of the IBM PC.

Coarse-Grained: A parallel processing system with each subprocessor working on large subsets of a programming procedure at the same time.

Compiler-Translator: A service program that translates from a higher-level language to the basic machine code language.

Computer Operator: A technician who ordinarily controls the sequence of operations of a computer, originally manually.

Converter: Electronic circuit to transform analog signal representation to digital, and conversely.

Digital: Method of representation of information by variables that can take on only a limited set of discrete values.

Digital Signal Processor: A special type of microprocessor designed specifically to manipulate streams of digital representations, usually of external analog signals.

Dynamic Random-Access Memory (DRAM): Storage device which must continually be refreshed to retain information.

Expert Systems: Programs which attempt to copy the effective behavior of human experts.

Fine-Grained Processing System: A parallel processing system with each subprocessor working on a very small portion of a programming procedure at the same time.

Finite-State Machine: A formal representation of mechanistic behavior describing the overall flow of performance in terms of inputs, outputs, internal states, and functions relating their local behavior.

Flag: Single binary digit indicating the existence of a particular situation—usually the recent occurrence of a particular event, such as an addition operation with overflow.

Floating Point: Numerical encoding in terms of powers of 2 or 10 with fractional coefficients, to allow computation without the overflow obtainable with fixed-length fixed-point numerical representation.

Fuzzy Set: Nontechnically, an imprecisely defined set which allows imprecise but hopefully useful reasoning to be carried out on its behavior.

Graphical User Interface (GUI): A pictorial presentation, usually on a cathode-ray tube, of the user's range of choices for the next step, allowing much easier programming and operation of a computer.

Handshake: A two-way passage of signals between two concurrent portions of an interacting system, that allows synchronization of their behavior.

Hardware: Generic term for any or all computer electronic equipment.

Hot Key: A key on the computer or terminal keyboard that is programmed to cause a sequence of operations to occur that would otherwise require a more elaborate sequence of key strokes.

Icon: A pictorial representation of a file or program, on a GUI.

Interpreter: A continuously resident service program that translates higher-level language on line at run time, performing actions based on the semantics of the linguistic elements.

Interrupt: An external signal from a peripheral to the CPU or microprocessor stating that it needs some type of service.

Local Area Network (LAN): An interconnection of computers usually within a contiguous geographical area.

Machine Code: The simplified code of the actual machine hardware, which translates at run time into actual electronic switching actions.

Macintosh: A very successful personal computer with a file and clipboard paradigm for its CRT presentation, using a mouse.

Main Frame: Classical term for a physically very large expensive CPU with all its peripherals.

Menu: A listing, as in a restaurant, for options—programs, data, etc.—that a programmer may choose to have the computer perform or operate on.

Microprocessor: A CPU fabricated, usually from silicon, with very small transistors and a very small chip substrate.

Multiple Instruction, Multiple Data (MIMD): Description of parallel processing systems that allow many individual processors to work simultaneously, in one program, on different data with different instructions.

Motherboard: A large printed circuit board, constituting the basic physical structure onto which a computer's electronic elements would be mounted.

Mouse: Small hand-held device used to move a cursor around the screen.

MS-DOS: A small operating system originally applied to the IBM PC as PC-DOS; often called simply DOS. (From Microsoft Disk Operating Systems.)

Neural Net: A detailed interconnection of processors with the aim of producing behavior comparable to that of human brain neurons or neuron groups.

Object Oriented Programming (OOP): The use of object-oriented languages to manipulate classes of data structures with common properties, including the partial ordering of inheritance.

Operating System: Control program that performs housekeeping for applications programs, including file storage and retrieval and input–output, also offering simplified language for control.

Parallel Processor: A digital computer made up of more than one subprocessor, which performs more than one instruction at the same time.

PC: Personal computer—a computer, first available about 1978, which usually interacted with only one person.

Pipeline: A processing structure taking sequential information, such as numerical elements in a vector, and processing more than one at a time, to speed up arithmetic or data manipulation.

Polling: Cyclic consultation of peripherals by a CPU or microprocessor.

Protocol: In nondiplomatic usage, the detailed recording of experiments, human interactions, or computer behavior, for example.

Pushdown Stack: A hardware or software structure allowing "last-in, first-out" behavior of storage into it, usually broadened to include even more elaborate storage procedures.

Random-Access Memory (RAM): An electronic read-and-write memory in which every stored element can be consulted equally easily.

Read-Only Memory (ROM): An electronically unchangeable memory that can be consulted at very high speed.

Reduced Instruction-Set Computer (RISC): A computer based on a set of simplified instructions; claimed because of its instructions' simplicity to perform far more effectively than previous designs.

Run Time: That interval when the computer is actually performing a program, as opposed to compile time, when the compiler is operating, or other preliminary intervals not associated with actual performance of the solution program.

Sequential Processor: A digital computer which performs operations only in sequence, not several at the same time.

Silicon Compiler: A compiler–translator whose target language is a linguistic description of an actual chip-fabrication plot.

Software: Generic term for any and all types of programs.

Spread Sheet: A computer program that presents a diagram ruled horizontally and vertically into which numbers, equations, and other information may be entered, to be operated upon by very general operations (such as matrix-vector multiplication, for example). The term "spread sheet" comes from the original paper equivalent.

Static Random-Access Memory (SRAM): Random-access memory that retains its contents without the need of repeated refreshing.

Stored Program: Class of computer where the problem solution procedure is stored in a changeable memory.

Time Sharing: A computer usage method by which many users at terminals share the performance of a powerful central processor.

UNIX: An operating system originally developed by Bell Laboratories about 1970.

User-Friendly: An adjective describing hardware or software which is easy for a nontechnically oriented user to interact with.

Utility Program: A program to aid in understanding and manipulating the contents of storage and behavior of the machine, often after nonpredicted behavior.

Very High-Level Description Language (VHDL): A language for describing computer architecture along with more detailed circuitry description down to integrated circuits.

Video-Tex: An interactive computer-driven public system for interrogating data bases such as telephone books, airline schedules, etc.

Very Long Instruction Word (VLIW): Describing a type of processor that allows concurrent behavior in a single instruction, and therefore speeds up each instruction.

Windows: Rectangular CRT areas in which different data or instruction sets can be presented, so that the user can deal with more than one group of information on the screen at the same time.

ACRONYMS

ALU: Arithmetic-Logical Unit
ASCII: American Standard Code for Information Exchange
ASIC: Application-Specific Integrated Circuit
BIOS: Basic Input–Output System
CAD: Computer-Aided Design
CASE: Computer-Aided Software Engineering
CISC: Complex Instruction-Set Computer
CPU: Central Processing Unit
CRT: Cathode-Ray Tube
DMA: Direct Memory Access
DOS: Disk Operating System
DRAM: Dynamic Random-Access Memory
DSP: Digital Signal Processor
GUI: Graphical User Interface
LAN: Local Area Network
MIMD: Multiple Instruction, Multiple Data
MISD: Multiple Instruction, Single Data
PC: Personal Computer
RAM: Random-access memory
RISC: Reduced Instruction-Set Computer
ROM: Read-Only Memory
SIMD: Single Instruction, Multiple Data
SISD: Single Instruction, Single Data
SQL: Standard Query Language
SRAM: Static Random-Access memory
VHDL: Very High-Level Development Language
VLIW: Very Long Instruction Word

INTRODUCTION

Conformational analysis is the study of the three-dimensional structure of molecules. It specifically deals with spatial arrangements that result from rotations about single bonds between the atoms in molecules (Carey, 1987). Conformational analysis is a major field of physics, chemistry, and biology because the conformation of a molecule has a significant effect on its physical and chemical properties and on its biological activity (Orville-Thomas, 1974).

The following are the objectives of this article:

Provide an overview of conformational analysis, including a complete definition of conformational analysis, a discussion of its importance, and a description of how scientists determine the conformation of a molecule.

Describe some of the major experimental approaches to conformational analysis, including x-ray diffraction, nuclear magnetic resonance (NMR), ultraviolet spectroscopy (UV), infrared spectroscopy (IR), circular dichroism (CD), and optical rotatory dispersion (ORD). This article will not describe all the physical techniques employed for conformational analysis. For a more complete description of experimental approaches, consult the list of Further Reading at the end of this article.

Describe the major theoretical (computational) approaches to conformational analysis, including *ab initio*, semiempirical, and empirical methods, which are part of the more general procedures of conformational analysis called molecular modeling, molecular mechanics, and molecular dynamics.

The example systems described in this article are restricted to organic (carbon-containing) compounds: simple hydrocarbons, peptides, carbon-based polymers, and biological polymers, with emphasis on biological applications. This article does not treat inorganic compounds, which often do not have rotatable single bonds and therefore occur in only one conformation. The reader should understand, however, that conformational analysis of inorganic compounds is also an important field of chemistry and physics. Fortunately, the principles and techniques discussed in this article also apply to inorganic compounds.

1. OVERVIEW OF CONFORMATIONAL ANALYSIS

Organic and biological molecules are made up of atoms joined together with covalent bonds. Most carbon-carbon, carbon-nitrogen, and carbon-oxygen single bonds can readily rotate at room temperature, whereas double and triple bonds have severely restricted rotations. A rotation of more than about 15° in a double or triple bond is extremely rare. Therefore, conformational analysis deals primarily with the different shapes of a molecule as a result of rotations about single bonds or about partially double bonds.

1.1 The Goals of Conformational Analysis

The major goals of conformational analysis can be expressed in terms of the following questions (see Cantor and Schimmel, 1980a; Zimmerman, 1985):

What is the three-dimensional shape of the molecule? The immediate aim of experimental and theoretical conformational analysis is to know the relative locations in space of all the atoms in the molecule being studied.

How does the shape of the molecule change in response to environmental changes? For example, what are the effects of temperature, pressure, and solvent? How does the conformation in the solid state differ from the conformation of the molecule in solution? What are the effects of small ions and other solutes on the conformation of the molecule in solution?

What is the relationship between the conformation of the molecule and its physical, chemical, and biological properties? This question addresses the important structure-function relationship in organic and biological molecules. The question is also important in materials science and polymer science, since the development of new materials depends on an understanding of the conformational properties of the molecules involved.

Can theoretical methods be used to predict the conformation of a molecule? One of the major goals of the modern field of molecular modeling, for example, is to use computational methods to predict the conformational properties of organic and biological molecules.

Given the conformational characteristics of a molecule with known biological activity, can other molecules be designed and synthesized having similar physical and biological properties? This question is the basis for drug design in modern pharmaceutical companies. If a certain molecule, for example, has desirable properties but also has some undesirable side effects, a related molecule can possibly be designed to enhance the desirable effects and diminish the undesirable effects.

1.2 Dihedral Angles

The conformation of a molecule is described completely by the *X*, *Y*, and *Z* Cartesian coordinates of all the atoms in the molecule. Since the conformation is independent of the location of the molecule in space, the number of independent variables is $3N-3$, where N is the number of atoms.

Often the molecule is treated as having fixed bond lengths and bond angles, and therefore the conformation can be described as a set of angles of rotation (called *dihedral angles* or *torsional angles*) about the single bonds. Because of bond stretching and bending, the bond lengths and angles between atoms are in fact not fixed but fluctuate about equilibrium locations. The concept and use of dihedral angles is still valid because the equilibrium locations are essentially constant.

Any dihedral angle θ is defined by the position of four atoms: two central atoms (see atoms 2 and 3 in Fig. 1) connected by the covalent bond whose torsional angle is being described, and two flanking atoms (see atoms 1 and 4 in Fig. 1), each attached to one of the

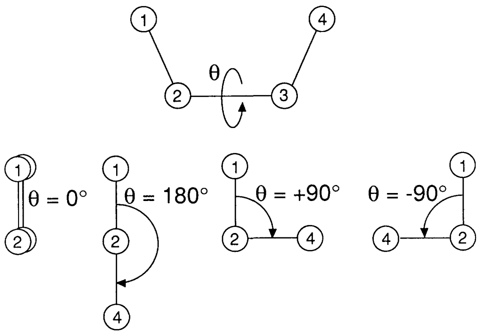

FIG. 1. Definition of the dihedral (torsional) angles θ. When the 1–2 and 3–4 bonds are eclipsed, $\theta=0°$; when those bonds are *anti* or *trans*, $\theta=180°$. Clockwise rotation of the 3–4 bond relative to the 1–2 bond gives positive values of θ; counterclockwise rotation gives negative values of θ.

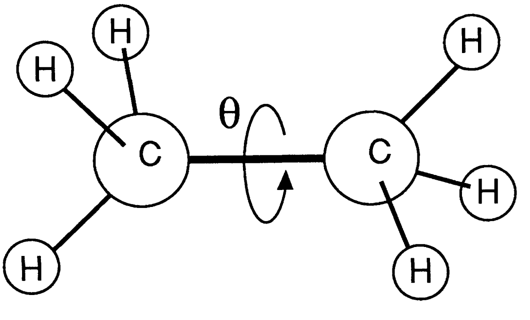

FIG. 2. Ball-and-stick model of ethane.

central atoms. If the four atoms are in the same plane with the two flanking atoms on the *same* side of the bond under consideration, then (by definition) the dihedral angle θ is zero (that is, $\theta=0°$). When atoms 1, 2, and 3 are kept stationary and atom 4 is moved by a clockwise rotation about the bond between atoms 2 and 3, the value of θ increases from 0° to 180°. When the bond is rotated counterclockwise, the value of θ decreases from 0° to $-180°$. When all four atoms are in the same plane but on *opposite* sides of the bond under consideration, the dihedral angle θ equals $\pm 180°$ (IUPAC-IUB, 1970). See Fig. 1.

1.2.1 The Dihedral Angle in Ethane and Butane. One of simplest organic compounds that can exist in different conformations is ethane, CH_3–CH_3. Figure 2 shows a ball-and-stick representation of the structure of ethane. Since the three hydrogen atoms on each carbon are equivalent, the four atoms used to specify the dihedral angle θ (for rotations about the C–C bond) include the two carbons and any one of the three hydrogens on each of the two carbons. The shape of the molecule with a specific θ value can be represented in several ways. The three most common are wedge-and-dash drawings, sawhorse drawings, and Newman projections. Figure 3 shows ethane in all three of these representations with $\theta=60°$, called the *staggered* conformation. Figure 4 shows ethane in the three representations with $\theta=0°$, called the *eclipsed* conformation.

Although all values of θ from $-180°$ to $+180°$ for rotations about the C–C bond in

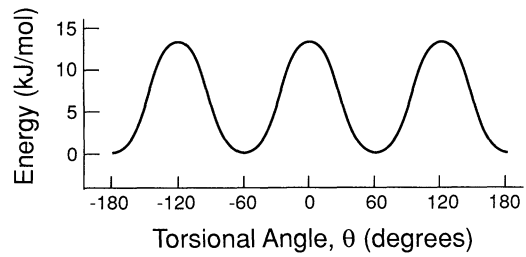

FIG. 5. The potential (conformational) energy of ethane as a function of the torsional angle θ.

ethane are possible, all values of θ are not equally probable, and therefore rotation about the C–C bond is not completely free. The diagram in Fig. 5, derived from experimental and theoretical conformational analysis, shows that the potential energy is a minimum at $\theta=+60°$, $-60°$, and 180°. These three values of θ are, in fact, the same conformation, which is the most stable (lowest-energy) form of ethane. The potential energy is a maximum (13 kJ) at $\theta=0°$ and $\pm 120°$. These values of θ also yield the same conformation, which is the least stable form of ethane.

The conformational properties of organic compounds are further illustrated by examining the rotations about the central C–C bond of butane, CH_3–CH_2–CH_2–CH_3. This molecule can exist in two different stable conformations, one called *gauche* (with $\theta=\pm 60°$) and one called *anti* (with $\theta=180°$). Although both the gauche and anti conformations are stable—that is, they both occur in minimum-energy conformations—anti is the *global* (overall) minimum, having a potential energy of 3.3 kJ lower than the gauche. The potential-energy diagram of butane is shown in Fig. 6.

1.2.2 The Dihedral Angles in Peptides.

Conformational analysis of peptides and proteins is a major field of biophysical chemistry

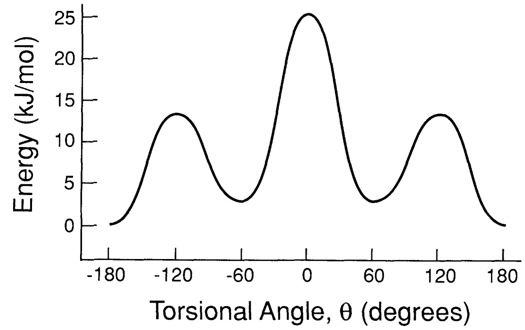

FIG. 6. The potential (conformational) energy of the central C–C bond of butane as a function of the torsional angle θ.

because the shape of a protein is the major factor in determining its biological function.

Peptides and proteins are composed of amino acids joined together with peptide bonds. Naturally occurring amino acids have the general structure shown in Fig. 7(a). Two amino acids joined together by a peptide bond are generally called dipeptides [Fig. 7(b)]; three amino acids joined together with two peptide bonds are generally called tripeptides; and so forth. Long, unbranched chains of amino acids joined together with peptide bonds are called polypeptides. If the polypeptide is a naturally occurring biological molecule, it is called a protein.

The dihedral angles that dictate the conformation of peptides and proteins are ϕ, ψ, ω, and χ (see Fig. 8). Angle ϕ is the dihedral angle described by the four atoms C′–N–C$^\alpha$–C′ that is, rotation about the N–C$^\alpha$ bond. (C$^\alpha$ is the α carbon, adjacent to the carboxyl carbon in an amino acid. C′ is the carbonyl carbon in a peptide unit.) Angle ψ is described by the atoms N–C$^\alpha$–C′–N, that is, rotation about the C$^\alpha$–C′ bond. Angle ω is described by the atoms C$^\alpha$–C′–N–C$^\alpha$, that is, rotation about the C′–N or peptide bond. The peptide bond has partial double-bond character because of the overlap of the unpaired electrons on the nitrogen with the π-electrons of the C═O double bond. Since the peptide bond has partial double-bond character, ω is usually found to have the value 180° (planar trans) or, on rarer occasions, the value 0° (planar cis). Angle χ is a rotation about a side-chain bond (see Fig. 8).

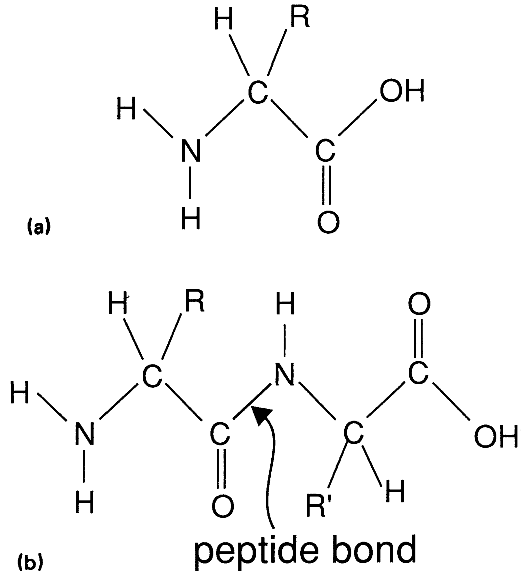

FIG. 7. (a) The structure of an amino acid (shown here in its un-ionized form). (b) The structure of a "dipeptide." R represents an organic substituent that defines a specific amino acid. For example, R is –CH$_3$ in the amino acid alanine.

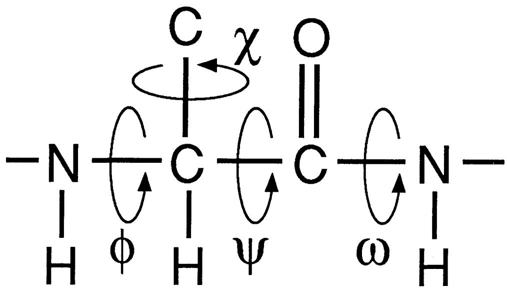

FIG. 8. The Greek letter designations of the angles of rotation in peptides and proteins.

A theoretical analysis of the molecule N-acetyl-N′-methylalanineamide (Fig. 9), a model of an amino acid unit within a polypeptide or protein, yields the contour plot (Fig. 10) of the conformational potential energy as a function of the dihedral angles ϕ and ψ, with ω and χ being fixed at 180° and 60°, respectively (see Zimmerman *et al.*, 1977). (A conformational-energy contour plot is a three-dimensional potential-energy curve analogous to the two-dimensional curves shown in Figs. 5 and 6.) The diagram shows lines of constant energy at increments of 1 kcal mol^{-1} (4.186 kJ mol^{-1}) above the global minimum at about $\phi = -80°$, $\psi = 80°$ (marked with a +). For simplicity, lines for conformational energies greater than 9 kcal mol^{-1} (40 kJ mol^{-1}) above the global minimum have been omitted from the plot. This large blank space indicates disallowed conformations in which the ϕ-ψ values cause

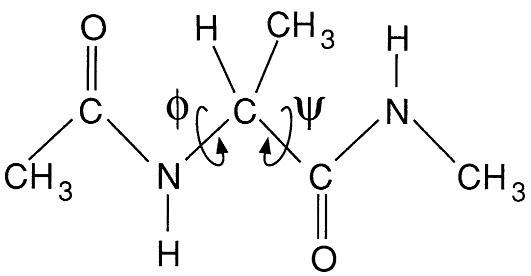

FIG. 9. The structure of N-acetyl-N′-methylalanineamide, a model of a single alanine residue in a peptide or protein.

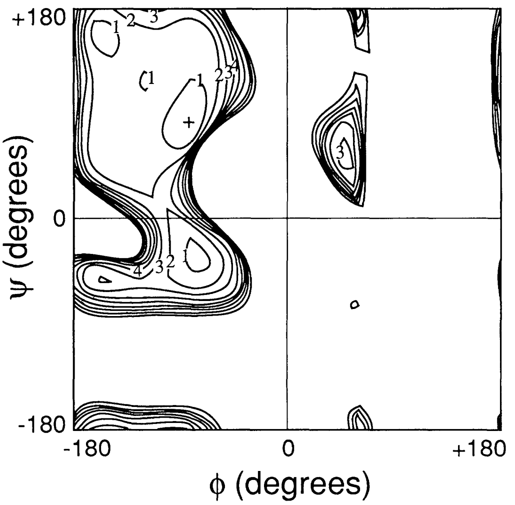

FIG. 10. The conformational energy contour map of the alanine residue (*N*-acetyl-*N'*-methylalanineamide). The + marks the global minimum. Lines of constant energy are drawn for 1–9 kcal mol^{-1} above the global minimum.

overlaps between one or more pairs of atoms in the peptide molecule.

Figure 11 shows the conformation of the global minima of N-acetyl-N'-methylalanineamide. This conformation ($\phi = -80°$, $\psi = 80°$) is called C_7^{ax} because the hydrogen bond forms a seven-member ring (or cyclic) structure and the alanine side chain is approximately in the same plane as (that is, axial to) the seven-membered ring.

The above discussion of butane, ethane, and peptides demonstrates the nature of conformational analysis and lays the foundation for the discussions of experimental and theoretical techniques in conformational analysis.

2. EXPERIMENTAL TECHNIQUES

Chemists and physicists have developed a wide range of experimental techniques for analyzing the conformation of organic and biological molecules. Each technique has its own special set of advantages and disadvantages, depending on the type and amount of information that the technique provides, the purity and size of sample required to perform the experiment, the ease of varying environmental conditions, the effort required to prepare samples and obtain results, and so forth (Cantor and Schimmel, 1980b; see MOLECULAR SPECTROSCOPY). In many cases, two or more techniques are required to yield the desired conformational data.

The following is a brief description of some of the most popular experimental techniques in conformational analysis.

2.1 X-Ray Diffraction

X-ray diffraction is a powerful technique for determining the precise location of the atoms in a molecule (see X-RAY DIFFRACTION). The technique is based upon three principles:

1. Electrons scatter x rays such that the amplitude of the scattered wave is proportional to the electron density of the sample;
2. the scattered waves recombine constructively or destructively; and
3. the way in which the scattered waves combine (interfere) depends upon the distances between the reflecting planes and the wavelength of the electromagnetic radiation.

For constructive interference to occur (that is, for the reflected waves to be reinforced), the equation

$$2d \sin\theta = n\lambda \qquad (1)$$

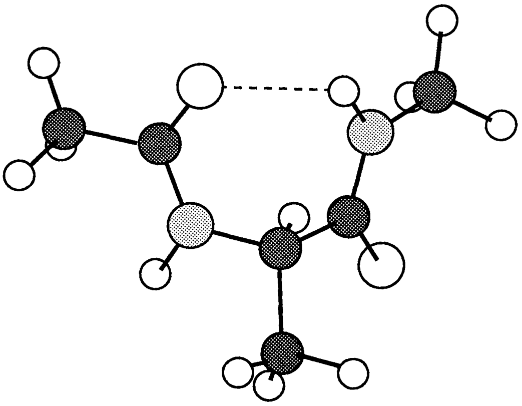

FIG. 11. The conformation of the alanine residue (N-acetyl-N'-methylalanineamide) in its global minimum. The dotted line represents a hydrogen bond. This conformation is called C_7 because the hydrogen bond forms a cyclic group of seven atoms. The large white atoms are oxygen; the small white atoms are hydrogen; the light gray atoms are nitrogen; and the dark gray atoms are carbon. The backbone atoms of alanine begin with the first nitrogen from the left and proceed right to the C^{α} atom and then to the C' (carbonyl) atom.

must be satisfied, where *d* is the perpendicular spacing between the lattice planes in the crystal, θ is the angle between the incident (or the reflected) beam and the plane of the reflecting particles, *n* is an integer, and λ is the wavelength. This is called the Bragg law.

Since bond lengths in molecules are $\sim 1.5 \times 10^{-10}$ m (~ 15 nm), the wavelengths of the radiation must also be in the range of ~ 15 nm. That is, the diffracting electromagnetic radiation must be x rays, which have wavelengths of 10^{-12}–10^{-7} m.

To determine the locations of the atoms within a molecule using x-ray diffraction requires these general steps:

1. Purifying and crystallizing the sample.
2. Measuring the diffraction angles and intensities using an x-ray diffractometer.
3. Calculating electron-density maps based upon the data gathered from the diffractometer and analyzed using Fourier transforms (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS).
4. Relating the location of the atoms within the molecules to the electron-density maps.

The major advantage of x-ray diffraction is that the precise location of all the atoms (except hydrogen) within the sample molecule can be obtained. The conformation of the molecule in the crystalline state is therefore known unequivocally. The major disadvantages of the technique are that

1. producing a crystal of sufficient purity and size can be difficult or even impossible, especially for large molecules;
2. gathering and analyzing data can be extremely time consuming (although modern diffractometers and computers have removed much of the tedium from the process); and
3. determining the dynamics of conformational change in response to environmental changes is usually impossible.

An x-ray structure represents the single most stable conformation of the molecule based upon intermolecular and intramolecular interactions. Molecules in the gas phase or in solution, on the other hand, can often exist in (and interconvert among) many different conformations. Therefore, the x-ray structure may have little relationship to the physical and chemical properties of the molecule in solution.

2.2 Nuclear Magnetic Resonance

Nuclear magnetic resonance (NMR) is one of the most popular tools for analyzing the conformation of organic and biological molecules (see NUCLEAR MAGNETIC RESONANCE; MAGNETIC RESONANCES, DETERMINATION OF STRUCTURES BY). This popularity results from three factors (Freifelder, 1982):

1. the theory of NMR is sufficiently developed to determine—at least in principle—the arrangement of all the atoms in a molecule from the NMR spectrum;
2. hydrogen atoms—whose electron densities are too low for observation by x-ray diffraction—can be located using NMR; and
3. different types of nuclei—such as ${}^{1}_{1}$H, ${}^{13}_{6}$C, ${}^{15}_{7}$N,—can be examined separately.

Moreover, NMR is effective in analyzing conformations in solution and in measuring conformational changes in response to environmental changes. For species with molecular weights < 500, NMR can usually yield the locations of all the atoms in the molecule. For larger species, where determining the precise locations of all the atoms may be impossible, NMR can still yield much valuable information about the conformation, including hydrogen-bonding schemes, interatomic distances between certain atoms, and binding by other species.

The principles of NMR can be understood from the quantum-mechanical description of atomic nuclei (see ELECTRONIC STRUCTURE OF ATOMS). Consider, for example, the nucleus of a hydrogen atom. Its proton possesses two possible "spin" quantum numbers (angular momentum eigenvalues): $+1/2$ and $-1/2$. Each of these spin states gives rise to a magnetic field whose strength and direction is expressed as the magnetic moment μ. When a proton is placed in an external magnetic field of strength H_0, the magnetic moment of the proton can assume one of two angles relative to the direction of H_0: θ (aligned with) or $180-\theta$ (aligned against the external magnetic field). The difference in potential energy between these two magnetic states is $2\mu H_0 \sin\theta$.

When a proton absorbs this amount of energy—which lies within the radio-frequency range of the electromagnetic spectrum—the proton undergoes a transition between the two magnetic states. The proton is said to "flip" from one orientation to the other.

What has been stated about protons (the nuclei of hydrogen atoms ^1_1H) is also true of other atomic nuclei, most notably $^{13}_6C$, $^{15}_7N$, $^{19}_9F$, and $^{31}_{15}P$. All have a quantum-mechanical spin number I of $\frac{1}{2}$, which gives rise to two nuclear energy levels in the presence of an external magnetic field.

If all nuclei exposed to the same applied magnetic field underwent a transition at the same frequency, NMR would have little value in determining molecular conformations. In reality, however, when a molecule is placed in an applied magnetic field, the individual nuclei within the molecule do not see the same magnetic field. The effective magnetic field, H_{eff}, seen by each nucleus differs from the applied magnetic field H_0, because each nucleus in a molecule is surrounded by electrons that also generate a magnetic field of their own, thus "shielding" the nucleus to some degree from the applied magnetic field. Moreover, the effective magnetic field seen by nucleus is influenced by the magnetic field of nearby nuclei. Thus, the observed resonance frequency of a particular nucleus depends on its environment. This is why NMR spectroscopy is valuable in conformational analysis; each nucleus of the same type has a resonance frequency that depends on the conformation of the molecule.

The major advantages of NMR are that the technique can

1. yield data from ensembles of conformation (although they are sometimes difficult to understand);
2. provide information about conformational dynamics;
3. yield spectra of samples in the solid, liquid, or gas states, including aqueous and nonaqueous solutions; and
4. provide a considerable amount of conformational information, including precise locations of atoms in small molecules.

The major disadvantages are that

1. the signals from water can sometimes interfere with the sample signal from proton (^1H) NMR (although taking the spectrum in D_2O or using high-resolution Fourier-transform NMR instruments can usually overcome this problem);
2. the spectra from dilute or impure samples are difficult to obtain; and
3. the spectra of large, complex molecules are difficult (and sometimes impossible) to interpret.

2.3 Ultraviolet Absorption Spectroscopy

Ultraviolet (UV) absorption spectroscopy has long been used as an analytical technique for identifying compounds and determining concentrations, but it also has value in analyzing conformational properties of compounds. For example, the UV absorption spectrum of a polypeptide can be used to demonstrate the presence of α-helices, β-pleated sheets, or nonregular ("random coil") structure, and to analyze helix-to-coil transitions.

UV spectroscopy cannot match x-ray crystallography or NMR spectroscopy for the amount of detailed information obtained, but UV spectroscopy has fewer experimental constraints. The major advantage of UV spectroscopy over most other popular techniques is that spectra can be obtained from only partially purified samples, from dilute solutions, and from small samples, with relatively inexpensive instruments. Moreover, changes in conformation as a function of change in temperature, pressure, or other environmental conditions are easily monitored with UV spectroscopy.

UV spectroscopy is based upon transitions between different electronic energy levels of the electrons upon absorbing UV light (electromagnetic radiation with a wavelength below 400 nm). For example, the amide unit in peptides and other molecules undergoes the so-called n-π^* transition at ~220 nm, the π_1-π^* transition at ~190 nm, and the π_2-π^* transition at ~165 nm. The exact values of these transitions depend upon the specific type of molecule and on its conformation. In the synthetic polypeptide poly-L-lysine, for example, the location of the maximum in the absorption spectrum is at 191 nm for the α-helix, 193 nm for the random coil, and 196 nm for a β-pleated sheet. Although these changes are small, they can be measured accurately. Moreover, the differences in the amount of absorption are more dramatic: the three types of conformation have molar absorptivities of 4300, 7100, and 7800, respectively (Gratzer, 1967).

UV spectroscopy, therefore, is a powerful technique in conformational analysis when the spectra of different conformations have been well characterized and the goal of the analysis is to determine the general conformation of the sample or to study its conformational changes.

2.4 Infrared Spectroscopy

Infrared spectroscopy (IR) is best known as a tool for determining structures of organic compounds, but it can also be used as a tool in conformational analysis. For example, O–H and H–H groups produce different IR absorption bands depending on whether or not they are involved in a hydrogen bond (see MOLECULAR SPECTROSCOPY).

IR spectroscopy is based upon the absorption of electromagnetic radiation by transitions in the vibrational levels (due to bond stretching and bending) in a molecule. The energies of these transitions are generally in the range of infrared radiation, which has a wavelength range of 10^{-6}–10^{-4} m (1–100 μm). IR spectra usually cover the range 2.5–16 μm, which corresponds to the wave-number range of 400–625 cm^{-1}. (Traditionally, IR absorption is plotted as a function of wave numbers rather than wavelengths.)

One of the major disadvantages of traditional IR spectroscopy is that the absorption band for H_2O (and in some cases even D_2O) occurs in the same wave-number range as the main absorption bands of many organic and biological molecules, greatly diminishing the value of IR spectroscopy in analyzing conformations in aqueous solutions. With the advent of Fourier-transform infrared spectroscopy (FT-IR), the technique has greatly increased in its usefulness as a method of conformational analysis.

2.5 Circular Dichroism and Optical Rotatory Dispersion

One of the most useful techniques for analyzing the conformations and the conformational changes of asymmetric (or optically active) compounds, particularly biopolymers, is circular dichroism (CD) and the related technique, optical rotatory dispersion (ORD). In concept, CD and ORD provide the same information, but in practice, CD has become the method of choice because its spectra show greater sensitivity to conformation.

When plane-polarized light passes through a sample of a chiral compound, the light is changed in two ways:

1. The maximal amplitude is no longer confined to a plane but rather traces out an ellipse. The resulting ellipticity of the light is defined as the arc tangent of the ratio of the minor axis to the major axis of the ellipse. CD is a measure of the ellipticity caused by the chiral compound.
2. The orientation of the ellipse may be rotated. In other words, the plane of polarized light is rotated. Optical rotatory dispersion is a plot of the amount of rotation as a function of wavelength.

Consider an alternative way of looking at ellipticity. Plane-polarized light can be resolved into two circularly polarized components of equal amplitude. The sum of the two components at all points results in the original plane-polarized wave. In an optically active medium, the left circularly polarized light (A_L) and the right circularly polarized light (A_R) are absorbed differently. This is called circular dichroism. When the two opposite circularly polarized waves are combined, the result is an ellipse, as shown in Fig. 12. Thus, CD is equivalent to ellipticity. A CD spectrum is a plot of the ellipticity θ (or specific ellipticity, $[\theta]$) as a function of wavelength.

The major advantages of CD and ORD are that the spectra are sensitive to conformational changes and that the environmental conditions are easily modified. Thus, conformational changes in biopolymers are easily monitored using ORD and CD. For example, Fig. 13 shows the CD spectra of poly-L-lysine (a model polypeptide) in α-helix, β-pleated sheet, and random coil conformations (Greenfield and Fasman, 1969). In the figure, $[\theta]$ is

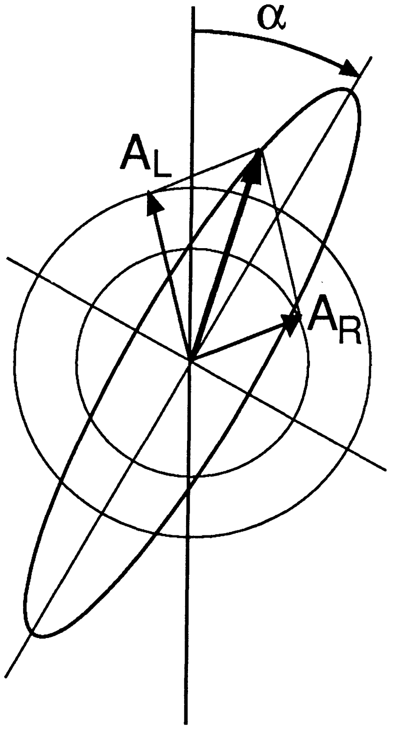

FIG. 12. Circular dichroism and optical rotation. The circular dichroism (or ellipticity) is proportional to the difference between the amplitude of the left circularly polarized wave A_L and of the right circularly polarized wave A_R. The optical rotation is given by α.

the specific ellipticity, and the wavelength λ is taken in the ultraviolet region where the peptide unit absorbs light. Notice the huge difference in the spectra for the three different types of conformation. CD can likewise be used to analyze the general conformation of proteins, carbohydrates, and nucleic acids, as well as other kinds of molecules.

2.6 Other Experimental Techniques

The five experimental techniques discussed above are the most popular methods for analyzing the conformation of molecules, but they are by no means the only methods. Other popular experimental techniques include fluorescence spectroscopy, ultracentrifugation (and other hydrodynamic techniques), light scattering, Raman spectroscopy, Mössbauer spectroscopy, electron paramagnetic resonance spectroscopy, and so forth. For a general description of these techniques, see Cantor and Schimmel (1980b) and Freifelder (1982).

3. THEORETICAL TECHNIQUES

Theoretical (computational) techniques are valuable in the conformational analysis of organic and biological molecules because the results of a theoretical analysis can

1. provide a model or framework to aid in choosing proper experiments;
2. help explain experimental results; and
3. provide information about conformational properties of molecules when experiments are difficult or impossible to perform.

The major objectives of theoretical analysis are

1. to calculate the conformational properties of a molecule given its covalent structure;

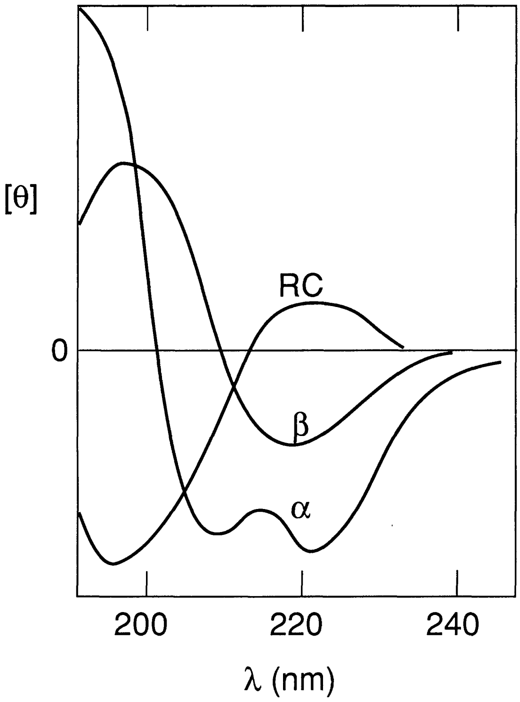

FIG. 13. The circular dichroism spectrum of poly-L-lysine in three different conformations: α-helix, β-pleated sheet, and random coil (RC). The conformational changes are induced by changing the pH. From Greenfield and Fasman (1969).

2. to determine the effects of the environmental conditions on the conformation; and
3. to relate the calculated conformation of a molecule to its physical properties and its biological activity.

3.1 Empirical Methods

Empirical methods of conformational analysis involve empirical equations (that is, equations based on experiment or observation without regard to fundamental theory) that relate the positions of the atoms to the conformational energy, and involve parameters used in the empirical equations. In a so-called molecular mechanics system, computer software employs the equations and parameters to calculate the conformational energy, minimize the total conformational energy for locating local and global minima, and display on a computer monitor a graphic representation of the conformations.

A commonly used empirical equation (Momany *et al.*, 1975; Feller *et al.*, 1989) is the so-called Lennard-Jones "6-12" potential:

$$U_{\mathrm{NB}}=F\epsilon\left(\frac{r_g}{r_{ij}}\right)^{12}-2.0\epsilon\left(\frac{r_g}{r_{ij}}\right)^{6}, \qquad (2)$$

where r_g is the equilibrium distance between the atoms i and j, ϵ is the energy at the equilibrium distance, and r_{ij} is the distance between atoms i and j. The positive (repulsive) term contains r^{12}, and the negative (attractive) term contains r^6. The attractive term is the London dispersion force (London, 1937). The F is an adjustment factor taken as 1.0 for 1–5 interactions (those between atomic pairs separated by at least four bonds) and as 0.5 for 1–4 interactions (those between atomic pairs separated by three bonds). The subscript NB stands for "nonbonded," meaning the energy of interaction between atoms that are not bonded to each other. The values of r_g and ϵ depend on the particular types of atoms involved in the interaction.

Along with the Lennard-Jones 6-12 potential, conformational energy calculations also require an equation to take into account the electrostatic interactions. For example, the most common equation for determining electrostatic energy between two atoms is

$$U_{\mathrm{el}}=kq_iq_j/Dr_{ij}, \qquad (3)$$

where k is a constant to ensure that the energy has the correct units, q_i and q_j are the partial charges on atoms i and j, D is the dielectric constant, and r_{ij} is the distance between atoms i and j.

For certain types of bonds (particularly double bonds), the nonbonded and electrostatic energies do not completely describe the restricted rotation observed for the bond. Therefore, torsional energy is also used in some procedures to determine the conformational energy:

$$U_{\mathrm{tor}}=\frac{U_0}{2}(1\pm\cos n\theta), \qquad (4)$$

where U_0 is the maximum torsional energy, θ is the torsional angle, and n is the symmetry of the barrier.

The total conformational energy of a molecule in a particular conformation is the sum of nonbonded energies U_{NB} and electrostatic energies U_{el} for all i,j pairwise interactions and of all the torsional energies U_{tor}. This procedure was used to calculate the total conformational energy at each ϕ, ψ point of the conformational energy contour map shown in Fig. 10. It can also be used to analyze the conformational properties of larger peptides and other biological and organic compounds. Because the calculations require large amounts of computer time, the procedure does not permit the complete conformational analysis of proteins, nucleic acids, carbohydrates, or other macromolecules.

In many approaches to molecular mechanics, the bond lengths and bond angles are also considered variable. Appropriate potential-energy functions include not only the interactions between the nonbonded atoms, but also between the bonded atoms (Burkert and Allinger, 1982).

3.2 Quantum-Mechanical Approaches

Pullman (1976) has argued that empirical energy functions "suffer from two obvious drawbacks. In the first place, whatever the practical justification for the partitioning of the total potential energy into a series of components, the procedure involves necessarily an element of arbitrariness and, possibly, incompleteness. In fact, most authors take into consideration different selected components only and frequently different sets of them in different publications. Secondly, the fundamental formulas and parameters used to define the various components are far from being well established and differ, often appreciably, from one author to another."

The conclusion that Pullman and others draw from these observations is that only quantum-mechanical methods, not empirical methods, have the ability to account for the subtle quantum-mechanical effects that may be part of the conformational properties of a molecule.

These arguments certainly have some merit. Quantum mechanics has indeed contributed to the field of theoretical conformational analysis (see QUANTUM MECHANICS). But in actual practice, quantum-mechanical methods also involve a certain degree of arbitrariness, require broad approximations, and involve huge amounts of computer time (Zimmerman, 1985). Both quantum-mechanical and empirical methods are valuable in addressing the problems of molecular conformations, since each approach brings to the problem its own strengths and weaknesses.

The most popular semiempirical molecular-orbital methods used for conformational analysis include the extended Hückel (EHT) method (Hoffman, 1963), the complete neglect of differential overlap (CNDO/2) methods (Pople and Segal, 1966), and the all-valence electron molecular-orbital (perturbative configuration interaction using localized orbitals) method (Diner *et al.*, 1969) (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES).

EHT is a molecular-orbital treatment in which the interactions between electrons in different orbitals are ignored. CNDO/2 assumes the atomic orbitals are spherical when electron repulsions are evaluated. Directionality of p orbitals is included, however, through the so-called one-electron resonance integrals. CNDO calculations are aimed primarily at reproducing electronic properties, such as dipole moment (Clark, 1985).

Perturbative configuration interaction using localized orbitals goes beyond CNDO/2 by including a refined molecular-orbital all-valence electron procedure that incorporates an appreciable fraction of the correlation energy (Maigret *et al.*, 1971).

Ab initio methods (see QUANTUM MECHANICS) are also used in theoretical conformational energy analysis (e.g., see Shipman and Christofferson, 1973; Peters and Peters, 1981).

3.3 Applying Theoretical Techniques

Whether using empirical, semiempirical (molecular-orbital), or *ab initio* theoretical methods, the theoretician utilizes the following general steps in determining the conformational properties of a molecule:

1. Selecting a set of initial trial conformations, either randomly (e.g., using a Monte Carlo method; see Li and Scheraga, 1987) or systematically (e.g., by stepping through all of conformational space).
2. Calculating the total conformational energy of the molecule in each of the trial conformations. If the theoretician selects and calculates enough trial conformations, the results will yield the most favored (lowest-energy) conformation or will provide an ensemble of conformational states on which to base a statistical-mechanical analysis.
3. Minimizing the total conformational energy for each of the trial conformations to yield local and global minima. If this method yields a large number of minima, the set of minima may constitute the partition function for a statistical-mechanical analysis of the conformational properties. If minimization yields a small number of minima, inspection of those minima may provide all the necessary information about the conformational properties of the molecule.

Applying these techniques to peptide molecules, as an example, has yielded important information about the structure-function relationship in biological systems (see Zimmerman, 1985).

GLOSSARY

α-Helix: A polypeptide or protein conformation in which the backbone chain forms a right-handed screw with 3.6 amino acid residues per turn and a pitch (rise per turn) of 54 nm.

β-Pleated Sheet: A polypeptide or protein conformation in which the backbone chains are extended and hydrogen bonded to adjacent chains.

Conformation: The overall three-dimensional shape of a molecule.

Contour Plot: A plot of the conformational energy of a molecule as a function of two variable dihedral angles. Each contour line represents conformations of equal energy.

Dihedral Angle: The rotational angle of a bond, defined such that the angle is 0° when the two bonds flanking the torsional bond are eclipsed when looking along the bond and 180° when the two flanking bonds are *anti* (or *trans*) to each other.

Global Minimum: The conformation of the lowest energy of a molecule.

Local Minimum: A conformation found at a minimum-energy point (not necessarily the lowest, or global, minimum).

Molecular Modeling: A technique that employs computer graphics and calculations to study molecular conformations and dynamics.

Molecular Mechanics: A method for calculating the conformations of molecules based upon empirical energy functions.

Random Coil: A statistical ensemble of polymer conformations in which the backbone of the molecule has no order.

Torsional Angle: See dihedral angle.

3.1
Introduction

This chapter discusses the fundamental physical constants of nature such as the speed of light in vacuum c, the mass of the electron m_e, the Newtonian gravitational constant G, the elementary charge e, the Planck constant h, the Avogadro constant N_A, Faraday constant F, the Rydberg constant (for infinite mass) R_∞, the fine-structure constant α, the Josephson constant K_J, and the von Klitzing constant R_K. Such constants are nature's true invariants in contrast to, say, the freezing point of gallium, or the time required for the Earth to revolve once about its axis, which can be changed–for example, the former by impurities and the latter by seasonal effects. It does not necessarily mean that there might not exist a deeper set of constants in terms of which the above fundamental constants may ultimately be expressed, as indeed some of them, such as the above Faraday, fine-structure constant, the Rydberg constant, and others may be already be expressed in terms of e, h, μ_0, and c. Thus, they have a unique place in science and technology and have even acquired a certain mystique. Determination of their values spurred a considerable amount of activity that peaked between about 1970 and 1985. There are many important combinations of the fundamental constants that are widely used in science and technology. The 2006 CODATA (Committee on Data for Science and Technology) evaluation of the ''best'' values for the fundamental constants contains some 300 recommended values for various combinations of the constants. It is convenient to discuss progress in this field of endeavor with respect to the recommended values referred to the chapter by Barry Taylor in the earlier edition of the *Encyclopedia of Applied Physics* on this topic that we update here.

In all of our fundamental theories, there appear a certain few parameters that characterize the fundamental particles and the interactions that we find in nature. These are termed the *fundamental physical constants*.The precision determination of the numerical values of these constants, in terms of International System of Units (SI) units when they are dimensioned constants, has long been and still remains one of the principal objectives of experimental science. This is not because there is any intrinsic virtue in accumulating lists of numbers with ever more decimal places, but because the fundamental constants are the quantitative links between our most basic theories and the physical reality of our universe that we wish them to describe. Our theories must stand

ISBN: 978-3-527-40666-1

or fall according to their ability to make quantitative predictions that agree with experimental observations to the maximum achievable accuracy. The progress of our understanding of the physical world is therefore very much interwoven with the advance of the art of precision measurement and its application to the determination of the fundamental physical constants.

This chapter provides an illustration of the *raison d'etre* for striving for increased measurement accuracy that Maxwell and many other scientists have long recognized:

> *... the opinion seems to have got*
> *abroad that in a few years all of*
> *the great physical constants will*
> *have been approximately measured*
> *and the only occupation which*
> *will be left to men of science will*
> *be to carry on these measurements*
> *to another place of decimals....*
> *But the history of science shows*
> *that even during that phase*
> *of her progress in which she*

> *subjugation of new regions which*
> *would have remained unknown*
> *if she had been content with*
> *the rough methods of her early*
> *pioneers.* (Maxwell, 1871)

Advances in accuracy continue to be made. Over the last 80 years, measurement accuracy has advanced about 10-fold every 15 years, a process that may well continue until natural limits are reached. Not only has this topic had its share of Nobel Prize winners but, in recent years, there also have been notable advances in both theory and experiment relevant to the fundamental constants with applications moving out into the market place. New technologies have made possible new levels of precision: Computers have made possible more complex calculations. The advent of increasingly stable lasers has led to new levels of accuracy being achieved in many different experiments, for example, optical spectroscopy in the visible region with Hertz-level, that is fractional 10^{-16} accuracy (Coddington, Swan, and Newbury, 2008; Ludlow *et al.*, 2008), and measurements of the Rydberg constant with fractional 10^{-12} accuracy level (Fischer *et al.*, 2004; Hänsch *et al.*, 2005). The discovery of the Josephson effects (JEs) in superconductors and the quantum Hall effect (QHE) in semiconductors have provided new ways to determine several important fundamental constants. Ion traps and atom traps of single particles have increased measurement times. There has been steady progress in precision measurements of the properties of fundamental particles and simple atomic systems.

Current theoretical and experimental efforts in this field span almost the whole of physics, from elementary particle theory to experimental solid-state physics. The intercomparison of measurements at the highest accuracy via very different methods in different parts of science permits detailed examination to be made of the coherence of science as a single entity. In an increasing number of cases, the experimental accuracy has reached an artificial limit set by our ability to realize the appropriate combination of the practical units of measurement, the SI. A consequence of this has been the increasing application of methods of measuring fundamental constants either to maintain more stable SI units, or to incorporate them into the definitions of the unit(s) concerned–as happened in 1983 when the value of the speed of light was adopted as the present definition of the meter. This is approaching the point where most of the SI base units are definable in terms of fixed values for fundamental constants.

There are also interrelationships between the measurable combination of fundamental constants and related quantities, for example, the Rydberg and fine-structure constants, $2e/h$ via the JE, realizations of the absolute ohm and ampere, the quantized Hall resistance, the electron and muon anomalous magnetic moments, the proton-to-electron mass ratio, the proton gyromagnetic ratio, Faraday, and Avogadro constants. Consequently it is appropriate, indeed even necessary, for the solid-state theorist to be aware of the work of the electrical metrologist; the atomic mass spectroscopist of the work of the precision electrochemist; and the quantum electrodynamics (QEDs) theorist of the work of the experimental semiconductor physicist. The fundamental constants of nature and closely related precision measurements are truly the common meeting ground for many of the disciplines of science and technology.

It is clear from the earlier part of this introduction, that the field of fundamental constants too broad for any one does more than touch upon a few key selected topics. However, these should provide the reader with a reasonable picture of the field, especially the very important interplay between theory and experiment that is the key to scientific progress. As elsewhere in science, much of the beauty of the subject lies in the detail, including how the measurements were made in the laboratory or the detailed calculations of the theoretician were brought to the meeting ground between theory and experiment at the fractional part in a billion (1×10^{-9}) level of accuracy to $<1 \times 10^{-12}$ and beyond. Both the measurement and the calculation may well have taken 10–15 years but the work is distilled into a four-page article!

The earlier reviews of the recommended values of the fundamental constants proceed at appropriate intervals of about once every 10 years. The date attributed to each review refers to the latest date for which published data was included. Thus the 2006 evaluation had a closure date of 31 December 2006 and was published in 2008. The values in this review replaced those in the 2002 review. It is important for the coherence of science that as far as possible scientists use the same values for the fundamental constants. Birge pioneered the subject and published the first major review of the values in 1929 (Birge, 1929) and most subjects were happy to adopt his recommended values. Since then the reviews have usually been mainly made by two or three people. However, since the 1970s, reflecting that the subject has become increasingly international, the reviewers have been supported by an international committee known as the *CODATA Task Group on Fundamental Constants.*Recently, the CODATA Task Group reviews have taken place every four years. From time to time others have been motivated to perform their own reviews, for example, the Taylor, Parker, and Langenberg review in 1969 (Taylor, Parker, and Langenberg, 1969) and the 1975 review by Tuninskii and Kholin (1975) and Tuninskii (1986). These reviews have been welcomed and, in several cases, have helped clarify discrepancies and have thereby served to progress the subject.

The main body of the chapter (Section 3.2) begins with a brief discussion of the "origins" of the fundamental constants, that is, how they might be usefully categorized; and a lengthier discussion of "the challenge and romance of the next decimal place,'' their importance and why their determination to ever greater levels of accuracy can have a profound effect on physics as a coherent whole by allowing any small differences between constants measured by very different measurements to be thoroughly investigated.

Besides the earlier example of the Millikan oil-drop determination of the elementary charge, a later illustration, which is featured here, comes from work in the late 1960s through the determination of the quotient $2e/h$ via the JE in superconductors (a topic in which two of the present authors participated). The derivation of a value of the fine-structure constant (α) from it, when combined with other constants, enabled the use of the resulting value of α to test the QED theory of the ground-state hyperfine splitting of the hydrogen atom to well beyond the sixth decimal place. A similar example that is still under active investigation is also presented in which a value of α obtained from the QHE is used to test the QED theory of the electron magnetic moment anomaly a_e.

In Section 3.3, we discuss how sets of the ''best values'' constituting the recommended values of the fundamental constants are derived, particularly concentrating on the 2006 CODATA least-squares adjustment of the constants, which is the most recent internationally accepted evaluation currently available. In this section, we include some of these recommended values for a comprehensive group of constants, which are taken from the 2006 CODATA set.

The realization of the definitions of the SI units is very time consuming. Modern science and technology relies on making measurements involving time and frequency and electrical quantities, and there is a universal need throughout the world to maintain a continuous representation of the SI units. In Section 3.4, we discuss the importance of the fundamental constants to technology by reviewing the 1 January 1990 introduction of new practical representations of the volt and ohm as defined in the SI. These representations, based on the JEs and quantized Hall effects, and the consequent internationally adopted values of the Josephson and von Klitzing constants K_J and R_K, are now being used worldwide in electrical metrology to derive and maintain representations of the volt and ohm to fractional accuracies of 10^{-9} or better.

In Section 3.5, we discuss the principal advances made in the fundamental constants field since the 1986 CODATA adjustment was completed and discuss their implications for the least-squares adjustment of 2006. In Section 3.6, we further consider the importance of the fundamental constants to modern technology, and illustrate these by exploring the likely future role of the constants in replacing the definition of the kilogram, the only SI base unit that is still defined in terms of a prototype material artifact, and to similarly replace the definitions of other SI units. In Section 3.7, we briefly discuss the question of why the constants have the particular values that they do, and their possible variation with time. Finally in Section 3.8, which concludes the main body of the chapter, we look ahead in an attempt to see where the fundamental constants field might be heading over the next decade.

It is useful at this point to mention briefly some aspects of the history of the measurements of the fundamental constants. Modern measurements of the fundamental constants really began at the start of the twentieth century modern physics, with the advent of quantum theory, relativity, and atomic and nuclear physics. The two notable exceptions were c and

G, which were first measured in the eighteenth century.

Extraordinary advances in determining the values of the constants were made immediately after 1945 as a result of the significant advances made in electronics, microwaves, and other technologies during World War II. A second period starting in about 1970 has also been especially productive because of the wide introduction of highly sophisticated digital electronic instruments, lasers, computers, and cryogenic techniques. To a considerable extent, the accuracy with which the fundamental constants have been known at any given epoch has depended upon the level of sophistication of the measuring instruments and apparatus available at the time. However, it is not only improvements in measurement technology that have led to more accurate values of the constants. The discovery of new phenomena, such as the JEs and the quantized Hall resistance effects, that provide new and better methods for determining certain constants have also led to significant advances in the field.

Measurements of the constants and the frontiers of measurement science or metrology, especially the development of new reference standards for the units of measurement, have always been closely linked, but in recent years the distinctions between them have all but disappeared. Perhaps the most striking example of this is the determination of c in the early 1980s based on extremely difficult measurements of the frequencies and wavelengths of several different laser radiations. As a direct consequence of this work, the definition of the SI unit of length, the meter, which, since 1960s was based on a particular optical transition in the ^{86}Kr atom, was replaced in 1983 with one that was based on an adopted value for the speed of light (Petley, 1983; Giacomo, 1984; Hudson, 1984).

As discussed in Section 3.6, if current efforts to determine h or N_A with a relative uncertainty of about 1×10^{-8} are successful, it is very probable that this scenario will be repeated with regard to the kilogram in the second or third decade of this century. There may be consequent changes to our definitions of the electrical units, while a fixed value for the Boltzmann constant may well be incorporated into a revised definition of the kelvin. This will be an important topic for the next meeting of the General Conference on Weights and Measures (CGPM) scheduled for 2011. Any changes to the definitions of the SI units are framed so as to ensure continuity in the sizes of the units concerned while ensuring that they anticipate or keep pace with the improvements in measurement accuracy enabled by, and demanded by, future progress in science and technology.

3.2
Conceptual Origins and Importance of the Constants

3.2.1
Conceptual Origins of the Constants

Three distinct ''sources'' of the fundamental constants may be identified. The first is the physical theories that have been developed to describe nature's basic laws, for example, Maxwell's theory of electromagnetism, Einstein's theories of relativity, quantum mechanics, and QED, and their application as appropriate to atomic systems. c, G, h, α, and R_∞, fall within this category. These particular constants (see Section 3.1) are of particular importance in science because c is the velocity of all electromagnetic radiation or photons (in vacuum) and the limiting velocity of all energy and matter; G determines the strength of the gravitational force between bodies; h is the fundamental constant of quantum mechanics and determines the energy of a quantum of radiation of a given frequency; R_∞ sets the scale of the energy levels of atoms; and α determines the strength of the electromagnetic force that governs how electrically charged elementary particles and electromagnetic radiation interact.

The second source is the fundamental particles such as the electron, proton, and neutron. The elementary charge e, the rest mass of the electron m_e, the rest masses of the proton and neutron m_p and m_n, the magnetic moment of the electron in units of the Bohr magneton, namely μ_e/μ_B, where $\mu_B = eh/4\pi m_e$, and the magnetic moments of the proton and neutron in units of the nuclear magneton, μ_p/μ_N and μ_n/μ_N, respectively, where $\mu_N = eh/2m_p$, respectively. These are all examples of quantities that characterize a basic property of the elementary building blocks of nature.

Conversion factors are the third source. Although not true fundamental constants like those in the first two categories, these quantities nevertheless play a critical role in the measurement of fundamental constants in terms of the SI units. Examples include the local value of the gravitational acceleration g, which relates mass to force; the ratio of the old X-ray unit of length or kilo-x-unit to the nanometer; and also the ratio of various so-called as-maintained electrical units in a particular national standard's laboratory to their SI definitions, for example, Ω_{NPL} where Ω_{NPL} is the National Physical Laboratory (NPL) as-maintained ohm. Prior to 1 January 1990 the laboratories local ohm standards were maintained as the mean resistance of a particular group of wire-wound standard resistors that were kept in an oil bath at 25°C.

It should be noted that $\alpha = e^2/(4\pi\varepsilon_0\hbar c)$ and $R_\infty = m_e c\alpha^2/(2h)$ are examples of constants that are actually combinations of other quantities, but are considered fundamental constants in their own right since the combination always appears in theoretical equations in the same way. (Here the magnetic constant, $\mu_0 = 4\pi \times 10^{-7}\ \mathrm{N\,A^{-2}}$, exactly, is the permeability of vacuum, and the electric constant $\varepsilon_0 = c^2/\mu_0$.). Many other similar examples are found in Table 3.1 of this chapter.

3.2.2
Importance of the Constants

There are at least four reasons why the fundamental physical constants play a critical role in science and technology and hence should be known as accurately as possible.

1. Accurate values of the constants are required for the critical comparison of theory with experiment, and such comparisons that advances in our understanding of the physical world. A closely related outcome is that by comparing the numerical values of the same fundamental constants obtained from experiments in the different fields of physics, the self-consistency of the basic theories of physics themselves can be tested with increasingly high accuracy (see Section 3.1).
2. The determination of the values of the fundamental constants more accurately fosters the development of new state-of-the-art measurement methods that may have a wider application. Determining the next decimal place is never trivial and usually requires an entirely new measurement technology that, as mentioned elsewhere, can take

Tab. 3.1 Recommended values of some selected physical constants.

Quantity	**Symbol**	**Value**	**Units**	**Relative uncertainty**
Speed of light in vacuum	C	299 792 458	$\mathrm{m\ s^{-1}}$	Exact
Permeability of vacuum	μ_0	$4\pi \times 10^{-7}$	$\mathrm{N\ A^{-2}}$	(Exact)

Rydberg constant	R_∞	10 973 731.568527(73)	$\mathrm{m^{-1}}$	6.6×10^{-12}
Avogadro constant	N_A, L	$6.02214179(30) \times 10^{23}$	$\mathrm{mol^{-1}}$	5.0×10^{-8}
Faraday constant	F	96 485.3399(24)	$\mathrm{C\ mol^{-1}}$	2.5×10^{-8}
Molar gas constant	R	8.314472(15)	$\mathrm{J\ mol^{-1}\ K^{-1}}$	1.7×10^{-6}
Boltzmann constant	K	$1.3806504(24) \times 10^{-23}$	$\mathrm{J\ K^{-1}}$	1.7×10^{-6}
Stefan–Boltzmann constant $(\pi^2/60)k^4/\hbar^3c^2$	σ	$5.670400(40) \times 10^{-8}$	$\mathrm{W\ m^{-2}\ K^{-4}}$	7.0×10^{-8}
Non-SI units accepted for use with the SI				
Electron volt	eV	$1.602176487(40) \times 10^{-19}$	J	2.5×10^{-8}
(Unified) atomic mass unit	U	$1.660538782(83) \times 10^{-27}$	kg	5.0×10^{-8}

The digits in parentheses represent the one-standard-deviation uncertainty in the last digit(s) of the given value.

Taken from the 2006 CODATA least-squares adjustment by Mohr, Taylor, and Newell (2008).

10–40 years to bring from conception to fruition. An example is the determination of the Avogadro constant N_A, which necessitated the development of techniques to measure the lattice spacing of pure, single crystals of silicon directly in terms of meter with a relative uncertainty of 1/10th of a part per million, all uncertainties are one-standard-deviation estimates.) The result has been the extension of our ability to make accurate measurements of length in SI units to the picometer or 10^{-12}-m range and the demise of the x-unit used for measurements of X-ray and γ-ray wavelengths. Work toward an improved Avogadro constant continues using isotopically pure silicon-28.

3. Measurements of the fundamental constants also provide the key to the development of a reproducible and invariant system of measurement units, which is also a major global goal of measurement science or metrology. This marks the culmination of a long path from the use of properties of seeds and the human body, and later via properties of water and properties of the Earth, to the units used at present based on fundamental constants. Notable early examples of the latter were the involvement of the Faraday constant to maintain the International ampere at the end of the nineteenth century and the more recent involvement of the speed of light in the definition of meter resulting from the improved measurement accuracy of high frequency radiation and other technology associated with the development of radar, which were later allied with the development of highly monochromatic and stable lasers through to the visible region and beyond, and the later satellite Global Positioning System (GPS).

From the time of Maxwell, Johnstone-Stoney, Planck, Dirac, and countless others, the development of SI units that are really constant in space-time has progressed to become a reality today. The future role of artifacts such as the platinum–iridium cylinder kept in a vault at the International Bureau of Weights and Measures (BIPM), that at present defines the SI kilogram, will be to act as a flywheel to maintain sufficiently constant representations of a mass unit defined in terms of a fundamental constant. The development of ever more accurate atomic clocks for terrestrial time in applications have led to astrophysical investigations well beyond the Solar System such as monitoring the stability of the millisecond pulsars or the comparison of different types of atomic clock enabling investigations pertaining to the invariance of dimensionless constants such as α and m_p/m_e over the age of the universe.

4. Finally, values of the fundamental constants are required for computations and measurements throughout science and technology–for example, the calculation of the excited states of atoms and molecules that play an important role in air pollution monitoring, nuclear energy, and nuclear fusion.

3.2.3

QED and the Josephson Effect Determination of $2e/h$

As an example of the significant role improved measurements of fundamental constants can play in increasing our understanding of physical theory, consider the accurate determination of the quotient $2e/h$ using the JE in weakly coupled superconductors by a method that was first reported in the late 1960s (Parker, Taylor, and Langenberg, 1967). This also provides an illustration of the way in which limitations in the accuracy of the realization of the electrical units in various countries impacted in a dramatic way on our knowledge of the fundamental physical constants.

When a Josephson tunnel junction–for example, two thin films of lead separated by a 1-nm-thick thermally grown oxide layer–is irradiated with microwave radiation of frequency f, its current versus voltage curve exhibits current steps at highly precise quantized Josephson voltages U_J (Barone and Paterno, 1982; Gallop, 1991). The voltage of the nth step, $U_J(n)$, where n is an integer, is related to f by

$$U_J(n) = nf/K_J \tag{3.1}$$

where K_J is known as the Josephson constant $(= 2e/h)$. Note that it is the inverse of the superconducting magnetic flux quantum $\Phi_0(= h/2e)$.

The theory of the JEs predicts that

$$K_J = 2e/h \tag{3.2}$$

and, to date, the experimentally observed universality of Equation 3.1 is entirely consistent with the prediction. The exactness of this equation when subject to changes in the operating conditions (frequency, temperature, material, different apparatus, etc.) has been verified with fractional uncertainties ranging from parts in 10^9 to 10^{16}. It follows from Equation 3.1 that a measurement of f and U_J for the nth step will yield a value of $2e/h$. The result reported in 1969 (Parker *et al.*, 1969) using 8–12 GHz microwaves was

$$K_J = 2e/h = 4.835\,976(12) \times 10^{14}\,\mathrm{Hz/V_{NIST-69}} \tag{3.3}$$

where $\mathrm{V_{NIST-69}}$ is the unit of voltage maintained at the US National Institute of Standards and Technology (NIST) in 1969[1]. We mention in passing that symbols for units are in upright Roman type, and in an italic font for quantities.

Their value was rapidly confirmed by the 36-GHz measurements of Petley and Morris (1970) at the NPL after due allowance was made for the different voltage units maintained in the two countries. It was swiftly confirmed by other national standards laboratories, notably in Australia and Germany. At that time the maintained volt was based on the mean electromotive force (emf) of a group of electrochemical standard cells. These had the disadvantage that their emf depends on temperature and other factors. The JEs enabled provided a known constant voltage and the existence of this enabled the technology of standard cell manufacture to be improved rapidly. In 1972, the Consultative Committee on Electricity (CCE) recommended a value for K_{J-72} for volt maintenance purposes. This value has since been revised as K_{J-90} and provides an internationally agreed representation of the SI volt.

---

[1] A note on uncertainties. In Equation 3.3, the number in parentheses represents the one-standard-deviation uncertainty in the last digits of the quoted value. It should also be noted that the uncertainty is a quasi-statistical combination of essentially two types of uncertainty, essentially one that represents the fluctuations of the measured value during the measurement and the second from quantities, which may be in error but have not varied during the measurement. Currently, these are characterized by the terms Type A and Type B, respectively, and have built on the earlier concept of random and systematic uncertainties (fluctuations in the measured value may well not be truly random and part of the art of this type of measurement lies in identifying as many as possible of these causes (e.g., someone using a hammer, switching off equipment, or thermostats, etc.). International agreement has been made on how to evaluate such uncertainties, see the document known as the

GUM : Guide to the expression of the Uncertainty of Measurement JCGM (1995). ISO/IEC Guide 98:1995 Guide to the expression of uncertainty in measurement (GUM). Geneva, Switzerland, International Organization for Standardisation (International Organization for Standardisation) (see also, e.g., *http://www.bipm.org/en/committees/jc/jcgm/wg1_bibliography.html* and *http://physics.nist.gov/Pubs/guidelines/TN1297/tn1297s.pdf*. Interestingly, uncertainty estimates are made by theoreticians as well as experimenters and it has also become essential to give an uncertainty for the numerical results of theoretical calculations.

The difference between K_{J-72} when expressed in SI units (hertz per volt) and the previous best value, namely, that resulting from the 1963 least-squares adjustment of the fundamental constants (Cohen and DuMond, 1965), was (35 ± 10) parts per million. As discussed later, the cause of this rather severe discrepancy was the use in the 1963 adjustment of a value of α derived from the early 1950s measurement of the fine-structure splitting of the deuterium atom (energy difference between the $2^2\mathrm{P}_{3/2}$ and $2^2\mathrm{P}_{1/2}$ atomic energy levels), which subsequently turned out to be incorrect.

Because QED, the relativistic quantum field theory that describes the interaction of charged particles and electromagnetic radiation or photons, is one of the most precise and important theories of modern physics (Kinoshita, 1990a), and involves knowledge of the fine-structure constant, it is essential to see how well the topic can withstand stringent experimental tests. The Josephson $2e/h$ determination is therefore significant for QED mainly because a reliable indirect value of QED-independent value of α can be derived from it, and this value can in turn be used to compare QED and experiment critically and unambiguously. This is in marked contrast to the situation that existed prior to 1967 when no such value was available and tests of QED were mainly checks of internal consistency.

The equation relating α to $2e/h$ may be written as

$$\alpha = \left[\frac{4R_\infty(\Omega_{\mathrm{LAB}}/\Omega)\gamma_p'(lo)_{\mathrm{LAB}}}{c(\mu_p'/\mu_B)(2e/h)_{\mathrm{LAB}}}\right]^{1/2} \tag{3.4}$$

where, as before, $\Omega_{\mathrm{LAB}}/\Omega$ is the ratio of the laboratory as-maintained ohm to the SI ohm; μ_p'/μ_{B} is the magnetic moment of the proton in units of the Bohr magneton (throughout, the prime means that the protons are not free but are in a spherical sample of pure water at 25°C); and $\gamma_p'(\mathrm{lo})_{\mathrm{LAB}}$ is the gyromagnetic ratio of the proton obtained by the so-called low (magnetic) field method and is measured in terms of the laboratory as-maintained unit of current, $A_{\mathrm{LAB}} = V_{\mathrm{LAB}}/\Omega_{\mathrm{LAB}}$. (Note that the more general subscript LAB (for laboratory) may be replaced by the subscript NIST, say, for measurements made at the US national standards' laboratory); and that $\gamma_p' = \omega_p'/B$, where ω_p' is the proton nuclear magnetic resonance or spin-flip angular frequency in the magnetic field (magnetic flux density) B. In the low-field method, B is established via a precision solenoid of known dimensions carrying a current known in terms of A_{LAB}.) The value of α derived from Equation 3.3 in 1969 (Taylor, Parker, and Langenberg, 1969) using the best data available was

$$\alpha^{-1} = 137.036\,08(26) \tag{3.5}$$

Included among the quantities that require an accurate value of α for comparing theory and experiment are the g-factors of the electron and muon; the energy levels in hydrogen-like atoms, especially the $n = 2$ Lamb shift ($2^2\mathrm{S}_{1/2} - 2^2\mathrm{P}_{1/2}$ splitting); and the ground-state hyperfine splitting in hydrogen, muonium (an electron bound to a positive muon or μ^+e^- atom), and positronium (a bound electron–positron pair or e^+e^- atom).

Of particular interest in the late 1960s was the hydrogen hyperfine splitting ν_{Hhfs}. This transition frequency, which corresponds to essentially the energy difference between a hydrogen atom in which the electron and proton spins are aligned and one in which they are in opposite directions, has been determined experimentally with the extraordinary accuracy of 1 part in 10^{12} using the hydrogen maser. The theoretical QED equation for ν_{Hhfs} is

$$\begin{aligned}\nu_{\mathrm{Hhfs}}(\mathrm{theor}) = (16/3)\, cR_\infty \left(\mu_p/\mu_B\right) \\ \times \left(1 + m_e/m_p\right)^{-3} \\ \times \alpha^2 \left(1 + \mathrm{h.o.c.}\right) \qquad (3.6)\end{aligned}$$

where h.o.c. are higher order corrections.

In contrast to the 1×10^{-12} relative uncertainty of $\nu_{\mathrm{Hhfs}}(\mathrm{expt})$, Equation 3.6 is limited to an accuracy of a few parts in a million because of the difficulty in calculating some of the higher order corrections. (Even in the late 1960s, c, R_∞, μ_p/μ_B, and m_e/m_p were sufficiently well known for their total contribution to the fractional uncertainty of $\nu_{Hhfs}(\mathrm{theor})$ to be considerably less than 10^{-6}.)

The most uncertain higher order correction to Equation 3.6 was $\delta_N^{(2)}$, the proton polarizability contribution, which arises from the various excited states or internal structure of the proton. In the late 1960s, theoretical calculations predicted $\delta_N^{(2)} = (0 \pm 5) \times 10^{-6}$. This was in conflict with what was implied by the value of α accepted at that time, which, as noted earlier, was derived from a measurement of the fine-structure splitting in deuterium. The deuterium value of α was used to calculate $\nu_{Hhfs}(\mathrm{theor})$ from Equation 3.6, when this result was compared to $\nu_{Hhfs}(\mathrm{expt})$ as obtained from the hydrogen maser and, when their difference was assumed to arise solely from the existence of a polarizability term, it was found that $\delta_N^{(2)} = (43 \pm 9) \times 10^{-6}$. This meant that the probability for $\delta_N^{(2)}$ to be as small as predicted by direct calculation was only 1 in 20 000, an obvious inconsistency. In contrast, when the value of α derived from the JE measurement of $2e/h$, Equation 3.5, was used in place of the deuterium value, it was found that $\delta_N^{(2)} = (2.5 \pm 9) \times 10^{-6}$, in keeping with the theoretical calculations.

Hence the JE value of α removed a discrepancy that during the 1960s was termed one of the major unsolved problems of QED. This example further illustrates the overall unity of science–a low-temperature, solid-state physics experiment has provided information about the excited states of the proton–as well as how precise measurements of the fundamental constants can illuminate apparent inconsistencies in our physical description of nature. It also illustrates why one of the most accurately measured quantities, the hydrogen maser frequency, does not contribute to our knowledge of fundamental constants other than the polarizability of the proton.

The other aspect of Equation 3.4 lies in the two methods of measuring the gyromagnetic ratio of the proton that are characterized by the terms $\gamma_p'\left(\mathrm{lo}\right)_{\mathrm{LAB}}$ and $\gamma_p'\left(\mathrm{hi}\right)_{\mathrm{LAB}}$, respectively.

In the low-field determination, the spin precession frequency is measured in a weak magnetic field, such as is produced by passing a current $i(\text{lo})_{\text{LAB}}$ through a precisely wound helical solenoid and in the high-field method the flux density is "measured" by weighing the force mg on a precisely wound rectangular that is suspended between the poles of an electromagnet, carrying a current $i(\text{hi})_{\text{LAB}}$, where m is the mass required to balance the magnetic force when the local gravitational acceleration is g. Taking both currents as having measured in terms of the same laboratory units one may combine the resulting two equations in two ways, one to eliminate the currents to obtain γ_p' and the other to eliminate γ_p' and hence obtain a realization of the SI definition of the ampere, also remembering that

$$\begin{aligned}&\gamma_p' B(\text{lo}) = \gamma_p'(\text{lo})_{\text{LAB}} B(\text{lo})_{\text{LAB}} \quad \text{and}\\ &\gamma_p'(\text{hi}) B(\text{hi})_{\text{LAB}} = \gamma_p B(\text{hi}) \qquad (3.7)\end{aligned}$$

Much of the difficulty of either method came from the need to measure the coil dimensions very accurately, yet the dimensions of γ_p' are coulombs per kilogram. This led Kibble (1975) to wonder whether there might be a way of adapting and combining the two methods into a realization of both quantities (Flowers and Petley, 2001). This led him to propose the method of realization of the electrical watt, which is the method behind the present best measure of determining h and the proposed new definition of the kilogram that is discussed in Section 3.5.

3.2.4
QED and the Quantum Hall Effect Determination of h/e^2

Another example of a critical test of QED, is one that is still under active experimental and theoretical investigation at present, this involves the QHE and the magnetic moment anomaly of the electron $a_e = g_e/2 - 1 = \mu_e/\mu_B - 1$, where g_e is the g-factor of the electron.

The current best experimental value for $a_e = (g_e-2)/2$, is that by Gabrielse *et al.* ([2006, 2007]) at Harvard using a single electron stored in a Penning-type ion trap. This work achieved a formidable fractional accuracy of 6.6 parts in 10^{10} and this is about six times smaller than an earlier Penning trap measurement at the University of Washington by Van Dyck, Schwinberg, and Dehmelt (1987).

$$a_e = 1.159\,652\,85(76) \times 10^{-3} \qquad (3.8)$$

The QED theoretical expression for a_e may be written as (Kinoshita and Lindquist, 1990b)

$$\begin{aligned} a_e(theor) &= A_1^{(2)}(\alpha/\pi) + A_1^{(4)}(\alpha/\pi)^2\\ &\quad + A_1^{(6)}(\alpha/\pi)^3 + A_1^{(8)}(\alpha/\pi)^4\\ &\quad + \ldots + \delta a_e A_1^{(2)} = 1/2\\ A_1^{(4)} &= -0.328478965579\ldots\\ A_1^{(6)} &= 1.181241456\\ A_1^{(8)} &= -1.7283(35) \qquad (3.9)\end{aligned}$$

The total uncertainty in a_e(theor) assuming α is exactly known is now $2.4 \times 10^{-10}\ a_e$, with the dominant uncertainty being that ascribed to the tenth order term, $A_1^{(10)} = 0.0(3.7)$. A test of QED, by comparing a_e(theor) with a_e(expt), to the full accuracies of a_e(theor) and a_e(expt) therefore requires a measured value of α having an uncertainty at or significantly less than $2.4 \times 10^{-10}\ a_e$. Such a value is not yet available, but one close to this has been obtained from the Harvard (Gabrielse *et al.*, 2006) and Washington (Van Dyck, Schwinberg, and Dehmelt, 1987) values for the fine-structure constant that are

$$\alpha^{-1} = 137.035999711(96) \quad \text{and}$$
$$\alpha^{-1} = 137.03599883(50) \qquad (3.10)$$

respectively.

The fractional uncertainty contribution from the QED theory to the conversion from a_e to α is estimated to be about 2.4×10^{-10}–a triumph of achievement for both theory and experiment.

The theory and measurement of the muon anomaly at Brookhaven, (Brown *et al.*, 2001) has similarly led to a measurement of a value of α^{-1}, denoted α_μ^{-1} of

$$\alpha_\mu^{-1} = 137.03567(26) \qquad (3.11)$$

which provides valuable confirmation of our understanding of the muon as an elementary particle. The hyperfine splitting in muonium has also been measured, and this can lead to a value for α^{-1}, of 137.036 0017(80).

Other tests of QED have been made by comparing the spin precession and cyclotron frequencies of hydrogen-like heavier atoms (highly ionized atoms with one electron remaining). Measurements of the g-factor ratio of hydrogen-like carbon and oxygen have been made at GSI Darmstadt and the University of Mainz (Werth *et al.*, 2002) by comparing the ratios of the spin precession and cyclotron frequencies in a Penning trap an experimental value of

$$\frac{g_g - (^{12}\mathrm{C}^{5+})}{g_e - (^{12}\mathrm{O}^{7+})} = 1.000497273218(41) \qquad (3.12)$$

and similarly a double Penning trap measurement of the ratio of the spin precession to the cyclotron frequency of hydrogen-like $^{16}\mathrm{O}^{7+}$ (that is oxygen from which all but one of its electrons have been removed) gave

$$\frac{f_s(^{16}\mathrm{O}^{7+})}{f_c(^{16}\mathrm{O}^{7+})} = 1.000497273218(41) \qquad (3.13)$$

Both of these are also in good agreement with some formidable QED calculations.

The QHE is a behavior characteristic of a completely quantized two-dimensional electron gas (Prange and Girvin, 1990; Yoshioka, 2002). Such a gas may be realized in a high-mobility semiconductor device such as a silicon metal-oxide-semiconductor field-effect transistor (MOSFET), or a device made from gallium–aluminum–arsenide as a heterojunction of standard Hall bar geometry in an applied magnetic flux density of the order of 10 T and cooled to about 1 K. Hence, in common with the JE, the QHE is a low-temperature, solid-state physics phenomenon.

It is found that for a fixed current I (typically 10–50 μA) through the device, there are regions in the curve of Hall voltage U_H, versus gate voltage for a MOSFET, or of U_H versus B, for a heterojunction, where U_H remains constant as either the gate voltage or B is varied. These regions of constant U_H are termed *quantum Hall plateaus.*Inthe limit of zero dissipation (zero voltage drop) in the direction of current flow, the Hall voltage-to-current quotient $U_H(\mathrm{i})/I$ or Hall resistance $R_H(\mathrm{i})$ of the ith plateau, where i is an integer (we consider only the integral QHE), is quantized and given by

$$R_H(i) = U_H(i)/I = R_K/i \qquad (3.14)$$

where R_K is the von Klitzing constant (named in honor of Klaus von Klitzing, who discovered the QHE in 1980 and for which he was awarded a Nobel Prize in 1985).

The theory of his effect predicts that

$$R_{\mathrm{K}} = \frac{h}{e^2} = \frac{\mu_0 c}{2\alpha} \tag{3.15}$$

Measurements show consistency with Equation 3.9 within a few parts in 10^{10}.

Since in the present SI, $\mu_0 = 4\pi \times 10^{-7}$ N A^{-2} exactly, and $c = 299792458\,\mathrm{m\,s}^{-1}$ exactly as a result of the 1983 redefinition of the meter in terms of the speed of light, it is apparent from (Equation 3.10) that a measurement of R_K in SI units (i.e., ohms) with a given uncertainty will yield a value of the fine-structure constant α with the same uncertainty.

In practice, R_K is measured in terms of Ω_{LAB} (indicated as $(R_K)_{\mathrm{LAB}}$) so that the conversion factor $\Omega_{\mathrm{LAB}}/\Omega$ must be determined in a separate experiment notably by using an apparatus known as a *calculable cross-capacitor* in which the unknown resistance of a reference resistor is compared with the known impedance of the capacitor. Nevertheless, the QHE has already yielded a value of α with an uncertainty of 2.4 parts in 10^8 (Shields, Dziuba, and Layer, 1989). When used to compare a_e(theor) with a_e(expt), it gives a difference of a_e(expt)$-a_e$(theor) $= a_e = (4.1 \pm 2.5) \times 10^{-8}$. Since the 4.1×10^{-8} difference is only 1.7 times the 2.5×10^{-8} standard deviation of the difference, the difference between theory and experiment a_e is within statistically acceptable limits. Since QED actually predicts the value of the entire electron g-factor, then a consequence of the near equality of $g_e(\mathrm{expt}) = 2(1 + a_e(\mathrm{expt}))$ and $g_e(\mathrm{theor}) = 2(1 + a_e(\mathrm{theor}))$, is that this agreement confirms the validity of the renormalization processes inherent in QED theory to the hitherto unprecedented level of four parts in 10^{11}.

3.2.5
The Quantum Metrology Triangle

The JE provides a measurement of $2e/h$ in terms of voltage, V, and similarly the quantized Hall resistance a measurement of h/e^2 in terms of resistance. There is an interesting third measurement that can be obtained from single electron tunneling (SET), which provides a measurement of the elementary charge e in terms of a current, I, and a driving frequency ν giving three relations with two unknowns.

The measurement of e by SET has been implemented on the charging of an isolated capacitor by the transfer of single electrons by the application of an alternating voltage at close to the maximum that a stochastic frequency can be counted; if this is 10 GHz, then one has a charging current of about 1.6 nA on a 10^{-16} F capacitor–a rather small current to measure with a fractional accuracy of about 10^{-6} or better. However, Mark Keller and his colleagues have achieved this accuracy at NIST in the United States (Keller, Zimmerman, and Eichenberger, 2007). This has excited considerable interest throughout the world and work is presently in progress in at least four national institutes: in France, Germany, United Kingdom, and United States. To date, this leg of the triangle has been verified to about a fractional part in 10^6 and is hoped to improve this accuracy by a further two orders of magnitude.

The closure provided by combining the three types of measurement has become known as closing the quantum metrology triangle. That is, if sufficient accuracy can be achieved with the SET work, the three measurements should provide an internally consistent set and thereby provide a valuable check of the underlying theory.

The 2006 evaluation showed that the JE $2e/h$ leg could be verified by internal consistency involving the moving coil watt determinations to a fractional uncertainty of about $\varepsilon_J = (-77 \pm 80) \times 10^{-9}$. There is some doubt over the reliability of this value due to the small amount of data and it is suggested that the agreement may be partly fortuitous. Similarly, the QHE leg could be verified to an uncertainty $\varepsilon_K = (20 \pm 18) \times 10^{-9}$ by both external and internal consistency. The SET method at present limits the accuracy and, to date, the triangle has been shown to provide closure with a fractional uncertainty at the 10^{-6} level (Gallop, 2005; Keller, 2008).

3.3
Obtaining "Best Values" of the Constants

As science and technology advances, so too our ability to measure particular combinations of the fundamental constants improve in accuracy. The particular combinations of the constants that can be best measured also change.

3.3.1
Relationships among the Constants

Equations 3.4 and 3.7 together with Equations 3.8 and 3.10 can provide values of α. However, because, in practice, a value of $\text{unit}_{\text{LAB}}/\text{unit}_{\text{SI}}$ is required to obtain α from Equation 3.10 as well as from Equation 3.4, the two values will not be completely independent. Moreover, $2e/h$ (in SI units) can be obtained from the relation

$$\frac{2e}{h} = \left[\frac{16R_\infty\left(m_p/m_e\right)N_\text{A}}{\mu_0 c^2 M_p \alpha}\right] \tag{3.16}$$

where M_p is the molar mass (atomic weight in units of kilograms per mole) of the proton and $\gamma_p'(\text{lo})$ from the equation

$$\gamma_p'\left(\text{lo}\right)_{\text{LAB}} = \left(\frac{F_{\text{LAB}}K_{A,\text{LAB}}^2\left(\mu_p'/\mu_B\right)\left(m_p/m_e\right)}{M_p}\right) \tag{3.17}$$

where F_{LAB} (Faraday constant) is measured in terms of the as-maintained ampere A_{LAB} in a particular laboratory, and

$$\begin{aligned} K_{A,\text{LAB}} &= A_{\text{LAB}}/\text{A} = (V_{\text{LAB}}/\Omega_{\text{LAB}})/(\text{V}/\Omega) \\ &= (V_{\text{LAB}}/\text{V})/(\Omega_{\text{LAB}}/\Omega) \\ &= K_{V-\text{LAB}}/K_{\Omega-\text{LAB}} \end{aligned} \tag{3.18}$$

Further, the Faraday constant is related to the Avogadro constant by $F = N_A e$, and $K_{A,\text{LAB}}$ may be obtained from direct measurements using a so-called ampere force balance as well as from the equation

$$K_{A,\text{LAB}}^2 = \frac{\gamma_p'\left(\text{lo}\right)_{\text{LAB}}}{\gamma_p'\left(\text{hi}\right)_{\text{LAB}}} \tag{3.19}$$

where $\gamma_p'\left(\text{hi}\right)_{\text{LAB}}$ is the gyromagnetic ratio of the proton as obtained by the so-called high (magnetic) field method. (The magnetic flux density B is determined by measuring the force it exerts on a conductor of known dimensions carrying a current known in terms of A_{LAB}.)

It is apparent that complex relationships can exist among groups of fundamental constants and conversion factors, and that a particular constant may be obtained either by direct measurement or indirectly by appropriately combining other directly measured constants. If the direct and indirect values have similar accuracy, both must be considered in order to arrive at a best value for the quantity. However, each of the various routes that can be followed to a particular constant, both direct and indirect, provides a somewhat different numerical value. The best way to treat this is by using the mathematical technique of least-squares, a technique that is backed by the rigor of statistics.

Least-Squares Adjustments of the Constants

The least-squares method furnishes a well-defined procedure for calculating best ‘‘compromise’’ values of the constants from all of the available data. It takes into account all possible routes to a particular constant and yields a single value for each constant by weighting the different routes according to their relative uncertainties. The weights themselves are obtained from the *a priori* uncertainties assigned to the individual direct measurements that constitute the original set of data.

The least-squares study of the constants was pioneered in the late 1920s by Birge (1929) and continued by others, notably DuMond and Cohen (1953) and Cohen and DuMond (1965). More recent reviews were those of Taylor, Parker, and Langenberg (1969), based on their JEs determination of $2e/h$; and of Cohen and Taylor ([1973, 1987]); and more recently by Mohr and Taylor ([1999, 2005], and Mohr, Taylor, and Newell (2008). Since 1973, reviews have usually been undertaken under the auspices of CODATA. The 2006 adjustment is the most recent one currently available, and the recommended set of constants resulting from it, are those officially adopted by CODATA for international use. Subsequent evaluations are scheduled to take place at four-year intervals and the values will be posted on the NIST Web Site at *http://physics.nist.gov/cuu/Constants/*.

3.3.2
The 2006 CODATA Adjustment

An important guiding principle for the wide acceptance of the evaluations for scientists is

1. to be clear how they are performed;
2. what data is included; and
3. the weight given to a particular input datum.

The standard statistical method gives weights to the input of the data according to the inverse square of its associated uncertainty. Common sense, backed by the history of the subject, supports the reality that there may be some unknown science that is as likely to be affecting the most accurate value as those of lesser accuracy. Indeed, history suggests that it would have been more realistic to double the uncertainty associated with the output values. This option has so far been rejected on the grounds that it might slow the pace of the subject because it could mask the recognition that there were unanticipated problems or unknown science associated with particular measurements.

An inherent consequence of applying the least-squares method is that a determination with an uncertainty that is three or more times greater than that of the smallest, has less than one-ninth of the impact on the weighted mean value than does the most accurate result. This puts very strong pressure on the ability of scientists to estimate their uncertainties. Therefore, it is usual to check the effect on the evaluated values of omitting the result with the smallest uncertainty. Similarly, one can test for the effect of all data pertaining to the QHE (say) or the JE and thereby verify the extent to which these phenomena do represent a measurement of the particular combination of the fundamental constants

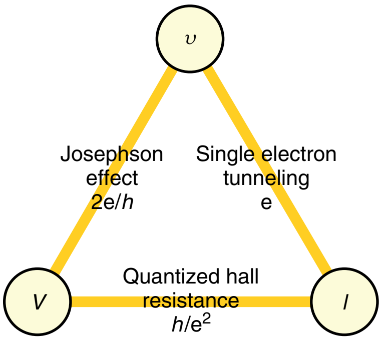

Fig. 3.1 The quantum metrology triangle links the Josephson effect, the quantum Hall effect and single electron tunneling, the sides of the triangle, to the electrical units and frequency, represented by the vertices, by using Ohm's law and tests the self-consistency of the expressions that are assumed in Equations 3.2 and 3.10.

concerned. The preliminary assessment of the input data is the most critical part of an evaluation because the computing thereafter is largely automatic–so the prudent approach to the rejection of "rogue" data suggested by the computer adage "garbage in: garbage out" can only be followed by subjective decisions by the reviewers backed by advice from the CODATA Task Group and other expert scientists.

If sufficient data on a particular topic are available, one may use a statistical quantity termed the *Birge ratio*,which amounts to comparing the value of χ^2 with the number of degrees of freedom for the group and expanding the assigned uncertainty to make the two values equal. Thus, in the 2006 evaluation, the determinations of G were analyzed in this way and the output uncertainty expanded by a factor of 4.26, and this is illustrated in Figure 3.2.

The present leading experimental values for G are also given in Table 3.2. It will be noted that the uncertainty in the CODATA recommended value was conservatively increased above that obtainable by statistical weighting of the results because it was judged that there were significant discrepancies among the published measurements.

Unfortunately, one of the major problems for the measurements of G result from the small size of the gravitational force between objects in the presence of the 10^9 times greater gravitational attraction of the Earth, or spurious electromagnetic fields. This places formidable requirement for the suspension, which must have a small and stable torsional constant combined with adequate strength and very good shielding from outside effects (including sidereal heating of the laboratory, or gravitational gradients). Consequently, the achievable experimental accuracy has not improved as rapidly as that of other constants and has only improved about a 100-fold over two centuries. Thus, the measurements of Cavendish (1798) led to $G = 6.75(5) \times 10^{-11}\ \mathrm{m^2\ s^{-2}\ kg^{-1}}$ and this may be compared with the CODATA 2006 recommended values of $6.67428(67) \times 10^{-11}\ \mathrm{m^2\ s^{-2}\ kg^{-1}}$.

In earlier evaluations, the data entering a least-squares adjustment of the constants were divided into two groups:

1. the more precise data or auxiliary constants and
2. the stochastic input data.

The auxiliary constants used in the 1986 adjustment, none of which had an assigned fractional uncertainty greater than 2×10^{-8}, included μ_0, c, R_∞, M_p, m_p/m_e, g_e, μ_e/μ_p, and the g-factor of the muon:

$$g_\mu = 2(1 + a_\mu) = 2\mu_\mu/(eh/4\pi m_\mu) \quad (3.20)$$

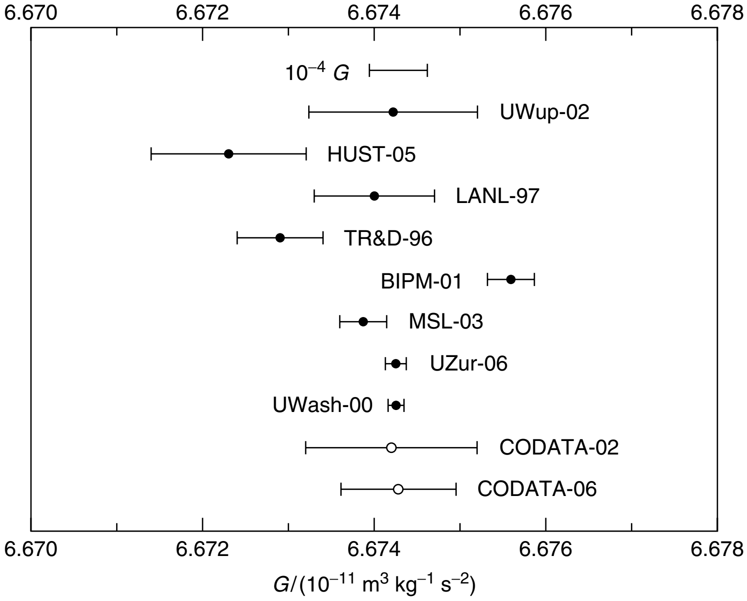

Fig. 3.2 Recent values of the gravitational constant. (Taken from CODATA 2006, see Mohr, Taylor, and Newell (2008) for details and designations.)

where a_μ is the magnetic moment anomaly of the muon and μ_μ is its magnetic moment.

Also included in the auxiliary constant category in 1986 were the representations of the volt, ohm, and ampere, expressed in terms of the common set of electrical units known as the *BIPM volt, ampere, ohm*, and the 1972 internationally agreed value for the Josephson constant $K_{J\text{-}72}$. In 1990, at the suggestion of the CCE, the latter was revised to the present internationally agreed value of K_J and assigned the designation $K_{J\text{-}90}$, together with a value for the von Klitzing constant $R_{K\text{-}90}$. The best values for K_J and R_K are obtained from the evaluations.

In the 1986 evaluation, the stochastic data were grouped into sets providing information on five constants. Since then, recognizing the greatly improved sophistication of calculations provided by modern computers that have progressively replaced the slide-rules and hand-cranked mechanical calculators of the Birge era, the distinction between auxiliary constants and stochastic input data has been dropped and all the relevant data has been included in the evaluation. This advance has now allowed any correlations between the input data to be taken into account.

Since the Rydberg constant, for example, is now measured to 12 decimal places, then, for the 2006 evaluation, the computer had to be able to perform a least-squares multivariate analysis comprising some 79 unknowns from some accepted 135 input data (the latter from an initial set of 150 input data), with the resulting large number of associated matrices, evaluated to a large number of decimal places. Birge could have scarcely imagined what scientific and technological progress would

accomplish within 70 years of his seminal work–but he would surely have approved.

Although the output values have associated uncertainties, the least-squares analysis results on correlations between the various output values and, for some purposes, the user may need to use the associated variance and covariance matrices that are also available from the NIST web site. Thus, the recommended uncertainty of the quotient e/h may differ from root sum of the squares of the uncertainties assigned to e or h.

An equation that relates a stochastic input datum to the M adjustable constants (with the aid of the auxiliary constants if necessary) is known as an *observational equation*.Thus, if there are n_1 items of stochastic input data, there are n_1 observational equations. However, the observational equations for data items of the same type are of the same form. The weight w_i of each stochastic datum and hence of each observational equation is related to the datum's *a priori* assigned uncertainty s_i by $w_i = 1/s_i^2$.

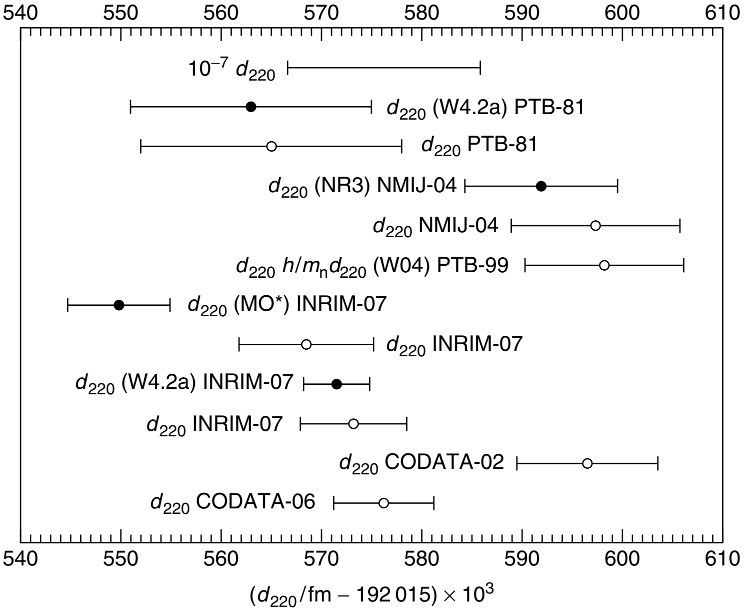

Fig. 3.3 Values of d_{220} inferred from various measurements. (Taken from CODATA 2006, see Mohr, Taylor, and Newell (2008) for details and designations.)

Consequently, if one value of a datum for a particular quantity has half the uncertainty of another, it carries four times as much weight in the adjustment. Taking into account the weight assigned to each observational equation, and with the aid of a present-day computer, the least-squares adjusted values of the M unknowns may be readily obtained. "Best values" in the least-squares sense for these M adjustable constants, with their variances and covariances, are thus the immediate output of the adjustment. The optimal values in the least-squares sense for most constants of interest not directly subject to adjustment may then be calculated from the M adjustable constants. In contrast to the auxiliary constants of the 1986 adjustment, for which no uncertainty exceeded 2×10^8, the fractional uncertainties assigned to the 138 items of stochastic input data initially considered in the 2006 adjustment were broadly in the range 10^{-12}–10^{-6}.

Because the d_{220} data were in such disagreement, as seen in Figure 3.3, a separate working group has been set up to coordinate the work in several countries in order to produce recommended value(s) for d_{220} and V_m(Si). The work in progress includes determination(s) of N_A resulting from measurements made with a sample of isotopically pure silicon produced in Russia (Becker, 2003; Becker *et al.*, 2006).

Because new results that can influence a least-squares adjustment of the constants are reported continually, it is always difficult to choose an optimal time at which to carry out a new adjustment and to revise the recommended values of the constants. In the case of the 2006 adjustment, all data available up to 1 January 2006 were considered for inclusion.

3.3.2.1 Uncertainty Assignment and Discrepant Data

Because the weight of each stochastic datum included in a least-squares adjustment of the constants is taken as $w_i = 1/s_i^2$, critical analysis of the input data and deciding what *a priori* uncertainty s_i should be assigned to each measurement is the main problem in successfully carrying out an adjustment. Modern data acquisition techniques mean that instead of making tens of observations one has thousands, but without sophisticated analysis and intelligent investigation of possible variables (e.g., by taking advantage of the sophistication provided by factorial replicate and other statistical analysis techniques), the apparently improved reduction in the uncertainty estimate may prove highly illusory. The uncertainty problem is made especially difficult because in most experiments sufficient data are taken to reduce the Type A uncertainties (formerly termed *random*effects) to negligible amounts, and the dominant uncertainty assigned to the experiment is primarily from estimates of the Type B uncertainties associated with the effects that remain substantially constant during the period of the measurement. Because such effects frequently arise from a phenomenon that the experimenter is not so familiar with, the quantitative estimation of the uncertainties is subjective and is necessarily based on "educated" guesses.

As shown above with the measurements of G, discussed above, another problem area is that of deciding how to handle "discrepant" data. These comprise measurements that differ from each other by statistically significant amounts in comparison with their assigned uncertainties s_i. Such data cannot be included in an adjustment uncritically because the inconsistencies imply either incorrect uncertainty assignments or the presence of unknown measurement errors. When confronted with such a situation, the reviewer can in general either include the inconsistent data, but only after expanding (increasing) their s_i so that they are no longer discrepant, or decide, on as sound a theoretical and experimental basis as possible, which of the inconsistent data are least reliable, and discard them. These two approaches clearly imply that different reviewers might treat the same data differently, thereby obtaining somewhat different sets of best values.

Motivated by the all-too-frequent occurrence of large changes in the recommended values of many constants from one adjustment to the next, new algorithms for handling discrepant data in least-squares adjustments of the constants were developed during the years between the 1973 and 1986 adjustments. These added increased objectivity to expanding *a priori* uncertainties and discarding inconsistent data were used extensively by Cohen and Taylor in carrying out the 1986 adjustment and, with their aid, the initial group of 38 items of stochastic input data was reduced to 22 items by deleting those that were either highly inconsistent with the remaining data or had assigned uncertainties so large that they carried negligible weight.

3.3.2.2 Recommended Values of the Constants

Table 3.3 gives the 2006 CODATA recommended values and the associated one-standard-deviation uncertainties ($\sim$65% probability) of a number of fundamental physical constants. As noted in Section 3.3, the direct output of a least-squares adjustment provides the best values (in the least-squares sense) for the adjustable constants, or unknowns, and their variances and covariances. For the 1986 adjustment, the five unknowns chosen for evaluation were α^{-1}, K_V,

Tab. 3.3 Comparison of the 1973, 1986, and 2006 CODATA recommended values and the assigned uncertainties of a selected group of constants implied by the data currently available.

Quantity	1973 fractional uncertainty σ_{73}	1986 fractional uncertainty σ_{86}	2006 fractional uncertainty σ_{2006}	Ratio $\sigma_{86}/\sigma_{2006}$	Fractional change δ of 2006 value from 1986 value	Change δ/σ_{86}
α^{-1}	8×10^{-7}	4.5×10^{-8}	6.8×10^{-10}	66.2	7.4×10^{-8}	1.73
E	2.9×10^{-6}	3.0×10^{-7}	2.5×10^{-8}	12	-5.3×10^{-7}	−1.75
H	5.4×10^{-6}	6.0×10^{-7}	5.0×10^{-8}	12	-9.9×10^{-7}	−1.65
m_e	5.1×10^{-6}	5.9×10^{-7}	5.0×10^{-8}	11.8	-8.3×10^{-7}	−1.40
N_A	5.1×10^{-6}	5.9×10^{-7}	5.0×10^{-8}	11.8	8.4×10^{-7}	1.43
m_p/m_e	3.8×10^{-7}	2.0×10^{-8}	4.3×10^{-10}	46.5	-1.6×10^{-8}	−0.79
F	2.8×10^{-6}	3.0×10^{-7}	2.5×10^{-8}	12.0	3.2×10^{-7}	1.07
$2e/h$, K_J	2.6×10^{-7}	3.0×10^{-7}	2.5×10^{-8}	12.0	4.6×10^{-7}	2.0
R	31×10^{-7}	8.4×10^{-6}	1.7×10^{-6}	4.9	-4.5×10^{-6}	−0.54
K	32×10^{-6}	8.5×10^{-6}	1.7×10^{-6}	5.0	-5.5×10^{-6}	−0.65
σ	125×10^{-6}	34×10^{-6}	7.0×10^{-6}	4.9	1.9×10^{-5}	−0.57
G	6.15×10^{-4}	3.4×10^{-4}	1.0×10^{-4}	3.4	2.5×10^{-4}	1.98
R_∞	7.6×10^{-8}	1.3×10^{-9}	6.6×10^{-12}	197	3.2×10^{-9}	0.70

K_Ω, d_{220}(Si), and μ_μ/μ_p. The number of "unknowns" was increased dramatically in the 2006 adjustment, However, the uncertainties of many of the output values were still largely determined by a comparatively few different types of measurements.

3.3.2.3 Comparison of the 1986 and 2006 Adjustments

The 1986 CODATA adjustment represented a major advance over its 1973 counterpart; the uncertainties of many recommended values were reduced by roughly an order of magnitude, and further progress has been made through advances made throughout the precision measurement-fundamental constants field between 1986 and 2006. This is apparent from column 4 of Table 3.3, which compares the recommended values and uncertainties of a selected group of constants as obtained from the two adjustments and from Figure 3.4 a plot of the changes in uncertainty tabulated in columns 1–3. It is also clear from the last column of Table 3.3 that unexpectedly large changes have occurred in the 1973 recommended values of several of these constants (there are changes that are large relative to the uncertainty assigned to their 1973 value). Many of these changes are a direct consequence of the 7.8×10^{-6} fractional decrease in the quantity K_V from 1973 to 1986, and the very high correlation between K_V and the calculated values of e, h, m_e, N_A, and F. Since $2e/h = K_{J-72}/K_V$, the 1986 value of K_V also implies that the value of $2e/h$ that was adopted by the CCE in 1972, (which was believed to be consistent with the SI value, and which most national standards laboratories adopted to define and maintain their national representation of the volt), was actually 7.59 μV smaller than the correctly realized SI value. As discussed

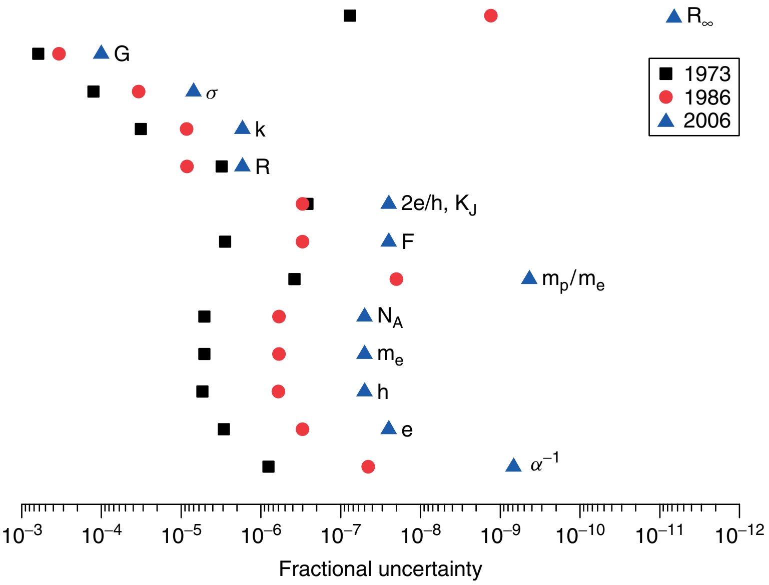

Fig. 3.4 Improvements in the fractional uncertainty of some selected constants from 1973 to 2006.

in Section 3.4, this unsatisfactory situation was rectified adopting the revised value for $2e/h$ with effect from 1 January 1990.

The large change in K_V between 1973 and 1986 would have been avoided if two determinations of F that seemed to be discrepant with the remaining data had not been deleted in the 1973 adjustment. In retrospect, the disagreement was comparatively mild. Fortunately, there are fewer similar disagreements in the 2006 adjustment; the measurements that were deleted were so discrepant, or of such low weight that if retained they would have a negligible effect on the adjusted values. Thus, it is unlikely that any reasonable alternative evaluation of the data considered in the 2006 least-squares adjustment could lead to significant changes in the 2006 recommended values. It is interesting that the spectacular improvement in the experimental and theoretical aspects relating to the accuracy of the Rydberg constant, largely as a result of the development of the ability to make direct frequency multiplication measurements through to the visible region and beyond (de Beauvoir *et al.*, 2000; Hänsch *et al.*, 2005), was not significantly changed when expressed in terms of the fractional uncertainty assigned to the 1986 value. None of the 1986 recommended values in Table 3.3 has been changed by more than two standard deviations.

3.4
Josephson and Quantum Hall Effect Representations of the Volt and Ohm

As pointed out in Section 3.2.2, the fundamental constants have a key role to play in the establishment of reproducible and invariant units of measurement. Exemplifying this role was the worldwide introduction on 1 January 1990 of new practical units of voltage and resistance based on standardized values for the

Josephson constant and quantum Hall constant, in the sections that follow. We consider first some aspects of the SI.

3.4.1
The SI and Representations of the Volt and Ohm

The SI is the system of units used throughout the world for expressing the results of physical and chemical measurements. The three SI base mechanical units are the meter (m), kilogram (kg), and second (s) (Taylor, 1991b). The derived SI unit of force, the newton (N), is then defined in terms of these three base mechanical units by $1N = 1\,\mathrm{m\,kg\,s^{-2}}$. The SI base unit of current, the ampere (A), is defined as that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} N per meter of length. This definition leads to $\mu_0 = 4\pi \times 10^{-7}\ \mathrm{N\,A^{-2}}$ exactly.

The SI derived unit of electric potential difference, the volt (V), and the SI derived unit of electric resistance, the ohm (Ω), are then defined in terms of the three base mechanical units and the base electric unit, the ampere. Formally, $1V = 1\,\mathrm{m\,kg\,s^{-3}\,A^{-1}}$ and $1\ \Omega = 1\ \mathrm{m^2\,kg\,s^{-3}\,A^{-2}}$.

In practice, the volt may be realized using a force balance in which an electrostatic or electromagnetic force is compared with a mechanical force; and the ohm may be realized by comparing the impedance of a calculable capacitor or inductor with that of a resistor. However, because both experiments are exceedingly difficult and time consuming to carry out and are of limited accuracy, it has become necessary to establish practical, or as-maintained, units of voltage and resistance, that is, representations of the volt and ohm that provide better long-term repeatability and constancy than the direct realizations of the SI units themselves.

Historically, practical representations of the volt were based on the mean emf of large groups of electrochemical standard cells. However, in 1972 (Terrien, 1973; Taylor, 1987), the CCE suggested that the national standards laboratories base their national representations of the volt on the JE in order to avoid the variation with time and severe temperature dependence of the emf of such cells. In particular, the CCE proposed, and the Conference International des Poids et Mesures (CIPM) subsequently approved the proposal, that the national standards laboratories adopt $K_{J\text{-}72} = 483\ 594\ \mathrm{GHz\ V^{-1}}$, exactly, as the conventional value of the Josephson constant for use in realizing and maintaining an accurate and stable national representation of the volt by means of the JE (Taylor and Witt, 1989). However, while most national laboratories accepted this value, three did not. Moreover, as pointed out in Section 3.3.3, the 1986 CODATA adjustment showed that $K_{J\text{-}72}$ was nearly 8×10^{-6} smaller than the correct SI value, implying that the national representations of the volt of those countries that used it should be changed accordingly.

During the late 1970s and early 1980s, the CCE also became increasingly concerned that, because most national standards laboratories based their representation of the ohm on the mean resistance of a particular group of precision wire-wound standard resistors, and because these artifact standards age, the various national representations of the ohm differed significantly from each other, and from the ohm of the SI definition, and some groups of resistors were aging excessively. Although, in principle, a calculable cross-capacitor can now be used to realize the ohm with an uncertainty of $<10^{-7}$, it is a difficult experiment to perform routinely. Only one laboratory in the world has had such an apparatus in continuous operation since the method was first developed in the early 1960s. Consequently, electrical metrologists throughout the world enthusiastically welcomed von Klitzing's 1980 discovery of the QHE since it promised to provide a method for basing a representation of the ohm on fundamental constants in much the same manner as the JE, discovered 19 years earlier in 1961, provided a method for basing a representation of the volt on fundamental constants.

3.4.2
The Conventional Values K_{J-90} and R_{K-90}

To address the problems associated with national representations of the volt and ohm discussed earlier, the CCE established the CCE Working Group on the JE and another working group on the QHE. Their proposals were subsequently approved by the CIPM and by the 18th CGPM (Giacomo, 1987; Quinn, 1989) and these proposals went into effect worldwide from 1 January 1990. The values are

$$\begin{aligned} K_{J-90} &= 483\,587.9\text{GHz/Vexactly} \\ R_{K-90} &= 25\,812.807\Omega \quad \text{exactly} \end{aligned} \tag{3.21}$$

The respective CCE Working Groups estimated that $K_{J\text{-}90}$ was consistent with the SI value of K_J to within a conservatively assigned one-standard-deviation uncertainty of 0.2 GHz V^{-1} or relative uncertainty of 4×10^{-7}, and that $R_{K\text{-}90}$ is consistent with the SI value of R_K to within a conservatively assigned one-standard-deviation uncertainty of 0.005 Ω or a relative uncertainty of 2×10^{-7}. This implies that an ideal representation of the volt based on the JE and $K_{J\text{-}90}$ should be consistent with the SI volt to within 0.4 μV, and that an ideal representation of the ohm based on the QHE and $R_{K\text{-}90}$ should be consistent with the SI ohm to within 0.2 μΩ. Reassuringly, the 2006 evaluation improved on this uncertainty and suggested that the maintained units were actually 0.019(25) μV lower and 0.0212 μΩ higher, respectively, and that the corresponding maintained ampere A_{90} differed from that of the SI definition by −0.003(25) μA. Hopefully, these small differences will be confirmed by measurements currently in progress.

Thus, measurements of the fundamental constants of nature have led to a very practical and significant improvement of the international uniformity of electrical measurements and their consistency with the SI. This will no doubt be of major benefit to science, commerce, and industry throughout the world for many years to come; not least because all measurements are a comparison of one quantity relative to another like quantity, and one is never otherwise sure whether the problem lies with a measurement or the reference quantity.

3.5
Implications of Recent Advances in the Fundamental Constants Field

As clearly discussed in Section 3.4, many advances have been made in the fundamental constants field since the completion of the 1986 CODATA least-squares adjustment. The new results lead to values of the constants that in general have uncertainties five to seven times smaller than the uncertainties assigned to the 1986 values. However, the changes in the values themselves are less than twice the 1986 one-standard-deviation uncertainties and thus are not highly significant. Although much new data has become available since 1986, three new results dominate the analysis: a value of h obtained from a realization of the watt; a value of α^{-1} obtained from a_e; and a value of the molar gas constant R obtained from a new measurement of the speed of sound in argon.

Surprisingly, the measurement of $K_W = W_{90}/W$ is actually a measurement of the Planck constant. This follows from the fact that $W_{90} = V_{90}^2/\Omega_{90}$, $W = V/\Omega$, so that $K_{\mathrm{W}} = K_{\mathrm{V}}^2/K_{\Omega}$. Also $K_V = K_{J\text{-}90}/K_J$, $K_{\Omega} = R_K/R_{K-90}$, $K_J = 2e/h$, and $R_K = h/e^2$. These relations lead to $h = 4/K_J^2 R_K$ and hence

$$h = \frac{4K_W}{K_{J-90}^2 R_{K-90}} \tag{3.22}$$

Since $K_{J\text{-}90}$ and $R_{K\text{-}90}$ are defined constants (with no uncertainty), a measurement of K_W (i.e., a measurement of W_{90} in watts or realization of the SI watt) with a given relative uncertainty yields a value of h with the same relative uncertainty.

Since 1986, the value of the molar gas constant R from which the Boltzmann constant k, Stefan–Boltzmann constant σ, and other thermophysical constants were derived has been replaced by a new value of R with a relative uncertainty of 1.7×10^{-6}, nearly five times smaller than the 8.4×10^{-6} relative uncertainty of the 1986 value.

3.6
Possible Role of the Fundamental Constants in Replacing the Kilogram

As indicated in Section 3.4, this section further demonstrates the important role that the fundamental constants can play in the practical metrology.

3.6.1
Problems with Present Kilogram

The unit of mass in the SI, the kilogram, is the only SI base unit still defined in terms of a material artifact; it is equal to the mass of the international prototype of the kilogram, a 90% platinum, 10% iridium (by weight) right circular cylinder about 39 mm in height and diameter. Established by the CGPM in 1889, it is rarely used for fear of damage. In fact, it has only been used on three occasions to compare against copies of the prototype since it was made.

The problems with the present material artifact kilogram may be summarized as follows (Quinn, 1991; Taylor, 1991):

1. it can be damaged, or even destroyed;
2. it cannot be used routinely for fear of wear;
3. it is available in only one laboratory;
4. its value may have changed in an unknown manner, perhaps by as much as 75 µg in the last 100 years (7.5 parts in 10^8); and
5. its mass is not well defined because, despite its being enclosed by three concentric bell jars, it accumulates foreign material and the latter are difficult to remove reproducibly and an empirical, "lavage" process has been specified.

Using the best available balances and cleaning the masses under the proper experimental conditions, Pt–Ir kilogram standards can be intercompared with an uncertainty of about 0.001 µg (or a fractional amount of 1×10^{-9}) or even less. However, it is generally agreed that a new definition of the kilogram based on a constant of nature, such as the mass of a stable elementary particle or atom, that could be realized, in practice, with a relative uncertainty of the order of 1 × 10^{-8} at the 1-kg level is all that is required to replace the current definition. The reason is that the uncertainties associated with the cleaning and aging of the international prototype, the air buoyancy correction required when masses of different densities are compared, and the scaling of masses up and down from the 1-kg level limit practical mass measurements to a relative uncertainty of a few parts in 10^8 at best. There are also losses of accuracy in moving to other in-house mass balances and to other national standards laboratories and to the ultimate users.

3.6.2
An Alternative Based on Fundamental Constants

There are at present three alternative approaches that might be developed to have the required precision.

3.6.2.1 The Measurement of *h*

The most promising method for redefining the kilogram, to date, arose from the result of the measurement of $\gamma_p'(\text{hi})$ by Kibble and Hunt, as mentioned in Section 3.2.3. The method proposed by Kibble (1975) effectively combined aspects of the measurements of $\gamma_p'(\text{hi})$ and $\gamma_p'(\text{lo})$ into one measurement process that is performed on the same coil of n turns and horizontal width w in the same magnetic flux density B in the presence of a vertical flux gradient $\partial\Phi/\partial z$. The two-aspect measurement process involves

1. measuring the force mg, required to balance the coil when a current I was passed through it and
2. measuring the induced emf, E, when the coil was moved vertically in a flux rate of change of $\partial\Phi/\partial t\,(= u\partial\Phi/\partial z)$, at constant velocity, u.

This resulted in two equations from which $\partial\Phi/\partial z$ could be eliminated to give the electrical power VI in absolute mechanical units. If the voltage is measured in terms of a Josephson voltage $V_J = hf_J$ and the current $i = \left(f_J'n\right)e/2$ is measured by combining the JE ($v = hf/2e$) and QHE ($R = h/ne^2$), (where n is a small integer, and f and f' are small frequencies). Thus, since $(h/2e)^2 \big/ (e^2/2h)) = h/8$, the Planck constant h can be measured directly in terms of its SI units, that is, in Joule-second. The experimental determination requires knowledge of the mass m, the vertical coil velocity u (which is measured by optical fringe-counting techniques), and the gravitational acceleration g local to the apparatus (again involving optical fringe-counting of a cube corner reflector catapulted vertically in a commercially available vacuum apparatus). The remaining parameters involve frequency measurements that can readily be measured with the required accuracy. To date, there have been two groups making determinations, Williams *et al.* at NIST, and Kibble *et al.* at NPL. The latest results from the two groups are

Source	**Value for *h***
Steiner *et al.* (NIST) (Steiner *et al.*, 2007)	6.626 068 91(24) × 10^{-34} J.s
Robinson and Kibble (NPL) (Robinson and Kibble, 2007)	6.626 070 95(44) × 10^{-34} J.s

These two-watt balance measurements differ at present by 308(48) nW/W, with the

Robinson and Kibble value being closer to that obtained from the Avogadro constant as shown in Figure 3.5.

It seems likely at present that this route will prove the most capable of achieving the desired 10^{-8} level of accuracy. That being so, the definition of the kilogram might be defined via the Einstein mass–energy equation ($E = mc^2$) in terms of the mass equivalence $h\nu_{def}/c^2$ (where ν_{def} is the frequency defined, e.g., in the definition below) and read, for example, Mills *et al.* (2005):

> *the kilogram, unit of mass*
> *is the mass of a body whose*
> *equivalent energy is equal to*
> *that of a number of photons*
> *whose frequencies sum to exactly*
> *$[(299\,792\,458)^2/662\ 606\ 93] \times$*
> *10^{41} hertz.*

It has to be admitted that this definition is likely to be difficult for many unsophisticated users to comprehend, despite representing the amount of mass converted into energy in a very powerful hydrogen bomb. Also, $h\nu_{def}$ is largely independent of h, rather depending on $\alpha^4 m_e$ instead (Flowers and Petley, 2005). The latter is a consequence of there being no single fundamental constant whose dimensions have solely the dimension of time, aside from the Planck time $t_P\left(=\left(\hbar G/c^5\right)^{1/2}\right)$, unless one considers, for example, such quantities as the Compton frequencies of particles, or the Rydberg constant as being more fundamental than those of the conventional basic set comprising h, e, c, G, k, and m_e. Much will depend on the degree of agreement achieved between the various methods, together with the combined views of users throughout the world, by the time that the decision is discussed by the CGPM at its next meeting in 2011.

3.6.2.2 Methods Involving the Avogadro Constant, N_A

An alternative approach to eliminating the artifact kilogram as the definition of the SI unit of mass is to replace it with a definition based on the mass of an atom, for example, carbon-12 (^{12}C). A possible definition might read as follows: the kilogram is the unit of mass; it is equal to the mass of 5.018×10^{25} free ^{12}C atoms at rest. To avoid introducing a discontinuity in the SI mass unit, the actual number $n(^{12}\mathrm{C})$ given in the definition would, to the fullest possible extent, be taken equal to the number of free ^{12}C atoms at rest whose total mass equals the mass of the international kilogram prototype. Thus we have

$$n\left(^{12}\mathrm{C}\right) = \frac{1kg}{m\left(^{12}\mathrm{C}\right)} = 1kg\frac{N_{\mathrm{A}}}{M\left(^{12}C\right)} \qquad (3.23)$$

where $m(^{12}\mathrm{C})$ is the mass in kg of a free ^{12}C atom at rest; N_A is the Avogadro constant in units of mol^{-1}; and also $M(^{12}\mathrm{C})$ is the molar mass of ^{12}C in units of kilograms per mole, and from the definition of the base unit mole in the SI is exactly 0.012 kg mol^{-1}. It follows from Equation 3.15 that once the new definition is implemented (i.e., once an exact value for n(^{12}C) is adopted), N_A and the atomic mass unit $u = m_u = m(^{12}\mathrm{C})/12$ will become exactly defined constants.

Mass–ratio measurements of single charged particles and ions cooled and trapped in a Penning trap have reached the point where the molar masses of most particles or atoms of interest, such as the electron, proton, or ^{1}H, are now known or soon will be known with a relative uncertainty of $(1–3) \times 10^{-9}$. Similarly, the 20×10^{-9} relative uncertainty of the reported value for the proton–electron mass ratio, $m_p/m_e = M_p/M_e$, should soon

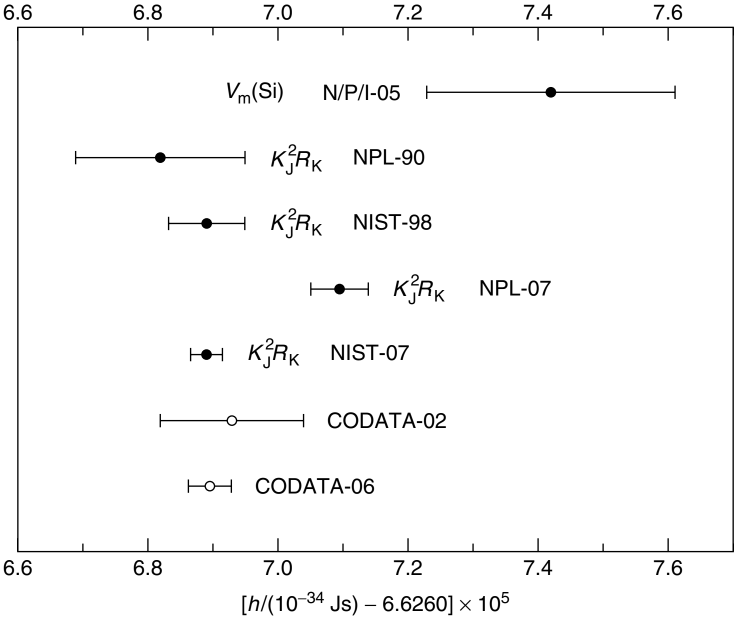

Fig. 3.5 Recent values of the Plank constant based on watt balance ($K_J^2 R_K$) and Avogadro V_m(Si) methods. (Taken from CODATA 2006, see Mohr, Taylor, and Newell (2008) for details).

be reduced by a factor of 10 or so. These small uncertainties imply that if the mass m of any elementary particle or atom can be obtained in kilograms with a relative uncertainty of 1×10^{-8}, then $m(^{12}\mathrm{C})$ and hence $n(^{12}\mathrm{C})$ will be known with essentially the same uncertainty. Further, Equation 3.16 implies that determining N_A with a relative uncertainty of 1×10^{-8} will lead to a value of $n(^{12}\mathrm{C})$ with the same uncertainty. Consequently, one needs to only consider the determination of N_A and, since the electron is the particle whose mass can be obtained most accurately at present, the determination of m_e.

Determining N_A and m_e As discussed earlier, values for constants may be obtained by direct measurement or indirectly from appropriate combinations of other directly measured quantities. Hence, as explained in Section 3.3, N_A may be determined

1. directly by the X-ray crystal density (XRCD) method in which one measures the molar mass, density, and unit-cell volume of a material such as silicon that can be prepared in the form of extremely pure and nearly perfect single crystals. For silicon, a cubic crystal with eight atoms per unit cell of edge length $a = d_{220}\sqrt{8}$ and volume $v = a^3$, the basic relation is $N_A = 8M(Si)/\rho(Si) \times \left(d_{220}\sqrt{8}\right)^3$.
2. N_A may also be obtained indirectly by a number of different routes but, since $m_e = M_e/N_A = M_p/[N_A(m_p/m_e)]$, any indirect measurement of N_A may be viewed as an indirect measurement of m_e.

Since m_e cannot yet be measured directly (one cannot yet "weigh" electrons), only indirect measurements (other than via N_A) need be considered. On the basis of the equations $R_\infty = m_e c\alpha^2/2h$, $\alpha = \mu_0 ce^2/2h$, and relations previously discussed, one can show that

$$
\begin{aligned}
m_e &= \frac{8R_\infty \alpha^{-2} K_W}{cR_{K-90} K_{J-90}^2} \\
&= \frac{16R_\infty \alpha^{-1} K_V^2}{\mu_0 c^2 K_{J-90}^2} \\
&= \frac{4\mu_0 R_\infty \alpha^{-3} K_A^2}{R_{K-90}^2 K_{J-90}^2}
\end{aligned}
\tag{3.24}
$$

where K_W, K_V, and K_A have the same meaning as in Section 3.5, namely, $K_W = W_{90}/W$, $K_V = V_{90}/V$, and $K_A = A_{90}/A$.

Now, in the SI, μ_0, c, R_{K-90}, and K_{J-90} are all exact constants; R_∞ is known with a relative uncertainty that is currently limited by the practical realization of the meter at visible wavelengths or about 6.6×10^{-12} and α^{-1} as obtained from a_e has a relative uncertainty of 6.9×10^{-10} and it should eventually be possible to reduce this to $(1 - 2) \times 10^{-10}$. Consequently, realization of the watt, volt, or ampere (i.e., determination of K_W, K_V, or K_A) with a relative uncertainty of about 1×10^{-8} could lead to a new definition of the SI unit of mass.

One can also show that

$$
\begin{aligned}
m_e &= \frac{2\left(\mu_p'/\mu_B\right)}{C_{K-90} K_{J-90} \gamma_p'(hi)_{90}} \\
&= \frac{2M_p \alpha^{-2} K_w}{R_{K-90} K_{J-90} (m_p/m_e) F_{90}}
\end{aligned}
\tag{3.25}
$$

where again the various quantities entering these relations have the same meaning as in the previous sections. The current relative uncertainty of μ_p/μ_B is 11×10^{-9} and can likely be significantly reduced if need be. The current relative uncertainty of m_p/m_e is 20×10^{-9}, and, as noted in Section 3.6.2, this will eventually be reduced by a factor of 10 or more. Consequently, a determination of either $\gamma_p(\mathrm{hi})_{90}$ or F_{90} with an uncertainty of about 10^{-8} can also lead to a value of m_e, and thus $m(^{12}\mathrm{C})$ and $n(^{12}\mathrm{C})$, having essentially the same uncertainty and therefore possibly lead to a new definition of the kilogram.

It should be recognized that Equations 3.17 and 3.18 are potentially useful as a basis for replacing the kilogram only because it is possible to calibrate laboratory voltage standards in terms of V_{90} with a relative uncertainty of about 1×10^{-9} or better using a Josephson-array voltage standard, and laboratory resistance standards in terms of Ω_{90} with a similar uncertainty using the QHE and all-cryogenic techniques.

The data pertaining measurements of the Avogadro constant provided an important input to the evaluations. This is a modernized version of the method from the 1930s era of Bragg and others, whereby the Avogadro constant is determined from a measurement of the lattice spacing d_{220}, and molar density $M(\mathrm{Si})$ of a pure silicon crystal.

There is considerable interest in this work for technological reasons because it is one of the two types of project providing the basis for decisions of whether and how to redefine the definition of the kilogram. This is a truly international project and technological input and measurements of various aspects are being made in USA, Japan, Belgium, Italy, Germany, Russia, and Australia.

A quantity d_{220} was introduced as an unknown in the 1986 and later adjustments. The two quantities d_{220} and $V_m(\mathrm{Si}) = M(\mathrm{Si})/(\mathrm{Si})$ were treated as separate items of stochastic input data, because the two available experimental values of d_{220} were in gross disagreement. If they had not been discrepant, then their weighted mean could have been used in conjunction with the single available value of $V_m(\mathrm{Si})$ to obtain a single value of N_A through the relation $N_A = 8V_m\,(\mathrm{Si}) \,/\, \left(d_{220}\sqrt{8}\right)^3$. This result could then have been included in the adjustment directly and there would have been no need to introduce d_{220} as an unknown. For the 2006 evaluation, four measurements of d_{220} were considered. One measurement differed markedly from the other three, but was included because it was supported by the value deduced from measurements of the Compton wavelength of the neutron, expressed as a measurement of $h/(m_n d_{220})$, where m_n is the neutron mass.

Work on resolving the present discrepancies continues. Silicon is not a single isotope element, and the relative isotopic abundances vary from one sample to another, or even throughout the volume of a particular sample. Consequently, it is very difficult to produce silicon crystals that are completely homogeneous. Moreover, there can be small faults and possibly impurities affecting both the density and lattice parameters. The vacuum zone refining method of purification produces gradients in the silicon isotopic abundances and, with this in mind, considerable efforts are being made to produce single isotope samples of very pure silicon and results are expected shortly.

3.6.3
Practical Mass Metrology Making Use of a New Definition of the Kilogram

Suppose that one of the above approaches eventually yields a value of m_e or h with the requisite relative uncertainty of about 1×10^{-8} and the kilogram is redefined in terms of either $n(^{12}\mathrm{C})$ or $h\nu_{\mathrm{def}}/c^2$, how would the newly defined kilogram be used in practice?

First, it should be recognized that either present-day platinum–iridium national kilogram standards (particularly those also made along with the prototype), or the prototype kilogram itself, would not be discarded. Rather, they would serve to act as ‘‘flywheels,’’ that is, as a means of preserving the unit of mass between realizations based on the new definition. Their periodic calibration would be performed by carrying out, for example, a watt-realization experiment, or an Avogadro-constant determination, in terms of the mass standard to be calibrated, taking as its value that is currently assigned to it. Any deviation of the measured value of h, or m_e and thus h, or $n(^{12}\mathrm{C})$ from their adopted value would/could be attributed to a shift in the mass standard (always assuming that there was not a really major problem with the data being input to the ‘‘best values’’ available by 2011). A new value would then be assigned to the standard, thereby recalibrating it.

For many years, only a few laboratories in the world would need to have the apparatus necessary to carry out such experiments, because the results obtained could be readily transferred between laboratories with sufficient accuracy by intercomparing mass standards. If more accurate values of relevant fundamental constants (e.g., R_∞, α^{-1}) became available, the adopted value of $n(^{12}\mathrm{C})$ or $h\nu_{\mathrm{def}}/c^2$ would not be changed. Rather, one would take into account any change in $n(^{12}\mathrm{C})$, or $h\nu_{\mathrm{def}}/c^2$, implied by the improved values of the constants by assigning new values to mass standards. Of course, before any new kilogram definition is adopted, the international prototype would be measured periodically (i.e., monitored) in terms of the proposed new definition to minimize introducing a discontinuity in the SI unit of mass.

A second major advantage of the change would be the elimination of a common, correlated, uncertainty from the values of many of the dimensioned fundamental constants, with the choice in terms of h having the added advantage of improved accuracy by removing the uncertainty in m_p/m_e from many constants.

The new kilogram definition would be realized for a kilogram that was in vacuum, but the transfer to a kilogram that is in air can already be made with the requisite accuracy, see Robinson and Kibble (2007), Robinson (1990), and Davidson, Brown, and Berry (2004). It remains to be seen whether future primary kilogram standards will be sustained in air or vacuum, or both.

3.7
Numerology and Time Variations of the Constants

Any chapter on the fundamental physical constants would not be complete without at least a brief discussion of why the constants have the values they do, and whether they are in fact really constant. For example, why does the ratio of the rest mass of the proton to that of the electron happen to be 1836.15267247(80)? Why does α^{-1} happen to equal 137.035999679(94)? Why not other, perhaps simpler, values?[2)] Three rather different points of view have evolved about the constants, especially their dimensionless combinations:

1. The numbers are not at all arbitrary, but can be calculated from some as yet unknown basic theory (or theories) in much the same way that the g-factors of the electron and muon can be calculated from QED, or even in the way that the ratio of the circumference of a circle to its diameter need not be experimentally determined, but can be calculated to arbitrary accuracy from mathematics. For example, in the late 1960s, an expression was derived for α and m_p/m_e involving only simple integers and, based on the volumes of

---

[2)] Viewed in the round, there are probably, to some extent, relationships between the digits in any group of numbers, with the frequencies of particular integers of the first and successive digits depending on the empirical Benford's Law. This was proposed in 1938 by the late Dr Frank Benford, and extended a discovery reported in 1881, by the astronomer/mathematician Simon Newcomb. If absolute certainty is defined as 1 and absolute impossibility as 0, then the probability of any number "d" from 1 to 9 being the first significant digit is given by

$$P\{d\} = \frac{\ln\left(1+\frac{1}{d}\right)}{\ln(10)} = \log_{10}\left(1+\frac{1}{d}\right) \tag{3.26}$$

and for the nth decimal place it is

$$P_n\{d\} = \frac{1}{\ln(10)} \sum_{k=10^{n-1}}^{10^n-1} \ln\left(1+\frac{1}{10k+d}\right) = \sum_{k=10^{n-1}}^{10^n-1} \log_{10}\left(1+\frac{1}{10k+d}\right) \tag{3.27}$$

(For numbers to base B replace the number 10 by B) Benford found that this formula also predicts the frequencies of numbers found in many categories of statistics. Although after a few decimal places all integers are equally probable, it is interesting that this law also applies to the fundamental constants (see, e.g., *http://www.mathpages.com/home/kmath302/kmath302.htm* and Torres *et al.*, 2007) and their determination. Thus, for the first digit is 1 for about 30% of the constants and 7, 8, or 9, for about 5% of the constants, rather than an equal spread of 10% for the digits 1–9 that one might have otherwise expected.

certain bounded spaces associated with the invariance group of a relativistic quantum wave equation, and giving a value for them which were in excellent agreement with the recommended value at the time (Wyler, 1969), although not in accordance with present-day values. However, the physical basis for his derivation was not at all clear, and it remains safe to say that there does not yet exist a physically meaningful ''derivation'' of an accurate value for a fundamental constant, or dimensionless ratio or combination of constants. When one considers that evaluation of the tenth order QED term of the calculation of the electron $g_e - 2$ requires the evaluation of some 12 672 Feynman diagrams, one can imagine that this task remains a formidable challenge for the future. It would, of course, be nice if some development led to the problems associated with renormalization in QED going the way of the epicycles of pre-Keplerian astronomy.

2. The second viewpoint is not aimed at explaining the values of the physical constants, but simply notes that if they were terribly different from their currently observed values, we would not be here to measure them–life as we know it on earth, and perhaps the existence of the universe itself, depends on complex physical processes that require the constants to have their observed values. This is the idea behind the so-called weak anthropic principle (or WAP) (Barrow and Tipler, 1988). The strong anthropic principle (or SAP) goes even further by speculating that the fundamental constants and laws of physics must be such that life, and the universe as we know it, can exist–which represents a considerable extension of the ''Cogito ergo sum,'' of Descartes of nearly six centuries ago.
3. An extreme statement of the third point of view is that the fundamental constants change with time as the universe evolves and therefore the currently observed values are not particularly significant. This idea had its origins in 1937 when Dirac noted that the ratio of the electric to gravitational forces between the electron and proton is of the order 10^{40}, very nearly equal to the age of the universe expressed in an appropriate atomic time unit, for example, the time required for light to travel a distance equal to the classical electron radius. He speculated that either the equality is accidental or it indicates a causal relationship among electromagnetism, gravitation, and cosmology. If such a relationship is in fact true, then since the universe is continually aging, the equality would remain unchanged only if one or more of the fundamental constants entering the two ratios changed–for example, the Newtonian gravitational constant G, or the elementary charge e. Grand unification theories (GUTs) imply that the fundamental constants were very different during the first second of the ''ig bang'' when there was a unification among the strong, weak, and electromagnetic forces, thereby providing a basis for some of Dirac's ideas on the topic.

These speculations have stimulated a considerable amount of theoretical and experimental work over the last 50 years, the latter quite often involving astronomical or geophysical observations. As a result, stringent limits (albeit frequently model dependent) have been placed on the possible time dependence of a number of physical constants. For example, it has been claimed that h changes less than 2 parts in 10^{12} per year; that G changes less than 3 parts in 10^{11} per year (these are essentially the variations of α and $\alpha_G = Gm_p^2 \big/ \hbar c$, respectively).

We have already entered the situation where the accuracy of laboratory determinations gives measures of the constancy of certain of the constants. This particularly applies to measures of the stabilities of atomic clocks that rely on energy transitions in different atoms.

The frequencies of different types of atomic clock using transitions in different atoms can also be intercompared and also provide information about the stability of α over laboratory timescales. Thus, by comparing transitions, frequencies in Al^+ and Hg^+ single-ion optical atomic clocks Rosenband *et al.* at NIST (Rosenband *et al.*, 2008) measured

$$\nu_{\text{Al}}^{+}/\nu_{\text{Hg}}^{+} = 1.052871833148990438(55) \tag{3.28}$$

and, by comparing measurements taken at various times over a period of about a year, they deduced that α changes by less than $(-1.6 \pm 2.3) \times 10^{-17}$ per year.

One can only infer the constancy of dimensionless quantities because one cannot usually assume that the reference quantity remains constant. In the above example, other dimensionless quantities are also involved in the theoretical expressions for the transition frequencies.

In the near future, the changes in the values of the fundamental constants caused by mankind's present limitations in understanding and implementing the science behind measuring them, will dominate any changes that might be caused by the inconstancy of Nature's laws. The underlying assumptions behind some of the above can be questioned. For example, there has been at least one example of a cosmological "measurement" of the constancy of h where a null result was guaranteed through measuring a quantity by a method that predetermined a null result.

3.8
Future Trends and Advances

The fundamental-constants field is ever evolving; new experiments are undertaken with each major new advance in measurement science. Indeed, roughly speaking, our knowledge of the values of many of the fundamental constants improved by an order of magnitude each decade during the last half of the twentieth century. However, the question naturally arises as to whether this sort of improvement can continue indefinitely. Will phenomena and measuring techniques yet to be discovered lead to continued reductions in uncertainty of this magnitude into the twenty-first century?

We have almost arrived at the era predicted by Maxwell (1870) when he forecast, at a time when the atomic nature of our universe was increasingly emerging, that

> *If we wish to obtain standards*
> *of mass of length, mass or time*
> *that shall be absolutely permanent,*
> *we must seek them not in the*
> *dimensions, or motion, or the*
> *mass of our planet, but on the*
> *wavelength, the period of vibration*
> *and mass of those imperishable*
> *and unalterable and perfectly*
> *similar molecules.*

The projected change to the international measurement system (the basis for the SI units) means that theoretical and experimental science will at last be performed in terms of the same sets of quantities with an exactness that our forbears could only dream of. An important consequence will be that it will be possible for experiments relating to the measurement of dimensioned fundamental constants to revert from the national standard's laboratories to the universities and elsewhere.

We are discussing changing the definition of the SI unit of mass at a time when the discovery of the Higgs boson seems imminent. Why is the Higgs so important? Because it is thought to pervade the universal vacuum; not, as with the old ether, to provide a material substrate for the propagation of electromagnetic waves, but rather to interact with particles and confer mass upon them. The Higgs ministrations are usually hidden away in the vacuum, but if enough energy is brought to bear in a tiny volume of space, at the point where two energetic particles collide, then the Higgs can be turned into an actual particle whose existence can be detected. Theoretical calculations made using the standard model of particle physics combined with previous experiments serve to limit the possible range of masses for the Higgs particle. Right now that mass is thought to lie between 114 and about 190 GeV. However, it is difficult to imagine that an increased understanding of the nature of mass will immediately impact on how we choose to define the mass unit of our very practical SI unit system, but in another 50 years metrology may be heading along a very different direction.

The American Physicist Richtmyer (1932) echoing Maxwell of 50 years earlier, again asked and answered the question: "*Why should one wish to make measurements with ever increasing precision?* He too responded: *Because the whole history of physics proves that a new discovery is quite likely to be found lurking in the next decimal place.*" The last 50 years have amply demonstrated the wisdom of their response. A reply that will undoubtedly continue to be demonstrated in the future.

Some day we must reach the ultimate limits. However, we can be sure that scientists will continue their efforts to advance our knowledge of the fundamental constants unabated as long as they believe there is even a slim chance of success.

Glossary

a_e: Electron magnetic moment anomaly; $a_e = g_e/2 - 1 = \mu_e/\mu_B - 1$, where g_e is the g-factor of the electron, μ_e is the magnetic moment of the electron, and μ_B is the Bohr magneton: $\mu_B = eh/2\pi m_e$, where e is the elementary charge, h is the Planck constant, and m_e is the electron mass.

α: Fine-structure constant, approximately 1/137, is the dimensionless coupling constant or the measure of the strength of the electromagnetic force that governs how electrically charged elementary particles (e.g., electron, muon) and light (photons) interact.

α^{-1} Inverse fine-structure constant; $\alpha^{-1} \approx 137$.

BIPM: Bureau International des Poids et Mesures (International Bureau of Weights and Measures), located in Sèvres, France, a suburb of Paris. BIPM is the international standards laboratory.

CCE: Comité Consultatif d'Électricité (Consultative Committee for Electricity), one of the eight advisory committees to the CIPM.

CGPM: Conférence Général des Poids et Mesures (General Conference on Weights and Measures), the highest international metrological authority established by the Convention du Mètre (Treaty of the Meter) signed in 1875; it is a diplomatic organization.

CIPM: Comité International des Poids and Mesures (International Committee for Weights and Measures), one of the organizations established by the Convention du Mètre (Treaty of the Meter) signed in 1875. The CIPM supervises the BIPM and is under the authority of the CGPM.

CODATA: Committee on Data for Science and Technology, an interdisciplinary committee of the International Council of Scientific Unions. It seeks to improve the compilation, critical evaluation, storage, and retrieval of data of importance to science and technology.

JE: Abbreviation for Josephson effect, a solid-state, low-temperature physics phenomenon characteristic of weakly coupled superconductors cooled below their transition temperatures. An example is two thin films of superconducting lead separated by a thermally grown oxide layer about 1-nm thick.

K_J: Josephson constant: characteristic of the Josephson effect and assumed equal to 2 e/h, where e is the elementary charge and h is the Planck constant.

K_J-90: Conventional value of the Josephson constant adopted by the CIPM for international use in basing a representation of the volt on the Josephson effect starting 1 January 1990; $K_{J-90} = 483\,597.9\,\mathrm{GHz\,V^{-1}}$ exactly.

Muonium: Hydrogen-like atom composed of a positive muon and an electron (μ^+e^-atom).

NIST: National Institute of Standards and Technology, the national standards laboratory of the United States (called the National Bureau of Standards or NBS prior to 23 August 1988).

NPL: National Physical Laboratory, the national standards laboratory of the United Kingdom.

ppm: Symbol often used to denote an uncertainty of a fractional part in 10^6. Being an English language, specific symbol it is not part of the internationally supported set of quantities in the International Standards Organization Standard: ISO 31 and, because it is not used in a consistent way, is not an internationally recommended symbol, and that consequently, where it is used by authors, its meaning must always be defined in the text.

QED: Quantum electrodynamics, the relativistic quantum field theory of the interaction of charged particles and electromagnetic radiation (photons). QED is an amalgamation of Maxwell's theory of electromagnetism, quantum mechanics, and Einstein's special theory of relativity.

QHE: Abbreviation for quantum Hall effect, a solid-state, low-temperature physics phenomenon characteristic of a two-dimensional electron gas. The latter may be realized in a high-mobility semiconductor device such as a silicon metal-oxide-semiconductor field-effect transistor (MOSFET) or GaAs-$\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ heterojunction cooled to about 1 K. The applied magnetic field (magnetic flux density) B must be of order 10 T.

R_K: von Klitzing constant characteristic of the quantum Hall effect and assumed equal to h/e^2, where h is the Planck constant and e is the elementary charge.

R_K-90: Conventional value of the von Klitzing constant adopted by the CIPM for international use in basing a representation of the ohm on the quantum Hall effect starting 1 January 1990; $R_{K-90} = 25812.807\Omega$ exactly.

SI: Système International d'Unités (International System of Units), the modernized metric system with the seven base units meter (m), kilogram (kg), second (s), ampere (A), Kelvin (K), mole (mol), and candela (cd); and numerous derived units such as the Hertz (Hz), Joule (J), Newton (N), watt (W), volt (V), and ohm (Ω).

INTRODUCTION

Copper and its alloys are used when the application requires high electrical and thermal conductivity, formability, ease of joining, corrosion resistance, and moderate to high strength. In addition to its traditional uses in building construction, electrical and electronic applications, industrial machinery, transportation equipment, and consumer products, new uses for copper are constantly being found. Some of these are in solar heating, electric vehicles, superconductors (both high- and low-temperature types), fire safety systems, and even pharmaceuticals.

We first discuss the basic electronic and physical behavior of copper. All of the valuable functional properties of copper find their foundation in this electronic behavior. As an example, we describe the features of the electronic structure that lead to the high electrical conductivity of copper.

The useful properties of copper in practice are determined not only by the ideal behavior based on the fundamental electronic and physical behavior, but also by the modifications of that behavior brought about by processing and the presence of impurities. In Sec. 2, we therefore discuss the impurity content characteristic of high-conductivity copper and then summarize some of the key physical and mechanical properties of copper. After doing this, we discuss the practical aspects affecting the utilization of copper: resources and raw materials, production, alloy terminology, and standards. In Sec. 6, we describe the utilization of copper in a variety of applications before providing a brief summary in the final section.

1. BASIC ELECTRONIC AND PHYSICAL BEHAVIOR

Copper (atomic number $Z=29$) is in subgroup 1*B* of the periodic table of the elements. The copper atom contains 2, 8, and 18 electrons in its inner shells and 1 electron in its outer shell. The cuprous ion (Cu^+) is formed by loss of the first electron and the cupric ion (Cu^{2+}) is formed by loss of a second electron. The atomic weight is 63.54. There are two stable isotopes, ^{68}Cu and ^{65}Cu. The specific gravity is 8.89 and the melting point is 1083 °C.

The most important attribute of the electronic behavior of copper is that it behaves like a monovalent metal such as the alkali metals, but with behavior modified by the existence of the filled *d*-shell states at an energy about 2 eV below the unfilled *s*-like states that provide the monovalent behavior. The two most conspicuous electronic-behavior-based properties of copper, its high electrical conductivity and its distinctively reddish "copper" color, follow as consequences of these features of the electronic structure.

To envision the relationship of electrical conductivity, optical behavior, and other properties to the electronic structure of copper we have to consider the first Brillouin zone for the face-centered-cubic (fcc) structure, as shown in Fig. 1, and the nature of the Fermi surface encompassing the filled electronic states within that zone (Callaway, 1964). For a perfect three-dimensional lattice, there are three primitive translations, $\mathbf{a}_1,\mathbf{a}_2,\mathbf{a}_3$, which define the periodicity of the lattice. The requirement that the potential acting on an electron moving through a solid be identical at any two points $\mathbf{r}$ and $\mathbf{r}'$ connected by any linear combination of multiples of these primitive translation vectors leads to the requirement that the electronic wave functions obey Bloch's theorem and are labeled by a crystal-momentum quantum number $\mathbf{k}$, which is specified in terms of primitive reciprocal lattice vectors $\mathbf{b}_1,\mathbf{b}_2,\mathbf{b}_3$. Thus,

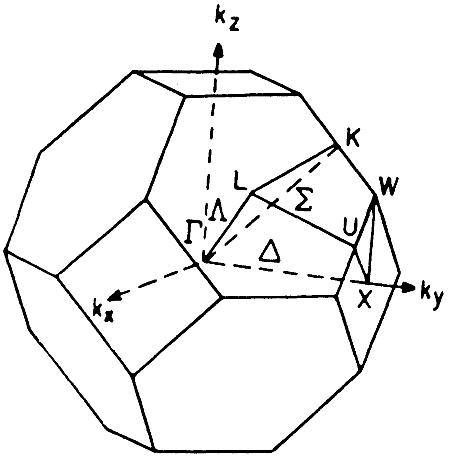

FIG. 1. The first Brillouin zone for the face-centered-cubic structure with points and lines of high symmetry labeled in conventional notation.

$$\mathbf{k}=2\pi\left(\frac{k_1\mathbf{b}_1}{N_1}+\frac{k_2\mathbf{b}_2}{N_2}+\frac{k_3\mathbf{b}_3}{N_3}\right), \qquad (1)$$

where k_1, k_2, k_3 and N_1, N_2, N_3 are integers with $k_1,k_2,k_3<N_1,N_2,N_3$, and

$$\mathbf{b}_1=\frac{\mathbf{a}_2\times\mathbf{a}_3}{\mathbf{a}_1\cdot(\mathbf{a}_2\times\mathbf{a}_3)}, \qquad (2)$$

with $\mathbf{b}_2$ and $\mathbf{b}_3$ obtained by cyclic permutation of the indices of the $\mathbf{a}$'s.

The *reciprocal-lattice vectors* $\mathbf{K}_m$, which are linear combinations of integral multiples of $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$, define a periodic lattice in reciprocal (or *lattice-momentum*, $\mathbf{k}$) space; The part of $\mathbf{k}$ space closer to the origin than to any nonzero $\mathbf{K}_m$ is called the *first Brillouin zone*, and is constructed by setting up planes that perpendicularly bisect the lines connecting the origin to all $\mathbf{K}_m$, and then taking the volume about the origin enclosed by these intersecting planes. Figure 1 shows the first Brillouin zone for the face-centered-cubic structure with conventional labeling of points and lines of high symmetry. Since the product $N_1N_2N_3$ is a very large number essentially corresponding to the number of copper atoms in a macroscopic sample ($\sim 10^{24}$), and k_1, k_2, k_3 are integers ranging from zero up to N_1, N_2, N_3, the $\mathbf{k}$ form a very finely spaced semicontinuum that in practice can be treated as a continuous variation of lattice momentum across the first Brillouin zone.

At each value of lattice momentum $\mathbf{k}$ in the first Brillouin zone there are a number of discrete electron energy states (E_m); and as $\mathbf{k}$ varies across the Brillouin zone, the set of curves given by the variation of the E_m with $\mathbf{k}$ gives the electronic energy band structure (Callaway, 1964). Because of the Fermi statistics obeyed by electrons, the first Brillouin zone can hold two electrons per real-space crystal lattice site per band. At absolute zero temperature the band states will be filled with electrons up to an energy level, the Fermi energy (E_F), such that all the electrons are accounted for. For a metal there are one or more partially filled bands. Thus there is a surface in reciprocal space separating filled from empty states. This surface is the *Fermi surface*. Since E_F is typically several electron volts and 1 eV is the energy equivalent of a temperature of 11 606 K, there is only a very slight blurring of the Fermi surface at finite temperatures. The properties of a metal are dominated either by the behavior of the electrons at or near the Fermi surface or by transitions between filled electron states below the Fermi energy and unfilled states above the Fermi energy. For example, the electrical conductivity is determined by the situation that, under the influence of a dc electric field, the only electrons that can respond are those at the Fermi surface, since they can be displaced into adjacent empty states with different lattice momenta. On the other hand, an optical-frequency electric field can cause transitions between filled states below the Fermi energy and unfilled states above E_F, and either or both states can be well separated in energy from E_F.

The simplest example of a Fermi surface is the spherical surface that occurs for a noninteracting electron gas, and the Fermi surface given by band theory for the monovalent alkali metals is quite close to spherical. For copper, as shown in Fig. 2, the Fermi surface is also basically spherical, but with distinctive *necks* contacting the hexagonal < 111 > faces of the first Brillouin zone (Segall, 1962). This behavior has its origin in the outer electron configuration of atomic copper and the way in which these outer electrons interact in the solid to form the energy bands. There is one valence electron state per copper atom, corresponding to the atomic 4*s* state; and it is these states that basically form the partially filled band, the filling of which determines the Fermi energy and Fermi surface. If this were the only effect determining the Fermi surface, it would be very similar to those of the alkali metals, quite close to spherical. However, the filled 3*d* states affect the electronic structure and consequent properties of copper in a very important way.

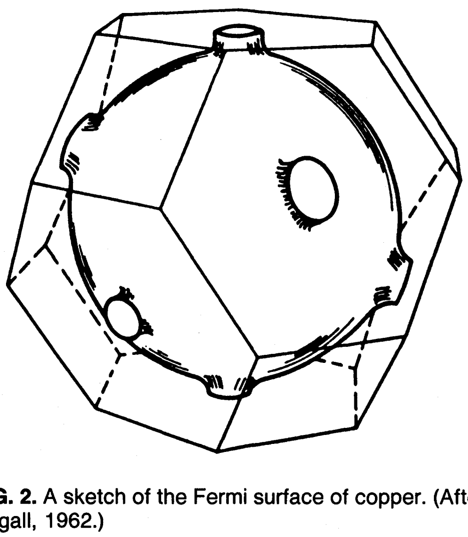

FIG. 2. A sketch of the Fermi surface of copper. (After Segall, 1962.)

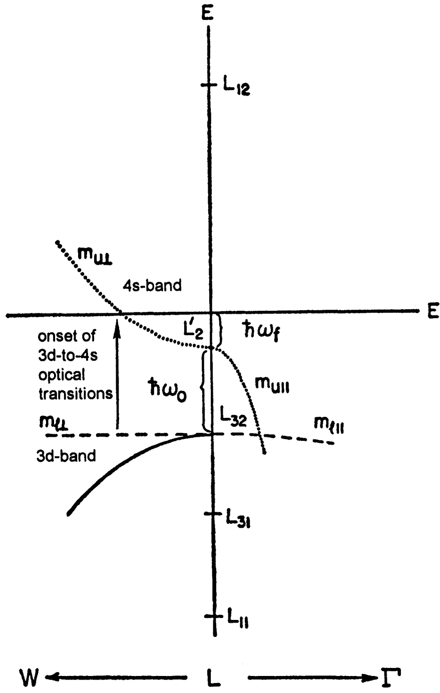

FIG. 3. The band structure near *L* in the first Brillouin zone for the noble metals. (After Cooper *et al.*, 1965.)

The 10 3*d* electrons per copper atom form filled bands in the solid and do not give a Fermi surface; however, these 3*d* states interact with the 4*s* states causing changed behavior (Segall, 1962) of the 4*s* band as shown in Fig. 3. The 4*s* band is "bent" upward by this interaction, so that the Fermi surface intercepts the hexagonal faces of the Brillouin zone with a ring-shaped intersection centered around the < 111 > direction in **k**-space. Thus it is the 4*s*-3*d* interaction (mixing) that causes the *necks* in the copper Fermi surface shown in Fig. 2.

The distinctive reddish color of copper corresponds to the sharp onset in frequency of strong interband optical transitions between filled states at the upper part of the 3*d* band (which has a relatively flat variation of energy with **k**) and empty conduction-band 4*s*-like states (Ehrenreich and Philipp, 1962; Cooper *et al.*, 1965). As can be seen from Fig. 3, these transitions become allowed only at an energy given by the energy difference between the $3d$ and $4s$ bands at the **k**-space locations where the $4s$ band cuts the Fermi energy E_F; and it is the associated sharp onset of strong interband optical transitions (indicated by the arrow in Fig. 3) that dominates the optical behavior of copper.

The high electrical conductivity of copper also arises from the modification of its free-electron-like (alkali-metal–like) monovalent behavior caused by the filled $3d$ states. The filled d shells cause (see Ziman, 1960, Chap. IX) the compressibility of copper to be much smaller than that of the alkali metals. Since the electrical resisitivity of copper at room temperature and above is dominated by scattering of electrons by thermal vibrations, the substantial decrease in amplitude of these vibrations, corresponding to the decreased compressibility, gives rise to the increased electrical conductivity.

2. CHARACTERIZATION AND PROPERTIES

The useful properties of copper in practice are determined not only by the ideal behavior based on the fundamental electronic and physical behavior described in Sec. 2, but in the modification of that behavior brought about by processing and by the presence of impurities. For example, we can consider such effects on the electrical conductivity. High-purity copper's electrical conductivity is slightly over 100% IACS (as based on a volume electrical resistivity of 0.0168 $\mu\Omega$ m). This value refers to the International Annealed Copper Standard (IACS) established in 1913 and is based on a copper standard defined as 100%, being given by 100 times the reciprocal ratio to the volume resistivity of annealed copper at 20 °C as measured at that time (0.017 241 $\mu\Omega$ m). Subsequent improvements in refining have raised the actual value of copper to slightly over 100% IACS. Electrical conductivity is temperature- and processing-sensitive; for copper it is 800% IACS at -240 °C and 38% IACS at 425 °C. Although copper does not become superconductive, its conductivity decreases markedly as temperature approaches absolute zero. Cold working of annealed copper to about 90% reduction in area results in a slight drop in electrical conductivity of 2–3% IACS. Conductivity is also affected by impurities or alloying elements.

Impurity content characteristics of high-conductivity copper are given in Table 1, while Table 2 summarizes some of the key physical and mechanical properties of such high-purity copper. Below we briefly summarize a number of the useful and interesting characteristic properties of copper.

2.1 Fatigue

Fatigue strength, usually specified at a life of 10^8 cycles, is enhanced by fine grain size and the absence of nonmetallic inclusions. The techniques used to strengthen coppers (see Sec. 2.3.1) are also effective in increasing resistance to fatigue.

2.2 Magnetic Properties

Copper and most of its alloys are nonmagnetic. Copper is a diamagnetic material and has a mass susceptibility (χ) of -0.086×10^{-6} cgs units per gram at room temperature. This is equivalent to a gram-atomic susceptibility of -5.1×10^{-6}. Susceptibility varies with increasing temperature; for example, it is -0.085 at 300 °C, -0.082 at 600 °C, and -0.079 at 900 °C.

2.3 Formability

Copper and its alloys are readily hot worked by all of the usual processes, and may be fabricated into end-use forms by rolling, bending, drawing, stretching, and coining. All operations that deform the metal result in work hardening to various extents depending on chemical composition and previous annealing or fabricating history.

Casting to shape, using sand or permanent molds, is a widely used process for copper and many of its alloys, including many specifically designed for this purpose.

2.3.1 Strengthening. In addition to cold working, copper alloys can be metallurgically strengthened by solid solution hardening, phase transformations, precipitation hardening (including spinodal decomposition), and grain size refinement.

Table 1. Chemical composition of some coppers.

Composition	C10100 Oxygen-free Electronic[a]	C10200 Oxygen-free[a]	C11000 Electrolytic Tough Pitch[b]

[a] ASTM B 170 Standard Specification for oxygen-free electrolytic copper-refinery shapes.
[b] Impurity elements vary according to process.

Solid solution hardening is achieved by short-range order, chemical interaction, lattice misfit, electrical and valence interaction, or a combination of these mechanisms.

Precipitation hardening is used primarily for chromium- and beryllium-containing coppers. The latter are the strongest generally available copper alloys, exceeding 1100 MPa tensile strength compared to 700–965 MPa reached by other forms of treatment.

Grain size refinement hardens copper alloys while retaining a high degree of ductility and toughness. A low-temperature anneal following cold working produces grain refinement in wrought material such as strip or wire.

2.4 Corrosion and Oxidation

Copper corrodes at low rates in unpolluted air, water, and deaerated nonoxidizing acids. It is not resistant to oxidizing acids, aerated nonoxidizing acids, oxidizing heavy-metal salts, sulfur, hydrogen sulfide, ammonia, and some sulfur and ammonia compounds, the latter of which forms highly soluble complexes with copper.

Copper and its alloys resist corrosion because of their low driving force toward the oxidized state and because their corrosion products form adherent protective films in some media. Under most outdoor conditions, the film eventually forms a green patina by reacting with moisture and oxides of sulfur in the air to form an artificial mineral, brochantite [$Cu_2SO_4 \cdot 3Cu(OH)_3$]. The actual color of the patina, ranging from blue-green to yellow- or brown-green will vary with the atmospheric environment to which the copper is exposed. The presence of sulfides in the atmosphere tends to blacken the patina and the presence of acids tends to dissolve it. Hence, the status of the patina on copper roofs, etc., is a good indicator of the degree of air pollution present.

Pure copper oxidizes in air at temperatures of approximately 250 °C and a film of Cu_2O is formed. Up to 100 °C, the oxide film grows linearly with the logarithm of time. From 100 to 1025 °C, the scale consists of an inner layer of Cu_2O and an outer layer of CuO. Oxidation behavior of alloys depends on alloying elements.

Hydrogen embrittlement at high temperatures occurs when hydrogen diffuses into copper and reacts with oxygen to form water vapor under high pressure. Subsequent defor-

Table 2. Physical and mechanical properties of oxygen-free copper C10100.

Property	English units	Metric units
Melting point	1981 °F	1083 °C

[d] At 100 million cycles.

mation results in cracking. Embrittlement is most common in oxygen-containing copper, typically C11000 (numbering system designates chemical composition, see Sec. 6.1), electrolytic tough pitch copper commonly used for applications where the highest electrical conductivity is not a requirement. Embrittlement is avoided by the use of oxygen-free or deoxidized grades.

2.5 Joining

Copper is easily soldered and brazed and can be welded. Mild fluxes or cleaning in a diluted acid bath is used to remove tarnish films. Commercial solders of lead plus tin in the range of 35–60% achieves a superior metallurgical bond, although such solders are prohibited in many areas for use in potable-water plumbing systems because, under certain conditions, the lead can leach into water. For plumbing use, antimony-tin, silver-tin, and copper-antimony solders are available. Copper is also easily brazed for higher-temperature applications. The welding processes most used for copper are resistance welding, gas-metal-arc (GMAW), and gas-tungsten-arc (GTAW). Electron-beam welding can be used for precision welds.

The brass alloys can be soldered, brazed, or welded. The other copper alloys are generally brazed or welded.

3. RESOURCES AND RAW MATERIALS

For at least 6000 years, copper has been one of the most important materials in the development of civilization and culture. The earliest copper objects were made by beating and hammering native copper, a form of metallic copper found mixed with copper-bearing ore. The earliest known copper object to have been melted and cast, a mace head dated at 5000 BC, was found at Can Hasan in Anatolia (now Turkey). Archaeological evidence shows that copper ore was first smelted between 4000 and 3500 BC, thus marking the beginning of the science of metallurgy. Current theory is that the smelting process evolved from observations of the reduction of copper minerals in the glaze used in pottery. Thus, the first smelting furnaces were undoubtedly pottery kilns. In 1965 archaeologists excavated the earliest furnace designed specifically for smelting copper at Timna in the southern Sinai in Israel. The furnace was dated at 3200 BC. Charcoal had been the reducing agent and iron oxide the fluxing agent.

By 3000 BC, silver, tin, and lead were being used, and copper began to be alloyed with these other metals. Alloying with tin produced bronze, a hard alloy used for tools, plows, weapons, armor, and decorative objects. Brass, an alloy of copper and zinc, has been in use for almost 2000 years. The first intentional use of brass was by the Romans, who used it for coins, ornaments, and decorative objects.

There was a thriving trade in bronze by 1500 BC, which gave this era the name of the Bronze Age. In the ancient world, copper was mined in Cyprus and other Middle Eastern sites; however, since there are no known tin deposits at the bronze-making centers of this region, the tin had to have been transported to the region. Evidence exists that it could have come from as far away as Cornwall, where it was transported from Penzance by the Phoenicians—the great metal traders of that era. Since the tin had to have come from a distant site, it is clear that the Bronze Age could not have started until a reliable network of trading contacts had been established.

By 1100 BC, iron had replaced bronze in most functional uses. The Iron Age came about both because of iron's wider availability and because swords made from iron were proven to be superior to those of bronze when the Hittites conquered Assyria and captured Babylon in 1300 BC.

The modern history of copper begins with the discovery of electricity, and electrical applications continue to be one of its principal uses. Copper ranks third in metal consumption after steel and aluminum. Copper is mined in about 58 countries, with the major producing countries accounting for nearly 95% of world production. The major producing countries, in order of production in 1990, were Chile, United States, Soviet Union, Canada, Zambia, Poland, China, Zaire, Australia, Peru, and Mexico. The leading copper refining countries in 1990 were United States, Soviet Union, Chile, Japan, Germany, China, Canada, Zambia, Belgium, and Poland. World mine production was 9 100 500 metric tons in 1990. Of this amount, the United States produced 1 565 100 metric tons. Despite copper's long history, about 75% of all copper ever mined has been consumed since World War II. Copper ore reserves in the United States and the world are considered more than adequate to meet cumulative demand in the foreseeable future.

4. PRODUCTION

In present-day mining operations, large quantities of low-grade ore are crushed and loaded into trucks or conveyor belts for delivery to the ore treatment plant. In the United States, the ore averages about 0.6% copper, the richer values having long since been mined out. The ore is treated by grinding and froth flotation to produce a beneficiated product containing about 25% copper. These concentrates are reduced to the metallic state by smelting to produce copper matte containing up to about 60% copper. The matte is converted by selective oxidation to blister copper containing 98.5% or more copper. This intermediate product is refined electrolytically into copper cathodes containing 99.9% or more copper.

In recent years, more and more mines are leaching waste dumps and oxide ores for recovery of copper. Sulfuric acid, recovered from smelter off-gases as part of air-pollution control, is used as the leachant. Acid liquors containing copper are purified by solvent extraction, and the copper is recovered, in the form of cathodes, by electrowinning.

Cathodes from both the electrolytic refining process and the electrowinning process are, for the most part, melted, cast, and rolled into wire rod—a precursor for drawing into wire. The remainder is melted and cast into cakes or billets for conversion into semifabricated forms by manufacturers of wrought copper and copper alloys. Approximately 75% of all newly mined copper and 50% of all copper (including scrap) is made into wire and cable by wire mills. Most of the remainder is made into sheet, strip, plate, rod, bar, pipe, tube, wire, forgings, and extrusions by brass mills. A small amount is used in castings by foundries or manufactured into powder. Certain mill products, such as wire and most tubular products, are used without further fabrication. Most flat-rolled products, bar, rod, mechanical wire, and forgings go through multiple forming, finishing, machining, and assembly operations before their ultimate use in a manufactured product.

Free-cutting brass rod, which exhibits outstanding machinability and good corrosion resistance, and brass strip, which has high strength, corrosion resistance, excellent formability, and good electrical properties, constitute more than three-fourths of the total tonnage of copper alloys shipped from U.S. brass mills. Other alloy types of major commercial significance include tin bronzes (phosphor bronzes), which are noted for their excellent cold-forming behavior and strength; tin brasses, known for outstanding corrosion resistance; copper nickels, which are strong and particularly resistant to seawater; nickel silvers, which combine a silvery appearance with good formability and corrosion resistance; beryllium coppers, which provide outstanding strength when hardened; and aluminum bronzes, which have high strength along with good resistance to oxidation, chemical attack, and mechanical abrasion.

Foundries use prealloyed ingot, scrap, and virgin metal as raw materials. Their chief products are shaped castings for many different industrial and consumer goods, the most important of which are plumbing products and industrial valves. Centrifugal- and continuous-cast products find major application as bearings, cylinders, and other symmetrical components. Powder plants produce powder and flake for further fabrication into powder metallurgy parts, chiefly small sintered bronze bushings for bearings.

In 1990, the United States consumed 3 064 000 metric tons of copper mill and foundry products. The total supply of copper and its alloys (wire mill, brass mill, foundry, and powder products) to U.S. domestic users totaled 6643 million pounds (metal content including alloying ingredients). Of this, the amounts to the five major end-use markets were (in millions of pounds) building construction, 2627; electrical and electronic, 1723; industrial machinery and equipment, 923; transportation equipment, 746; and consumer and general products, 624.

A large proportion of copper supply is provided by scrap. This recycled material is responsible for about 45% of the total copper supply in the United States.

In 1990, the United States was self-sufficient in copper, exporting 400 000 metric tons of concentrates and refined copper more than it imported, and exporting 4400 metric tons of scrap more than the 95 600 metric tons of copper contained in imported semifabricated products it imported. Imports of copper metal, in the form of primary refinery shapes or mill products, were about 7% of U.S. total supply.

5. COPPER AND ALLOY TERMINOLOGY AND STANDARDS

To ensure orderly identification of specific wrought and cast copper chemical compositions, a six-digit Unified Numbering System is used in the United States and Canada. This system has been adopted by North American specifying bodies such as the American Society for Testing and Materials (ASTM), Society for Automotive Engineers (SAE), and various federal organizations in specifying standards for copper and copper alloy products.

Besides the ASTM standards used in the United States and Canada, other national specifications are BS in the United Kingdom and DIN in Germany.

In the designation system, numbers from C10000 through C79999 denote wrought alloys. Cast alloys are numbered from C80000 through C99999. Within these two categories, the compositions are grouped into the following families of copper and copper alloys:

Coppers (C10000–C15999 and C80000–C81299): Metal that has a designated minimum copper content of 99.3% or higher.

High-Copper Alloys (C16000–C19999 and C81300–C82999): For the wrought products, these are alloys with designated copper contents less than 99.3% but more than 96% that do not fall into any other copper alloy group. The cast high-copper alloys have designated copper contents in excess of 94%, to which silver may be added for special properties.

Brasses: These alloys contain zinc as the principal alloying element with or without other designated alloying elements such as iron, aluminum, nickel, and silicon. The wrought alloys comprise three main families of brasses: copper-zinc alloys (C20500–C28599); copper-zinc-lead alloys (leaded brasses) (C31200–C38599); and copper-zinc-tin alloys (tin brasses) (C40400–C49999).

The cast alloys comprise four main families of brasses: copper-tin-zinc alloys (red, semi-red, and yellow brasses) (C83300–C85899); "manganese bronze" alloys (high-strength yellow brasses)(C86100–C86399); leaded "manganese bronze" alloys (leaded high-strength yellow brasses)(C86400–C86899); and copper-zinc-silicon alloys (silicon brasses and bronzes) (C87300–C87999).

Bronzes: Broadly speaking, bronzes are copper alloys in which the major alloying element is not zinc or nickel. Originally "bronze" described alloys with tin as the only or principal alloying element. Today, the term is generally used not by itself but with a modifying adjective. For wrought alloys, there are four main families of bronzes: copper-tin-phosphorus alloys (phosphor bronzes)(C50100–C52499); copper-tin-lead phosphorus alloys (leaded phosphor bronzes) (C53200–C54899); copper-aluminum alloys (aluminum bronzes) (C60600–C64499); and copper-silicon alloys (silicon bronzes) (C64700–C66199).

The cast alloys have four main families of bronzes: copper-tin alloys (tin bronzes) (C90200–C91799); copper-tin-lead alloys (leaded and high-leaded tin bronzes) (C92200–C94599); copper-tin-nickel alloys (nickel-tin bronzes) (C94700—C94999); and copper-aluminum alloys (aluminum bronzes) (C95200–C95900).

The family of alloys known as "manganese bronzes," in which zinc is the major alloying element, is included in the brasses, above.

Copper-Nickels (C70100–C71999 and C96200–C96999): These are alloys with nickel as the principal alloying element, with or without other designated alloying elements.

Copper-Nickel-Zinc Alloys (C73000–C79999 and C97300–C97999): Known commonly as "nickel silvers," these are alloys that contain nickel and zinc as the principal and secondary alloying elements, with or without other designated elements. They contain no silver.

Leaded Coppers (C98200–C98999): These comprise a series of cast alloys of copper with 20% or more lead, with usually a small amount of silver present, but without tin or zinc.

Special Alloys (C99300–C99999): Alloys whose chemical compositions do not fall into any of the above categories.

6. APPLICATIONS

Copper and its alloys are widely used commercially because of their excellent electrical and thermal conductivity, resistance to corrosion, and ease of fabrication, with good strength and fatigue resistance. Pure copper is used for electrical applications such as wire and cable, bus bars, electrical contacts, and any part required to conduct electricity. Copper and certain brasses, bronzes, and copper nickels are used for automobile radiators, heat exchangers, home heating systems, solar-energy panels and other applications requiring high thermal conductivity. Copper, brass, some bronzes, and copper nickel are used for corrosion-resistant pipe, valves, and fittings in potable-water, process-water, and other aqueous fluid systems. The copper-nickel and bronze alloys are most noted for their application in marine systems. Copper and the brass and bronze alloys are widely used in architecture, for both functional and decorative purposes, in such applications as roofing and guttering, locks and hinges, railings, and window and door mullons.

Copper chemicals, such as copper sulfate, carbonate, oxychloride, and oxides, are used in a wide range of applications: as an algicide in water treatment; as a micronutrient in chicken and cattle feed and on copper-deficient agricultural soil; as a fungicide and bactericide on crops grown in tropical areas; as a wood preservative; in antifouling marine paint; and as oxidation catalysts in petroleum product and organic chemical manufacture.

Copper and copper alloys are used in a number of newly developed technologies. For example, copper is an important material in the use of semiconductors and microcircuitry, where it is used in lead frames and in printed circuit boards. It is used as the stabilizer in superconducting cables. Here the superconducting alloy filaments are embedded in a matrix of pure copper. In this role, the copper acts as the electricity conductor when the filaments are not in their superconducting state and acts as a heat transfer agent to cool the filaments to the temperature at which they are superconducting. In the conventional, low-temperature system, the superconducting filaments are niobium-titanium or niobium-tin alloy. In the new high-temperature system, the superconducting filaments are ceramics that may themselves contain copper oxide.

Copper has also made possible the use of a number of new technologies, and its use is growing as a result. For example, in telecommunications the FAX machine would not be possible without copper wire, and increasing use of FAX for information transmission has greatly increased the use of copper telecommunications cable. Likewise, more and more automation and instrumentation is being used in automobiles. This has been made possible by copper wire and, as a result, has significantly increased the use of copper in an average automobile, now standing at approximately 45 lb per vehicle.

New uses are continually being developed for copper and its alloys and compounds. Among these are applications that take advantage of its bacteriostatic properties such as for clean surfaces in hospitals and public buildings; as a biofouling- resistant surface on ships and other marine structures; in fire safety sprinkler systems and gas distribution systems; and for pharmaceuticals used in diseases where tissue damage is involved.

7. SUMMARY

Copper has been one of the most important materials in the development of civilization, and even today is a significant factor in the development and application of new technologies. The modern growth of the industry is linked to the widespread use of electricity and the continual development of new ways to use electricity. Copper's high electrical and thermal conductivity, formability, and corrosion resistance account for its major applications today.

INTRODUCTION

If the thermodynamic properties of matter in equilibrium are surveyed, it will be found that they fall into two groups: those that are smooth and continuous, and those that have sharp discontinuities. As examples of the first group we may cite the properties of ideal or nearly ideal gases (energy, entropy, specific heat, and equation of state), of ideal or nearly ideal solids, of ideal or nearly ideal mixtures of gases or solids, paramagnetism and diamagnetism, and properties of electrons and phonons in normal metals. The second group is usually associated with phase transitions of various types: liquid–vapor equilibrium and the critical point, the melting of solids, phase separation in liquid or solid mixtures or solutions, order–disorder transitions in alloys, ferromagnetism, antiferromagnetism, superconductivity, and λ-point anomalies (e.g., liquid helium).

Standard statistical mechanics (see STATISTICAL MECHANICS, CLASSICAL; STATISTICAL MECHANICS, QUANTUM) can deal with the first group with relative ease. The macroscopic body under consideration can be decomposed into microscopic constituents (molecules, harmonic oscillators, spins, and electrons) that can to a good approximation be treated as noninteracting. Of course there must be interactions present to ensure that thermal equi-

librium is attained, but in describing the behavior of the macroscopic bodies these interactions can be ignored. The energy levels of the macroscopic body can be easily related to the energy levels of the microscopic constituents, and with the aid of some elementary combinatorial analysis, a partition function can be constructed from which the equilibrium behavior of the macroscopic bodies can be derived. Elementary mathematical considerations show that the thermodynamic properties will be continuous.

In general, the discontinuities described in the properties of the second group above originate in *interactions* between the microscopic constituents, and the problem of how to take such interactions into account in calculating a partition function will be central to our discussions. Much of the mathematics involved in a proper treatment of interactions is specialized and sophisticated. The major aim of the present article will be to convey the results and significance of the calculations, which, we believe, can be understood by the general physicist even if the detailed mathematical techniques are beyond him or her.

When the interactions between the constituents are weak, PERTURBATION METHODS (*q.v.*) can be used, but as long as only a finite number of terms are considered, the continuity of the thermodynamic properties will not be destroyed. Discontinuous behavior can be introduced only by taking the perturbation series to infinity so that the mathematical character of the partition function is changed. In fact, the problem to be tackled in dealing with phase transitions is the "strong interaction" problem in which the interactions can no longer be treated as a small perturbation, but play a dominant role in the calculations and in the resulting physical properties.

We will be largely concerned with behavior near critical points of fluids, magnets, and solutions, and with various types of λ-point transition. The past two decades have seen great progress in the theoretical understanding of how this behavior depends on the nature of the intermolecular interactions, e.g., their symmetry and range. We shall endeavor to describe this progress and bring the reader up to the frontiers of current research.

Our treatment will follow the historical development of the subject, and we shall divide this history into four periods:

1869–1944	The classical period
1944–1965	The Onsager revolution
1965–1971	Reconciliation of Onsager with van der Waals
1971–	Renormalization group

In the first period the term classical is used in the sense of "well established" and not with any relationship to quantum theory. The subject starts with the introduction of the term "critical point" by Thomas Andrews in his Bakerian Lecture of 1869 to the Royal Society. Andrews had used the term before in 1863, but the exposition of the true nature of the critical point of a fluid took place in the Bakerian Lecture in which he discussed in detail the experimental behavior of the isotherms of carbon dioxide. A few years later van der Waals provided a theoretical explanation of Andrews's results. The classical period is characterized by the interplay of experiment and theory, and the introduction of new concepts that seemed adequate to provide a qualitative and quantitative description of the phenomena under consideration. Developments that took place in different areas of physics seemed to have many features in common and led eventually to the idea of a unified description of all phenomena involving critical points or λ points.

The second period was initiated by a mathematical *tour de force*, the exact solution by Onsager of a realistic two-dimensional model, giving results that were in basic disagreement with the classical calculations. This period was characterized by further exact calculations of the Onsager kind and also by "down-to-earth" numerical calculations that made extensive use of computers; in addition, new experimental techniques were exploited to furnish more accurate data than had been available previously. As a result the classical theories were completely discredited in relation to quantitative predictions of critical behavior. However, no coherent new pattern was formulated to put in its place.

This led Uhlenbeck to suggest at a conference on "Phenomena in the Neighbourhood of Critical Points" at the National Bureau of Standards in April 1965 that the most important task facing workers in the field was to reconcile Onsager with van der Waals. Indeed, shortly after this, a wider framework emerged into which the new theoretical and experimental results seemed to fit. During the period 1965–1971 this framework was explored in more detail, and the pattern of behavior was summarized most succinctly in the hypothesis of universality. However, the pattern was obtained empirically — there was no theoretical explanation.

The latest phase supplied the theoretical understanding that has made the field "respectable." It was initiated in 1971 by Kenneth Wilson, who suggested a brilliant application of the renormalization group, a concept taken from field theory, to behavior near a critical point. The burst of research activity stimulated by Wilson's ideas has opened up many new avenues of exploration; Wilson's work received rapid recognition and he received a number of important awards culminating in the Nobel prize for physics in 1982. The recognition accorded Wilson is also a recognition of the field of critical phenomena and of the work of all those who helped build the structural foundation on which the renormalization group could base itself.

1. THE CLASSICAL PERIOD

1.1 Liquid–Gas Critical Point

The relation between gases and liquids was the subject of much attention during the first half of the 19th century. It was realized quite early that the liquid phase ceased to exist above a certain temperature, but the general assumption was that it disappeared into the gaseous phase. Thus Faraday talked of the "disliquefying point," while Mendelev used the term "absolute boiling temperature" for the point at which the latent heat of evaporation becomes zero.

In addition to careful and accurate experiments on carbon dioxide described in the Bakerian Lecture of 1869, Thomas Andrews introduced a new concept of symmetry between the liquid and gaseous phases; the two phases merged at the critical point into one fluid phase, "but if any one should ask whether it is now in the gaseous or liquid state, the question does not, I believe, admit a positive reply." He emphasized this feature in the title of his lecture "On the Continuity of the Gaseous and Liquid States of Matter," and pointed out how it was possible, by suitable choice of path, to pass from the liquid to the gaseous phase without any discontinuity. Figure 1 represents the isotherms of carbon dioxide taken from Andrews's Bakerian Lecture (1869). The difference of behavior below and above the critical temperature is manifest. Andrews estimated the critical temperature at 30.92 °C.

Only four years elapsed before van der Waals used the newly developing ideas on the kinetic theory of gases to give a plausible theoretical explanation of Andrews's experimental data. Van der Waals assumed that a gas is made up of molecules with a hard core and a long-range mutual attraction. The range of the attractive forces was assumed to be long compared to the mean free path, and they give rise to a negative "internal pressure." To calculate its value van der Waals made use of the virial theorem that Clausius had introduced in 1870 only a few years before, which states that

$$\left\langle \sum_i \tfrac{1}{2} m v_i^2 \right\rangle = -\tfrac{1}{2} \left\langle \sum_i (x_i X_i + y_i Y_i + z_i Z_i) \right\rangle , \qquad (1)$$

where v_i is the velocity, (x_i, y_i, z_i) the coordinates, and (X_i, Y_i, Z_i) the force on the ith molecule. He found that

$$P_{\text{internal}} = 1/v^2, \qquad (2)$$

where $v = V/N$ is the volume per molecule. For the hard core he made the simplest assumption that the available volume is reduced from v to $v-b$. Hence the equation he put forward was

$$P = P_{\text{internal}} + RT/(v-b), \qquad (3)$$

$$(P + a/v^2)(v-b) = RT. \qquad (4)$$

Van der Waals was a doctoral student, and the above ideas were put forward in his thesis in Dutch. Their importance was quickly recognized by Maxwell, who reviewed the thesis in *Nature* in 1874, and in a lecture to the Chemical Society in 1875 he wrote as follows:

"The molecular theory of the continuity of the liquid and gaseous states forms the subject of an exceedingly ingenious thesis by Mr. Johannes Diderick van der Waals, a graduate of Leyden. There are certain points in which I think he has fallen into mathematical errors, and his final result is certainly not a complete

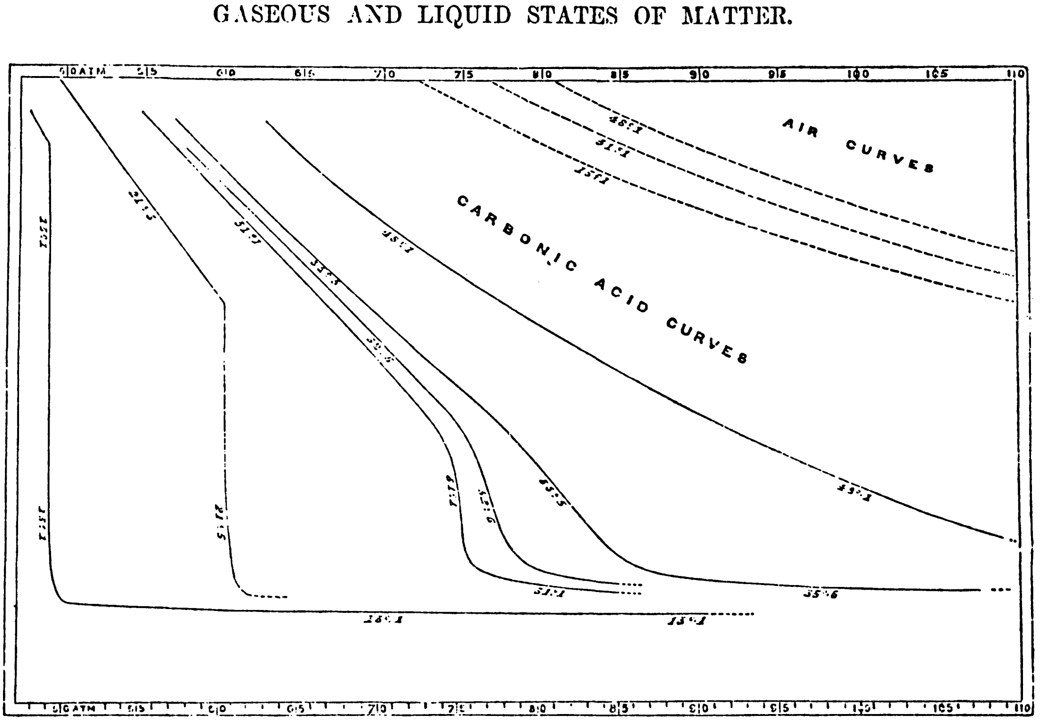

FIG. 1. Isotherms of carbon dioxide taken from Andrews's Bakerian Lecture to the Royal Society in 1869. Andrews's estimate for the critical temperature was 30.92 °C.

expression for the interaction of real molecules, but his attack on this difficult question is so able and so brave, that it cannot fail to give a notable impulse to molecular science. It has certainly directed the attention of more than one inquirer to the study of the Low-Dutch language in which it is written."

The form of isotherms given by van der Waals's equation (4) is shown in Fig. 2. In order to compare them with the experimental results of Andrews, it was necessary to decide where to draw the horizontal line that represents the liquid and gas in equilibrium. Here Maxwell put forward his "equal area" construction, which is illustrated in Fig. 3.

Boltzmann too was impressed by van der Waals's results, and although he said that "unfortunately, van der Waals had to abandon mathematical rigour at a certain point in order to carry out his calculation," he was nevertheless impressed by the practical value of his theory.

It is significant that both Maxwell and Boltzmann were reasonably happy with the attractive a/v^2 term; their main anxiety was the repulsive term.

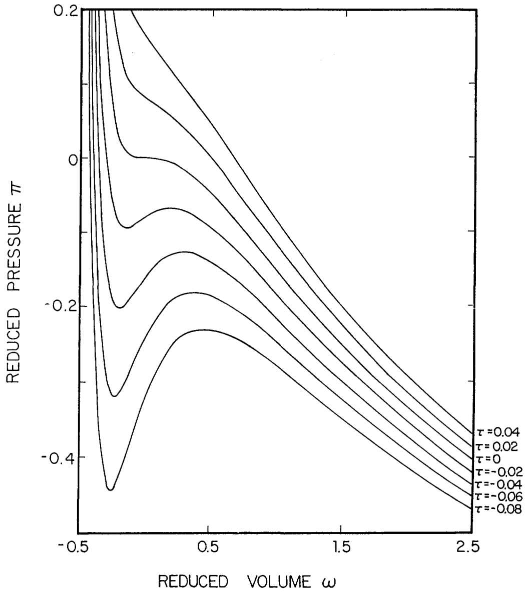

FIG. 2. Isotherms corresponding to van der Waals's equation (4). Reduced pressure $\pi(=P/P_c)$ is plotted against reduced volume $\omega(=V/V_c)$.

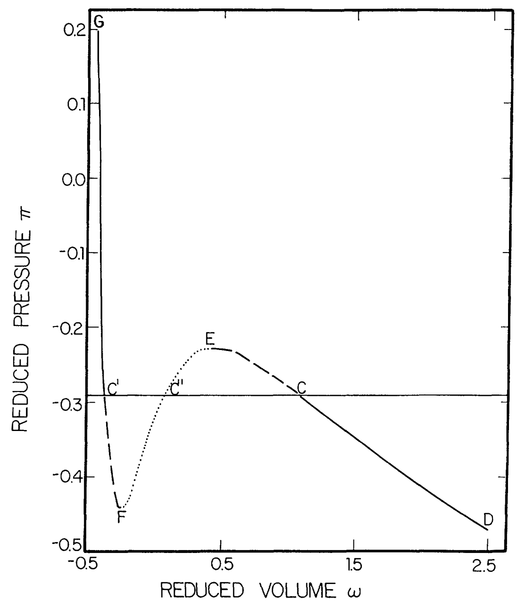

FIG. 3. Maxwell's "equal area" construction to determine the horizontal part of the isotherm in van der Waals's equation. Area $C'FC''$ = Area $C''EC$. The construction was proposed in a lecture to the Chemical Society in 1875.

The new concept of "internal pressure" that van der Waals introduced was to bear fruit 30 years later in a completely different area of physics.

1.2 Magnet–Fluid Analogy: Curie Point of a Ferromagnet

The fact that a magnet loses its magnetic power at high temperatures was noted by Gilbert in his famous treatise "De Magnete" in 1600. A more detailed quantitative investigation started in the 19th century involving Faraday in the 1830s, Barrett in 1874, Bauer in 1880, and Hopkinson in 1889, who was the first to introduce the term "critical temperature" for "the temperature at which the magnetism disappears." But the definitive paper for magnets comparable to that of Andrews for fluids was written by Curie in 1895 before he started his more famous investigations of radioactivity.

One of the most interesting new ideas put forward in this paper is the analogy between magnets and fluids. Taking pressure P as the analog of magnetic field and density ρ as the analog of magnetization, Curie points out the close similarity between the P-ρ and M-H isotherms (Fig. 4). The paramagnetic state at high temperatures corresponds to the gaseous phase and the ferromagnetic state at low temperatures to the liquid phase. Curie says that this analogy could be used to suggest new and useful experiments, and he poses the question whether there exists a precisely defined critical point with associated critical constants for a ferromagnet analogous to a fluid.

It was this analogy that led Pierre Weiss in 1907 to postulate his *molecular field* hypothesis, in which he assumed that the mutual interactions between the molecules could be replaced by a uniform field nM proportional to the magnetization in the same direction. He states, "One may give to nM the name *Internal Field* to mark the analogy with the internal pressure of van der Waals."

For the magnetic susceptibility of a gas, Curie had discovered experimentally the inverse temperature dependence

$$\chi = C/T, \tag{5}$$

and Langevin had applied the techniques of statistical mechanics to explain this result theoretically (see PARAMAGNETISM). For an ideal gas of molecules each having magnetic moment μ_0, Langevin derived the magnetic equation of state (analogous to $PV=RT$ for an ideal gas)

$$M = L(\mu_0 H/kT), \tag{6}$$

where $L(x)$ is the Langevin function $\coth x - x^{-1}$.

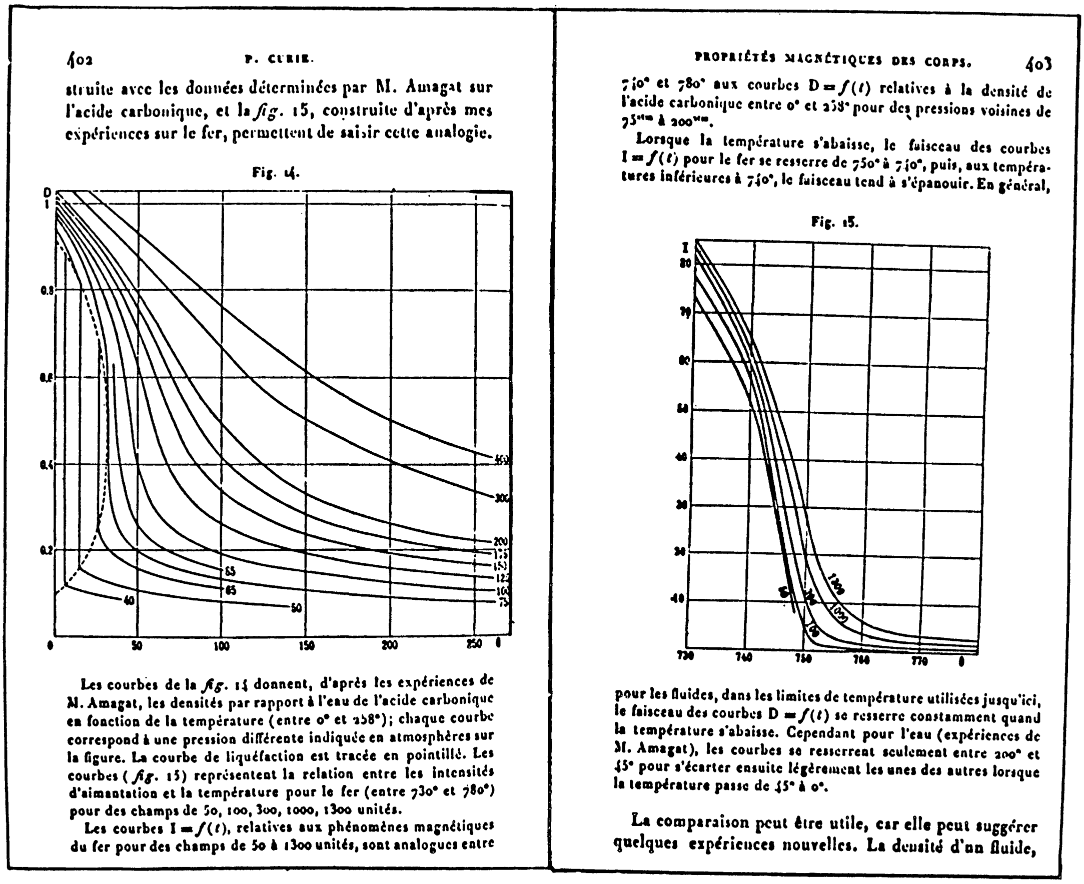
For a ferromagnet Weiss put forward the simple modification

$$M = L[\mu_0(H + H_{\text{int}})/kT] \quad (H_{\text{int}} = nM), \tag{7}$$

and this led to far reaching conclusions. There is indeed a sharply defined critical point analogous to that for a fluid; Weiss and Kamerlingh Onnes later termed this the *Curie point* in memory of Curie, who had been killed in an accident in 1906. Below the Curie temperature there is a nonzero spontaneous magnetization; in the paramagnetic state above the Curie temperature T_c, Curie's relation (5) for the susceptibility is modified to

$$\chi = C/(T - T_c), \tag{8}$$

and this is usually called the Curie–Weiss law.



402 P. CURIE.

struite avec les données déterminées par M. Amagat sur l'acide carbonique, et la *fig.* 15, construite d'après mes expériences sur le fer, permettent de saisir cette analogie.

Fig. 14.

Les courbes de la *fig.* 14 donnent, d'après les expériences de M. Amagat, les densités par rapport à l'eau de l'acide carbonique en fonction de la température (entre 0° et 258°); chaque courbe correspond à une pression différente indiquée en atmosphères sur la figure. La courbe de liquéfaction est tracée en pointillé. Les courbes (*fig.* 15) représentent la relation entre les intensités d'aimantation et la température pour le fer (entre 730° et 780°) pour des champs de 50, 100, 300, 1000, 1300 unités.

Les courbes $I = f(t)$, relatives aux phénomènes magnétiques du fer pour des champs de 50 à 1300 unités, sont analogues entre

PROPRIÉTÉS MAGNÉTIQUES DES CORPS. 403

740° et 780° aux courbes $D = f(t)$ relatives à la densité de l'acide carbonique entre 0° et 258° pour des pressions voisines de 75^{atm} à 200^{atm}.

Lorsque la température s'abaisse, le faisceau des courbes $I = f(t)$ pour le fer se resserre de 750° à 740°, puis, aux températures inférieures à 740°, le faisceau tend à s'épanouir. En général,

Fig. 15.

pour les fluides, dans les limites de température utilisées jusqu'ici, le faisceau des courbes $D = f(t)$ se resserre constamment quand la température s'abaisse. Cependant pour l'eau (expériences de M. Amagat), les courbes se resserrent seulement entre 200° et 45° pour s'écarter ensuite légèrement les unes des autres lorsque la température passe de 45° à 0°.

La comparaison peut être utile, car elle peut suggérer quelques expériences nouvelles. La densité d'un fluide,

FIG. 4. The analogy between fluids and magnets noted by Curie in 1895. On the left-hand side are Amagat's density–temperature curves for CO_2, at different pressures, and on the right-hand side are Curie's own measurements of the magnetization–temperature curves for iron at different magnetic fields.

The magnet–fluid analogy that proved so fruitful seems to have been forgotten for more than 30 years until it was rediscovered in the lattice-gas model by Cernuschi and Eyring in 1939. It was fruitful again in subsequent developments after 1944.

1.3 Microscopic Critical Behavior of Fluids

The experiments of Andrews were concerned with the thermodynamic properties of bulk fluids. An experimental phenomenon that excited theoretical interest at the beginning of the 20th century was critical opalescence, in which a colorless transparent fluid suddenly becomes opaque in a narrow region of temperatures near T_c; the onset of opacity is accompanied by dramatic changes of color. (These experimental results had been known much earlier, an initial observation having been made by Andrews.) It was clear that a considerable increase in light scattering takes place near the critical point, and this was explained by Smoluchowski and Einstein as arising from large fluctuations in density as follows.

In 1910 Einstein showed how Boltzmann's formula relating the probability of any state of a system to its entropy (see STATISTICAL MECHANICS, CLASSICAL) could be used to calculate fluctuations of thermodynamic quantities. For the density he derived the formula

$$\langle \Delta\rho^2 \rangle = (\rho^2 kT/V) K_T, \tag{9}$$

where K_T is the isothermal compressibility,

$$K_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial P}\right)_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T. \tag{10}$$

Assuming that a change in density is accompanied by a change of refractive index according to the Lorentz–Lorenz law

$$(\epsilon-1)/(\epsilon-2)=A\rho \tag{11}$$

and that scattering takes place randomly, Einstein came to the conclusion that the scattering of light of wavelength λ should be proportional to K_T/λ^4. Since van der Waals's equation leads to an infinite value of K_T at T_c, this seemed to provide a satisfactory explanation of critical opalescence.

It was remarkably perceptive of Ornstein and Zernike (1914, 1916) to note an inconsistency in the treatment arising from the assumption that the fluctuations in all elements of volume are independent of one another. In fact, they pointed out that there must be a correlation between different elements that increases indefinitely in range as the critical point is approached.

To treat this correlation, Ornstein and Zernike introduced a basic new function, afterwards called the "pair distribution function," which has played a central role in the theory of liquids ever since. Let $v(d\mathbf{r})$ be a random variable representing the number of molecules in a volume $d\mathbf{r}$ centered at $\mathbf{r}$. Since $d\mathbf{r}$ is very small, the probability of occupation by more than one particle being of order $d\mathbf{r}^2$ can be neglected. Hence we can write

$$\langle v(d\mathbf{r})\rangle=n_1(\mathbf{r})d\mathbf{r}, \tag{12}$$

where $n_1(\mathbf{r})$ is the density, which Ornstein and Zernike took to be a constant ρ. Similarly for the correlation between particles at points $\mathbf{r}_1$ and $\mathbf{r}_2$,

$$\langle v(d\mathbf{r}_1)v(d\mathbf{r}_2)\rangle=n_2(\mathbf{r}_1,\mathbf{r}_2)d\mathbf{r}_1d\mathbf{r}_2, \tag{13}$$

and for a homogeneous isotropic fluid $n_2(\mathbf{r}_1,\mathbf{r}_2)$ is of the form $n_2(r)$ $(r=|\mathbf{r}_1-\mathbf{r}_2|)$.

Ornstein and Zernike introduced the function

$$g(r)=n_2(r)/\rho^2, \tag{14}$$

which approaches 1 at large distances where the correlation becomes negligible. They used the fluctuation relation (9) to derive a fundamental identity between K_T and $g(r)$. But they also obtained an integral equation for $g(r)$ that they were able to solve explicitly.

The basic physical idea behind Ornstein and Zernike's treatment was to differentiate between the direct influence of molecular interactions, which should be short ranged and was represented by a function $f(r)$, and the correlation between densities, represented by $g(r)$ above, which should become long ranged as the critical temperature is approached. The integral equation relates $g(r)$ and $f(r)$.

Their calculations suggested that the correlations fall off asymptotically as

$$\frac{1}{r}\exp(-\kappa r), \tag{15}$$

where the value of κ can be determined from van der Waals's equation [$\kappa \sim (T-T_c)^{1/2}$]. Their detailed conclusions about light scattering differed from those of Einstein; near the critical temperature the λ^{-4} Rayleigh dependence on wavelength ceases to be valid, and there is a "whitening" of the scattered light. By temperature T_c the wavelength dependence has become of the form λ^{-2}.

1.4 Critical Behavior of Binary Alloys

The early years of the 20th century saw the development of x-ray diffraction as a powerful tool in the investigation of crystal structures, and compounds such as NaCl were found to have a regular ordered structure. However, the ionic bond between Na and Cl is so strong that no significant disordering occurs when the temperature is raised; the crystal melts before it disorders.

In 1919 Tammann suggested that similar ordering might occur in metallic alloys, and this was demonstrated experimentally a few years later (Bain, 1923; Johansson and Linde, 1925) by the existence of superlattice lines in the x-ray diffraction pattern of copper–gold alloys. However, for such systems there were soon indications that significant disordering takes place with an increase in temperature and that this is accompanied by an anomalous specific heat.

The mathematical description of the disordering process is usually associated with the names of Bragg and Williams. In their classic paper in 1934 they introduced a parameter S to characterize the *degree of order* and used Boltzmann's principle to calculate its behavior as a function of temperature. They found a pattern closely analogous to the Weiss theory of ferromagnetism, with S falling rapidly to zero at a critical temperature T_c and remaining zero for $T > T_c$. In fact, for a binary alloy with equal concentrations of constituents the equation derived for S was

$$S=\tanh(ST_c/T), \tag{16}$$

which is of the same form as Eq. (7) with $H=0$ and $\tanh x$ replacing the Langevin function $L(x)$.

In 1935 Bragg and Williams wrote a second paper elaborating their ideas. Because of the analogy with ferromagnetism they called T_c the *Curie temperature* of the alloy; S was now termed *long-distance order* to differentiate it from another parameter that had been introduced by Bethe to characterize the *short-range order* that persists above T_c. But they also apologized in this paper for having ignored the work of other investigators, notably Gorsky, Borelius, and Dehlinger, who had been thinking along similar lines.

The important new concept of long-range order is clearly described in the second paper, and a significant distinction is drawn between long-range order and long-range forces. It is stated clearly that short-range forces can give rise to long-range order, a conclusion exactly parallel to that of Ornstein and Zernicke for fluids described above, of which Bragg and Williams were apparently unaware.

1.5 Universality of Second-Order Transitions (Landau)

It was L. D. Landau (1937) who first attempted to provide a unified description for all second-order transitions. In addition to the phenomena described above, experimental evidence was accumulating about specific heat anomalies that were termed λ-point transitions in liquid helium, ammonium chloride, and a number of other substances, and the superconducting transition was also in this category. In 1933 Ehrenfest had introduced a thermodynamic classification of higher-order transitions, but there were difficulties associated with his treatment, and we shall avoid describing λ-point transitions as second-order phase transitions although this terminology is common.

Landau generalized the idea introduced in the theory of alloys to all systems manifesting λ-point transitions. He suggested that for every such system one must identify an *order parameter* analogous to the long-range order in an alloy, which would be zero on the high-temperature side of the transition and nonzero on the low-temperature side. He emphasized the important role that symmetry plays in phase transitions, and suggested that the important features of behavior in the vicinity of a λ point could be determined by expanding the free energy in a power series as a function of the order parameter η. In the ferromagnetic transition, the order parameter is the spontaneous magnetization, and in the fluid, the density difference between liquid and gas; Landau argued that for reasons of symmetry the form of the expansion of the Gibbs function would be

$$\phi(P,T,\eta)=\phi_0(P,T)+A(P,T)\eta^2+B(P,T)\eta^4 +\cdots, \tag{17}$$

and the Curie temperature would correspond to

$$A(P,T)=0, \quad B(p,T)>0. \tag{18}$$

Above the Curie temperature $A>0$ and the solution corresponding to a minimum of ϕ is $\eta=0$; this is the phase of higher symmetry. Below the Curie temperature the minimum of ϕ corresponds to a nonzero value of η given by

$$\eta^2=-A/2B, \tag{19}$$

and this is the phase of lower symmetry.

Landau's theory enabled one to understand why all the systems discussed previously had the same essential pattern of critical behavior; even though equations of state such as Eqs. (4) and (7) look very different, they both conform to Eq. (18). Critical exponents are the same for all λ-point transitions, and in later terminology the transitions would be described as universal.

The behavior of typical thermodynamic quantities for a ferromagnet near T_c were as follows ($t = T/T_c - 1$):

$$\begin{array}{lll} \text{spontaneous magnetization} & M_0 \sim (-t)^{1/2} & (t<0), \\ \text{initial susceptibility} & \chi_0 \sim t^{-1} & (t<0), \\ \text{critical isotherm} & H \sim M^3 & (t=0), \\ \text{derivative of susceptibility} & \dfrac{d\chi_0}{dH} \sim t^{-4} & (t>0). \end{array} \qquad (20)$$

The specific heat tended to one value C_- on approaching the transition from a lower temperature, and to another C_+ from above. The transcription to appropriate thermodynamic variables can be readily made for other systems.

Landau developed an alternative approach to that of Ornstein and Zernike to deal with critical fluctuations. His method was to seek a Taylor expansion of the excess free energy arising from variations in density (for a magnetic system it would arise from variations in magnetization, and in other systems from variations in the appropriate order parameter). We can divide the total Helmholtz free energy ΔF into contributions from different spatial regions,

$$\Delta F = \int \Delta a(\mathbf{r}) dV, \qquad (21)$$

where $a(T,\rho)$ is the local free energy expressed in terms of the density. $\Delta a(\mathbf{r})$ depends on $\delta\rho(\mathbf{r})$ and combinations of the derivatives of ρ, which are spherically symmetrical. In an expansion of $a(\mathbf{r})$ the first derivatives of ρ can enter only as $(\operatorname{grad}\rho)^2$ and the second derivatives as $\nabla^2\rho$. Terms in $\nabla^2\rho$ can be integrated to give a surface contribution that can be ignored and to give a bulk contribution of the form $(\operatorname{grad}\rho)^2$. We are thus led in the first order to an expansion of the form

$$\Delta a(\mathbf{r}) = \tfrac{1}{2}c\delta\rho^2 + \tfrac{1}{2}b(\nabla\rho)^2 + \cdots, \qquad (22)$$

where $c = (1/\rho)(\partial P/\partial\rho)_T$ is zero at T_c, and b must be greater than 0 for $\Delta a(\mathbf{r})$ to correspond to a minimum at T_c.

If $\delta\rho$ is broken down into Fourier components, then ΔF is a sum of contributions from independent normal modes. The absence of interaction between the modes is due to the truncation of expansion (22) at the square term. Assigning an average energy kT to each mode, Landau was led to the universal formula (15) for the pair correlation function.

The approximation of stopping with the gradient terms in the expansion in Eq. (22) is reasonable for long-wavelength fluctuations which are responsible for critical behavior. However, since c is zero at T_c it is reasonable to assume that a higher-order term $d(\delta\rho)^4$ is needed to get a valid picture in the critical region. This was the suggestion of Landau and Ginzburg for the order parameter of the superconducting transition. Its adoption complicates the above treatment very considerably and has far-reaching consequences, as we shall see in Sec. 5.4.

2. ISING MODEL: EXACT SOLUTIONS

2.1 Ising Model

In 1925 W. Lenz, who had been looking for a simple model that might serve to explain ferromagnetism, put forward the following suggestion to his graduate student E. Ising. Assume that each atom possesses a spin and hence a magnetic moment μ_0, which can orient either parallel or antiparallel to an external magnetic field H. There is an interaction between nearest-neighbor spins in the lattice, parallel spins having an interaction $-J$ and antiparallel spins $+J$ ($J>0$). Lenz hoped that the model might manifest a nonzero spontaneous magnetization, i.e., that as $H\rightarrow 0$ the ratio

$$(N_2 - N_1)/(N_2 + N_1) \qquad (23)$$

might tend to a nonzero value. Here N_1 and N_2 are the number of spins antiparallel and parallel to the field H.

Ising was able to solve the problem in one dimension only, where the statistical problem is quite simple, and the solution did not possess a spontaneous magnetization at any temperature above zero. He concluded wrongly that the model would not give rise to a spontaneous magnetization in higher dimensions. In 1936 Peierls was the first to demonstrate convincingly that for a two-dimensional Ising model, at sufficiently low but nonzero temperatures, the ratio (23) does not tend to a nonzero value as $H \to 0$.

The Hamiltonian for the Ising model can be conveniently written in the form

$$\mathscr{H} = -J \sum_{\langle i,j \rangle} \sigma_i \sigma_j - \mu_0 H \sum_i \sigma_i, \tag{24}$$

where the sum i is taken over all N spins of the lattice and $\langle i, j \rangle$ over all of the nearest-neighbor pairs of the lattice, counting each pair once only. Each σ_i takes on the values ± 1 according as the spin i is pointing in the direction 1 or 2. Ising considered only a model of spin $\frac{1}{2}$; the natural generalization to spin s is

$$\mathscr{H} = -\frac{J}{s^2} \sum_{\langle i,j \rangle} s_{zi} s_{zj} - \frac{\mu_0 H}{s} \sum_i s_{zi}, \tag{25}$$

where s_{zi} are standard quantum spins taking on the values $s, (s-1), \ldots, -(s-1), -s$. The normalization is chosen to keep the maximum interaction between nearest-neighbor spins, and the maximum interaction with the external field, independent of s. The term Ising model without qualification usually refers to the model of spin $\frac{1}{2}$; it is sometimes called the simple Ising model for greater clarity.

Let us now consider the partition function (see STATISTICAL MECHANICS, QUANTUM) for the Ising model. Any configuration of spins characterized by the numbers N_1 and N_2 of spins pointing in directions 1 and 2, and N_{11}, N_{12}, and N_{22} different types of nearest-neighbor pairs, will have energy

$$\mu_0 H(N_1 - N_2) + J(N_{12} - N_{11} - N_{22}). \tag{26}$$

It is easy to establish the relations

$$2N_{11} + N_{22} = qN_1, \quad 4N_{12} + N_{22} = qN_2, \tag{27}$$

by enumerating all q bonds that originate in each atom of the lattice (q being the coordination number of the lattice).

For convenience, to avoid surface effects, we adopt the usual solid-state physics device of cyclic boundary conditions, so that all lattice sites are equivalent. Also we know that

$$N_1 + N_2 = N; \tag{28}$$

hence Eq. (26) can be written

$$-(\mu_0 H + \tfrac{1}{2} qJ)N + 2\mu_0 H N_1 + 2JN_{12}. \tag{29}$$

If $J > 0$ the lowest-energy state corresponds to $N_1 = 0$, $N_{12} = 0$, i.e., all the spins are aligned in direction 2. Of the five numbers introduced only two are free, and these are conveniently taken to be N_1 and N_{12}.

The major difficulty in the calculation of the partition function is the combinatorial problem of determining how many states there are on a lattice with a given (N_1, N_{12}). If we denote this by $g(N; N_1, N_{12})$, the partition function can be written as

$$\begin{aligned} Z_N^I &= \exp(-\beta \mathscr{H}) \\ &= y^{-N/2} z^{-qN/4} \sum_{N_1, N_{12}} g(N; N_1, N_{12}) y^{N_1} z^{N_{12}} \end{aligned}$$

$$[y = \exp(-2\beta\mu_0 H), \quad z = \exp(-2\beta J),$$

$$\beta = 1/kT]. \tag{30}$$

We now consider the problem of an alloy consisting of N_A atoms of type A and N_B atoms of type B on the same lattice ($N_A + N_B = N$). Since the alloy has a fixed composition, N_A and N_B remain fixed, in contrast to N_1 and N_2 above. But since N_A and N_B represent particular values of N_1 and N_2, relations (27) are valid for N_A, N_B, N_{AA}, N_{AB}, and N_{BB}. To calculate the energy of a given configuration it is reasonable to use a model taking account only of nearest-neighbor interactions, since interatomic forces decrease rapidly with distance. Let us denote the interactions of AA, AB, and BB pairs of neighbors by $-\epsilon_{AA}$, $-\epsilon_{AB}$, and $-\epsilon_{BB}$, respectively. Consider a configuration in which there are N_{AA}, N_{AB}, and N_{BB} such pairs. The energy of the configuration is

$$\begin{aligned} w &= -N_{AA}\epsilon_{AA} - N_{AB}\epsilon_{AB} - N_{BB}\epsilon_{BB} \\ &= -\tfrac{1}{2} q(N_A \epsilon_{AA} + N_B \epsilon_{BB}) - N_{AB}\epsilon \end{aligned}$$

$$[\epsilon = \epsilon_{AB} - \tfrac{1}{2}(\epsilon_{AA} + \epsilon_{BB})]. \tag{31}$$

If $\epsilon < 0$ the lowest-energy state corresponds to the minimum of N_{AB}, i.e., to two separated phases of A and B atoms. This gives rise to the analog of an Ising ferromagnet in the realm of alloys, a *solid solution*.

The partition function for the solid solution is, from Eq. (30),

$$Z_N^s = z_A^{(1/2)qN_A} z_B^{(1/2)qN_B} \sum_{N_{AB}} g(N;N_A,N_{AB}) z^{N_{AB}}$$

$$[z_A = \exp(\beta\epsilon_{AA}),\ z_B = \exp(\beta\epsilon_{BB}),\ z = \exp(\beta\epsilon)]. \quad (32)$$

On comparing Eqs. (32) and (30) we see that, except for the ground-state terms, the partition function for the alloy is obtained by picking out the coefficient of y^{N_A} in the partition function for the magnet. In statistical-mechanical terminology (see STATISTICAL MECHANICS, QUANTUM) the partition function for the magnet corresponds to the *grand partition function* for the alloy. Writing

$$\Lambda_N(y,z) = \sum_{N_1,N_{12}} g(N;N_1,N_{12}) y^{N_1} z^{N_{12}}, \quad (33)$$

the behavior of both the ferromagnet and the alloy can be calculated from a knowledge of $\Lambda_N(y,z)$.

In Sec. 1.4 we referred to order–disorder transitions in binary alloys that form superlattices at low temperatures. This corresponds to $\epsilon > 0$ in Eq. (31) which gives rise to a lowest-energy state with N_{AB} a maximum. The magnetic analog with $J < 0$ is an Ising model of an antiferromagnet in which the lowest-energy state corresponds to alternating up and down spins. Both of these problems are likewise determined by $\Lambda_N(y,z)$ defined in Eq. (33) but for a different range of values of the variable z.

The introduction of a specific model (25) enables us to mention an important alternative method of deriving the classical result. If we focus attention on the field acting on a given spin as a result of interactions with its neighbors, this field will fluctuate as the orientation of the neighbors changes. The exact solution must take these fluctuations into account exactly. But we can approximate by replacing the fluctuating field by its mean value, and from this a self-consistent equation can be derived for the magnetization. This is equivalent to the classical result, and is usually called the *mean-field approximation.* We would expect from the statistical considerations that it would be a reasonable approximation when the number of interacting neighbors is sufficiently large.

2.2 The Lattice-Gas Model

In 1939 Cernuschi and Eyring realized that the Ising model could readily be adapted to provide a simple model of liquid–gas equilibrium. If, in the solid-solution model of the previous section, type A atoms are replaced by the molecules of the fluid, and type B atoms by holes, i.e., unoccupied cells, the possibility of varying the number of holes allows for changes in free volume, one of the essential features of a liquid. Any two neighboring occupied cells have an attractive interaction; the fact that an occupied cell cannot accept another molecule provides a crude representation of a hard-core repulsion, and the model thus represents the two basic features of intermolecular forces. The concentration of holes is not fixed but allowed to vary, and this is taken into account by means of the grand partition function, as indicated in the previous section. The interactions ϵ_{AB} and ϵ_{BB} are zero, ϵ_{AA} represents the intermolecular attraction, and ϵ defined in Eq. (31) is equal to $-\frac{1}{2}\epsilon_{AA}$.

For this model the magnet–fluid analogy discussed in Sec. 1.2 is formulated precisely, and the thermodynamic quantities associated with fluids, such as pressure and density, can be given exact magnetic analogs. All of the classical results discussed in Sec. 1 can be related to a simple function of two variables $\Lambda_N(y,z)$ defined by Eq. (33), and we can understand the similarities in experimental behavior of the various systems. However, when we come to examine the critical behavior of the function $\Lambda_N(y,z)$ we shall find that it differs very significantly from the Landau pattern described in Sec. 1.5.

2.3 Transfer Matrix

For a one-dimensional assembly of systems each having t possible energy levels, a general treatment is possible that reduces the evaluation of the partition function to the determination of the largest eigenvalue of a matrix. Let $U(x_i,x_{i+1})$ denote the energy between any two systems x_i and x_{i+1}, each x_i taking t possible values. For simplicity we shall deal with a ring of systems in which the Nth is connected cyclically to the first. The partition function for N systems is then given by

$$Z_N = \sum_{x_i} \exp\{-\beta[U(x_1,x_2)+U(x_1,x_2)+\cdots$$
$$+U(x_N,x_1)]\}$$
$$= \sum_{i,j,\ldots,k=1}^{t} V_{ij}V_{jk}\cdots V_{kl}V_{li}, \qquad (34)$$

where $V_{ij}=\exp(-\beta U_{ij})$ corresponds to the interaction between neighboring systems in states i and j. The elements V_{ij} thus form a $t\times t$ matrix V and the continued product (34) will readily be identified as the trace of V^N. Thus if $\lambda_1,\lambda_2,\ldots,\lambda_t$ are the eigenvalues of V, then

$$Z_N=\lambda_1^N+\lambda_2^N+\cdots+\lambda_t^N. \qquad (35)$$

For sufficiently large N only the largest eigenvalue, λ_1, is significant, and we may identify Z_N with λ_1^N. It should be noted that if the interaction U_{ij} is symmetric in i and j, the matrix V is symmetric. Also the ith diagonal element of V^N is proportional to the probability that a particular system is in state i.

The above method of treating one-dimensional assemblies was suggested independently in 1941 by Kramers and Wannier, by Lassettre and Howe, and by Montroll. It constituted the first preliminary step towards modern theories of critical behavior, focusing attention on the exact calculation of the partition function. The matrix V is usually called the *transfer matrix.*

For the one-dimensional simple Ising model $t=2$, and the eigenvalues in Eq. (35) can readily be calculated:

$$\left.\begin{matrix}\lambda_1\\ \lambda_2\end{matrix}\right\}=\tfrac{1}{2}(1+y)\pm[(1-y)^2+4yz^2]^{1/2}. \qquad (36)$$

This is the solution found by Ising in 1925. For large N we can ignore λ_2, and since λ_1 is a smooth analytic function of (y,z) there are no singularities. There is no spontaneous magnetism for $T>0$; the only manifestation of singular behavior occurs at $T=0$ where the susceptibility takes on the value $\beta\mu_0^2\exp(\beta J)$, which becomes infinite.

The method outlined above can be applied to a finite strip of width l, and the number of different states t to be taken into account for the transfer matrix is then 2^l. Similarly, for a three-dimensional block of dimensions $l\times m$ the transfer matrix is of order 2^{lm}. As long as the transfer matrix is finite and the largest eigenvalue is nondegenerate, it is easy to show that it involves no singularities. To achieve singular behavior the matrices must be infinite; hence for the Ising model only systems infinite in at least two dimensions can manifest singular critical behavior. Such dimensional considerations were completely absent in the classical Landau theory (Sec. 1.5).

2.4 Onsager's Solution for the Rectangular Lattice

In 1936 Peierls had demonstrated rigorously that the Ising model on the quadratic lattice in two dimensions does indeed possess a spontaneous magnetization. In 1944 Onsager published an exact solution for this model in zero magnetic field, which exercised a revolutionary impact on the whole subject, since its properties differed essentially from those of the classical theories. This will be seen from the following brief summary:

1. *The specific heat* manifests a striking singularity at the Curie point. It is logarithmically infinite on both sides of the Curie temperature, and is shown in Fig. 5 for the symmetric net. For temperatures near to T_c the following approximation may be used:

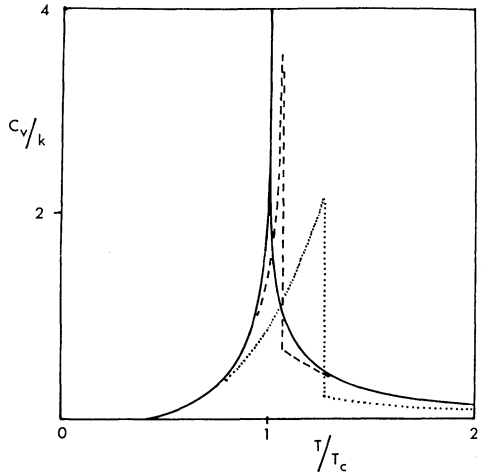


FIG. 5. Onsager's classic calculation (1944) of the specific heat of the spin-$\frac{1}{2}$ Ising model on a simple quadratic lattice. The solid curve represents the true specific heat, which is logarithmically infinite. The dotted curve represents a closed-form approximation due to Bethe, and the dashed curve an improved closed-form approximation due to Kramers and Wannier.

$$C_v/NK \cong (2/\pi)(\ln \cot \pi/8)^2 \times (K_1 - 1 - \pi/4)$$

$$\cong 0.4945 \ln |T - T_c|$$

$$[K_1 = \ln(2^{1/2}|K - K_c|),\ K = \beta J]. \quad (37)$$

It should be noted that the specific-heat curve differed substantially from any curves that had been observed experimentally, particularly in regard to the magnitude of the "tail" above the Curie temperature. This can be seen more clearly from the critical value of the entropy, which shows that the entropy change above T_c ($=0.387$) is greater than that below T_c ($=0.306$).

For an asymmetric net with interactions J, J' in the principal directions, the logarithmic nature of the specific-heat anomaly is unchanged. As one of the interactions J' becomes small the Curie temperature moves to zero, but this movement is very slow; if the interaction J' is J/v, then the reduction in T_c is of order $\ln v$ for large v. The specific-heat curve for an asymmetric net in which $J' = J/100$ was calculated by Onsager, and is shown in Fig. 6 for comparison with the symmetric net, and with the specific heat of a one-dimensional chain ($J' = 0$). The abscissa is $2kT/(J+J')$ so that the areas under all the curves are the same. It will be seen that the large asymmetry reduces the Curie temperature by a factor of 2 only. Also there is an essential difference below the Curie temperature between a two-dimensional net with one small interaction and a one-dimensional chain.

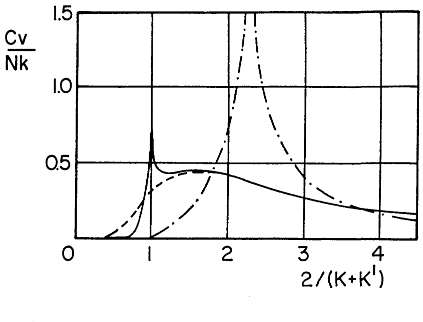

FIG. 6. Onsager's calculation of the specific heat of an asymmetric rectangular lattice with a ratio of interactions 100:1. The logarithmic infinity is retained in contrast to the specific heat of the linear chain (dashed line). The central curve (–·–) corresponds to the symmetric quadratic lattice.

2. *Other thermodynamic quantities.* The internal energy E has a vertical tangent on both sides of the Curie point. Near the Curie point it is of the form

$$A_0 + B_0(T - T_c)\ln|T - T_c|. \quad (38)$$

The free energy F involves an integral of the internal energy and therefore has infinite curvature at the Curie point. All thermodynamic quantities have a singularity at T_c, so that *no Taylor expansion of the type envisaged by Landau* (Sec. 1.5) *is possible.*

3. *The specific heat of a finite crystal.* The specific heat of a finite crystal of n rows is finite at all temperatures, since the partition function is an analytic function of the temperature, but a maximum occurs near the transition point of the infinite crystal. Onsager showed that for large n the maximum specific heat is given approximately by

$$C_v/Nk = 0.4945 \ln n + 0.1879. \quad (39)$$

4. *Correlations.* In Sec. 1.3 we described the classical theory of correlations between the molecules of a fluid as formulated by Ornstein and Zernike. By analogy, for a magnetic system we introduce the correlation between spins. For the simple Ising model we define

$$\langle \sigma_0, \sigma_r \rangle = (\Sigma \sigma_0 \sigma_r \exp(-\beta \mathscr{H}))/Z_N^I, \quad (40)$$

which plays a role analogous to $g(r)$ in Eq. (14). The calculation of correlations is more sophisticated than that of thermodynamic quantities, and a number of important exact results were derived by Kaufman and Onsager in 1949. Of particular significance was their conclusion that at T_c the correlations decay with distance as $r^{-1/4}$. In his original paper Onsager had calculated the mean range over which correlation persists for $T > T_c$ as $\sim (T - T_c)^{-1}$. For the classical theory [Eq. (15)] the corresponding behavior was r^{-1} and $(T - T_c)^{-1/2}$.

5. *Long-range order and spontaneous magnetization.* It can be readily shown that for the simple Ising model the long-range order and spontaneous magnetization are effectively identical. Onsager in 1947 and Yang in 1951 concluded independently that its critical behavior is $\sim (T_c - T)^{1/8}$, whereas classical theory gave $(T_c - T)^{1/2}$ [Eq. (20)].

2.5 Other Exact Results

For some time after 1944 hopes ran high that a solution of the three-dimensional Ising model might soon be forthcoming. But as a variety of different methods were advanced to rederive the Onsager solution, none of which could be extended to three dimensions, the realization spread that the three-dimensional model is a problem of exceptional difficulty.

However, solutions were derived for a variety of other two-dimensional lattices, e.g., the triangular and honeycomb. The analytic character of the solution was individual to each lattice. But the critical behavior followed the same pattern as Onsager's solution and indicated that properties like the coordination number of the lattice have little relevance to critical behavior.

In 1952 Yang and Lee proved that the function $\Lambda_N(y,z)$ in Eq. (33) is analytic for all values of y except for $y=1$ $(H=0)$ and $T<T_c$. This important result established the pattern of singularities and showed rigorously that the lattice-gas model is capable of accounting for the pattern of discontinuities in the isotherms representing liquid–gas equilibrium that were described in Sec. 1.

3. THREE-DIMENSIONAL MODELS

3.1 The Challenge of Onsager's Solution

Onsager's solution demonstrated clearly that the classical treatment was incorrect for the two-dimensional Ising model, and there was no valid reason for thinking that it would be correct for a three-dimensional model. But the thermodynamic functions arising from Onsager's solution differed radically from experimental results. The spontaneous magnetization, which comes to zero with an eighth power law, was much steeper than anything that had been observed in magnetic materials. The specific heat has a large tail that did not accord with measurements of order–disorder and λ-point transitions, and the logarithmic singularity symmetric on both sides of T_c seemed strangely unreal. Was the disagreement with experiment due to the dimensionality of the model, the neglect of forces other than nearest neighbor, or perhaps the inadequacy of the Ising interaction?

It was therefore of great importance to look for alternative methods that could provide reliable information on three-dimensional models and on alternative forms of interaction. The most useful source of such information in the initial period following Onsager was the development of series expansions at high and low temperatures. Further important information was extracted from Onsager's solution, and other exact solutions were discovered corresponding to unrealistic interactions but nevertheless providing insight into the relationship between critical behavior and intermolecular forces. The cluster integral theory of fluids, which had been one of the triumphant theoretical developments of the late 1930s, had seemingly come up against a barrier in its attempt to explain critical behavior. Onsager's work aroused interest in the far more primitive lattice-gas model, which is isomorphic with the Ising model. And finally the exact results for the two-dimensional Ising model and the new theoretical conjectures that began to emerge for other models provided a challenge to experimentalists to look for systems in nature that might be expected to conform to the theoretical models, and to provide accurate measurements of their critical behavior.

3.2 More General Models

In 1928 Heisenberg suggested that the origin of the large interactions giving rise to ferromagnetism lay in the quantum-mechanical exchange forces, which can be represented by a vector coupling of spins,

$$J\mathbf{s}_i\cdot\mathbf{s}_i=J(s_{xi}s_{xj}+s_{yi}s_{yj}+s_{zi}s_{zi}). \qquad (41)$$

Here s_x,s_y,s_z are quantum-mechanical noncommuting operators representing the components of spin. Because of the noncommutation of the spin operators the quantum-mechanical Heisenberg model presents special difficulties in calculation. If we allow s to become infinite, we derive the *classical Heisenberg model* with an interaction

$$J\sigma_i\cdot\sigma_j, \qquad (42)$$

where $\sigma_i\sigma_j$ are unit vectors that take on all possible orientations.

The Heisenberg model has spherical spin symmetry. A generalized Ising model of spins s has been defined in Eq. (25) by the interaction of

$$Js_{zi}s_{zj}, \tag{43}$$

where each s_z can take on $2s+1$ values. The Ising model has anisotropic spin interaction.

It is possible to combine the above interactions into a more general Heisenberg–Ising interaction

$$J_1s_{xi}s_{xj}+J_2s_{yi}s_{yj}+J_3s_{zi}s_{zj}. \tag{44}$$

The particular case $J_3=0$, $J_1=J_2$ is called the x-y model; it has two-dimensional circular spin symmetry. When $s\to\infty$ it leads to a classical Heisenberg model with two-dimensional spins.

We shall see in Sec. 6 that the spin dimension plays an important role in modern theory and is usually denoted by n. Confining attention to isotropic spin interactions, the Ising model corresponds to $n=1$, the x-y model to $n=2$, and the Heisenberg model to $n=3$.

3.3 Series Expansions

During the two decades that followed the publication of Onsager's solution, the critical properties of model systems had to be established on an individual basis — each model and each property entailed a separate calculation. The most useful tool turned out to be the generation of lengthy perturbation series expansions at high and low temperatures.

The idea of generating lengthy series expansions and correlating the coefficients with critical behavior was first advanced by Domb (1969). Onsager's solution applies only in zero field, and the first target was to explore the properties of the model in a nonzero field.

The method was developed with the help of Rushbrooke and Wakefield at Oxford and Sykes, Fisher, and other members of the Theoretical Physics Department at King's College, London, and applied to a number of problems. A few general remarks are necessary to clarify the basis of the method. In normal statistical work it is hazardous to attempt to extrapolate asymptotic behavior from a finite number of terms. However, in the case of a ferromagnet one could anticipate on physical grounds a pattern of expected critical behavior, and use the coefficients of the series to obtain the best fit to parameters such as critical temperature and critical exponents in the assumed asymptotic form for the coefficients. Moreover, the methods of analysis and fitting could be tested on Onsager's exact solution to see how well they worked and to get an idea of the error to be expected. The method proved capable of furnishing important reliable information, and as numerical techniques improved, its use became widespread.

The actual generation of terms required a close familiarity with graph theory, and the programming of sophisticated graphical enumeration problems on computers. There are basically three different types of series expansion.

1. *High-temperature expansions* are derived by expanding the partition function in powers of β:

$$\langle \exp(-\beta\mathscr{H})\rangle = 1-\beta\langle\mathscr{H}\rangle+\frac{\beta^2}{2!}\langle\mathscr{H}\rangle-\cdots$$
$$+\frac{(-\beta)^n}{n!}\langle\mathscr{H}^r\rangle-\ldots, \tag{45}$$

where $\langle\ \rangle$ denotes the classical average or quantum-mechanical trace.

Those familiar with statistics will recognize Eq. (45) as the analog of a *moment-generating function* and will doubtless remember that it is more convenient to take logarithms and evaluate the *cumulant generating function*

$$\ln\langle e^{-\beta\mathscr{H}}\rangle = -\beta\langle\mathscr{H}\rangle+\frac{\beta^2}{2!}(\langle\mathscr{H}^2\rangle-\langle\mathscr{H}\rangle^2)$$
$$-\frac{\beta^3}{3}(\langle\mathscr{H}^3\rangle-3\langle\mathscr{H}\rangle\langle\mathscr{H}^2\rangle$$
$$+2\langle\mathscr{H}\rangle^3)+\ldots\,. \tag{46}$$

Such expansions were developed for all of the models described in the previous section (Sec. 3.2). For the Ising model of spin $\frac{1}{2}$ simplifications arise, and the expansions could be taken to considerable length. The terms of the expansion for the free energy in zero field, and the magnetic susceptibility and its field derivatives, are usually positive in sign. These expansions were the most useful from which to obtain information about critical behavior.

2. *Density expansions* use the variable y [$=\exp(-2\beta\mu_0H)$, Eq. (30)] or its equivalent, and since one expects asymptotically that

$$\Lambda_N(y,z) \sim [\Lambda(y,z)]^N, \tag{47}$$

they give rise to an expansion of the form

$$\ln \Lambda(y,z) = yg_1(z) + y^2 g_2(z) + \cdots + y^r g_r(z) + \cdots . \tag{48}$$

For a lattice-gas model these expansions are equivalent to the well-known Mayer cluster integral expansions that were developed in the late 1930s.

In principle, such expansions could be determined for all the models of the previous section, but calculations were practicable only for the Ising model. The expansions start from a state of complete alignment of the spins in a large magnetic field, and terms of Eq. (48) correspond to groups of 1,2,3,... overturned spins.

3. *Low-temperature expansions* have proved practicable only for the Ising model. They use z [$=\exp(-\beta J)$, Eq. (30)] as expansion variable, the coefficients being functions of y. They are simply a rearrangement of the density expansions (48).

As a typical example of a high-temperature series we reproduce the expansion of the initial magnetic susceptibility χ_0 for the simple Ising model on the fcc lattice:

$$\begin{aligned}\chi_0/\beta\mu^2 &= 1 + 12w + 132w^2 + 1404w^3 \\ &\quad + 14\,652w^4 + 151\,116w^5 \\ &\quad + 1\,546\,322w^6 + 15\,734\,460w^7 \\ &\quad + 59\,425\,580w^8 + \ldots \\ &\quad (w = \tanh \beta J).\end{aligned} \tag{49}$$

Before discussing the analysis of the terms we make a few observations on power series. Consider a function $f(z)$ defined by

$$f(z) = \sum_{n=0}^{\infty} a_n z^n. \tag{50}$$

Then, if

$$\lim_{n\to\infty} |a_n|^{1/n} \tag{51}$$

exists and is equal to $1/z_c$, the series converges for $|z| < z_c$. We can then write

$$|a_n| \sim \phi(n)/z_c^n, \tag{52}$$

where

$$\lim [\phi(n)]^{1/n} = 1. \tag{53}$$

There is always a singularity on the circle $|z| = z_c$. If all the a_n are consistent in sign, then the dominant singularity lies on the positive real axis. Replacing z by $-z$, we see that if the a_n alternate regularly the dominant singularity lies on the negative real axis. More irregular alternations indicate dominant singularities in the complex plane. If a_n is real, these must occur in complex pairs $(1/z_c) \exp(\pm i\sigma)$. For a single pair we should expect

$$a_n \sim [\phi(n)/z_c^n] \cos n\sigma.$$

If σ is a simple fraction, this gives rise to cyclic behavior; otherwise it is more random.

If the a_n are all known *exactly*, we can (in principle) continue the function analytically across the whole plane. Asymptotic values of a_n determine the behavior near to the dominant singularity. A dominant singularity on the positive real axis corresponds to a positive temperature and can reasonably be identified with the Curie point. Hence we see that series of terms consistent in sign are particularly useful since a numerical analysis of the a_n provides direct information about critical behavior.

In view of Eq. (53) a simple assumption for the asymptotic behavior of $\phi(n)$ is

$$\phi(n) \sim An^g, \tag{54}$$

and to test whether this assumption is in accord with the numerical data, it is convenient to plot a_n/a_{n-1} for series (49) as a function of $1/n$. If assumption (54) is valid, then

$$a_n/a_{n-1} \sim (1/w_c)(1+g/n), \tag{55}$$

and hence a straight line should be obtained whose intersection with $1/n = 0$ determines w_c and whose slope determines g. Such *ratio plots* are reproduced in Fig. 7 for the susceptibility and specific heat, and it will be seen that they approach an asymptotic linear value quite rapidly. Both lead to the same value of $1/w_c$, as one might expect on physical grounds.

In contrast to high-temperature series, low-temperature series for the simple Ising model are inconsistent in sign and irregular in behavior for many common lattices. For example, the spontaneous magnetization m_0 for the fcc lattice can be put in the form

$$m_0/\mu_0 = 1 - 2u^6 - u^{11}(24 - 26u + 48u^4 + 252u^5$$

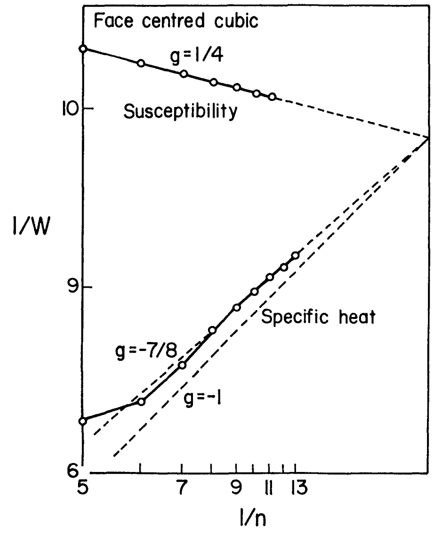

FIG. 7. An example of the use of series expansions to determine critical behavior. The susceptibility and specific heat are expressed as high-temperature expansions $\Sigma_n a_n w^n$ where $w = \tanh J/kT$. The ratios a_n/a_{n-1} of successive terms in the series expansion are plotted as a function of $1/n$, and from this an estimate can be obtained of their asymptotic behavior for large n. The ratios approach linearity, the extrapolated lines meeting the axis $1/n=0$ at $w=w_c$, the critical value, and the slopes give the critical exponents. If $a_n \sim n^{g-1}$, the corresponding thermodynamic quantity has a singularity of the form $(1-T_c/T)^{-g}$. *From this plot the estimates $\gamma \cong 5/4$, $\alpha \cong 1/8$ were derived (based on work by M. F. Sykes and his collaborators in* 1967 *at King's College London).*

$$-720u^6+438u^7+192u^8+984u^9 +1008u^{10}-12\,924u^{11} +19\,536u^{12}+\cdots)\quad (u=z^2), \qquad (56)$$

and it is difficult to detect any pattern in the coefficients.

A breakthrough in dealing with series of this kind occurred in 1961 when Baker introduced the Padé approximant into the field. This piece of mathematics, which had lain dormant since the end of the 19th century, enables *all* the singularities of a function defined by a power series to be studied; the unphysical singularities can be ignored, and attention can be focused on the singularity of physical interest.

Density series were of importance in attempting to find the m-H behavior at T_c. A power series in y is obtained from Eq. (48), the coefficients being evaluated at the critical value, z_c, of z estimated from high-temperature expansions.

3.4 Critical Exponents

Assumption (54) corresponds to a branch-point singularity at T_c. We therefore define a critical exponent (or index) θ of a thermodynamic quantity Ψ by the relation

$$\theta = \lim_{t\to 0} \frac{\ln \Psi}{\ln t}, \quad \Psi \sim A t^{\theta}. \qquad (57)$$

This definition ignores logarithmic factors. In a more refined analysis one might need to modify Eq. (57) to

$$\Psi \sim A t^{\theta} (\ln t)^{\phi}. \qquad (58)$$

Fortunately, in the practical application to critical phenomena in two and three dimensions, Eq. (57) is usually sufficient, although in four and more dimensions Eq. (58) is often needed. Also, when $\theta=0$ it is usual to specify whether the behavior is discontinuous (e.g., classical specific heat), or logarithmic (e.g., specific heat in the Onsager solution).

The notation for magnetic critical exponents developed empirically and the standardization provided by Fisher in 1965 at the Washington Conference on "Phenomena in the Neighbourhood of Critical Points" received wide acceptance. Table 1 defines the commonly used exponents and lists their classical values.

The Ising model served as a *trailblazer* in unravelling the general pattern of behavior of critical exponents. For the simple two-dimensional model α, α', β, ν, and η were known from the exact calculations quoted in Sec. 2. The remaining exponents were estimated from series expansions (e.g., $\gamma = 7/4$, $\delta = 15$) and were later shown to be exact.

In general, high-temperature series expansions relating to the initial susceptibility χ_0 were the most useful, and as the exponent γ was evaluated for different lattices and different models, a number of general conjectures were advanced as follows:

1. Critical exponents for a given model depend on dimension and not on lattice structure.
2. Critical exponents for the Ising model are independent of the spin s.
3. High-temperature critical exponents are

Table 1. Magnetic critical exponents ($t=T/T_c-1$, $t'=-t$).

Exponent	Quantity	Definition	Curve	Classical Value
$T>T_c$				
α	Specific heat	$C_m\sim t^{-\alpha}$	$m=0$	0 (discontinuous)
γ	Initial susceptibility	$\chi_0\sim t^{-\gamma}$	$m=0$	1
ν	Coherence length $\sim\delta$	$\kappa\sim t^{\nu}$	$m=0$	$\frac{1}{2}$
2Δ	Derivatives of susceptibility	$d^2\chi_0/dH^2\sim t^{-\gamma-2\Delta}$	$m=0$	3
$T<T_c$				
α'	Specific heat	$C\sim t'^{-\alpha'}$	$m=0$	0 (discontinuous)
β	Spontaneous magnetization	$m_0\sim t'^{\beta}$	$H\rightarrow 0+$	$\frac{1}{2}$
γ'	Initial susceptibility	$\chi_0\sim t'^{-\gamma'}$	$m=m_0$	1
ν'	Coherence length	$\kappa\sim t'^{\nu'}$	$m=m_0$	$\frac{1}{2}$
Δ'	Derivatives of susceptibility	$d\chi_0/dH\sim t'^{-\gamma'-\Delta'}$	$m=m_0$	$\frac{3}{2}$
$T=T_c$				
δ	Field vs magnetization	$H\sim m^{\delta}$		3
η	Pair correlation function	$\Gamma(\Gamma,0)\sim r^{d-2+\eta}$	$m=0$	0

ordered in a one-to-one manner with the symmetry of the magnetization in the ground state.

These conjectures represented important steps towards the hypothesis of universality (Sec. 4.3). The significance of the last conjecture can be illustrated by reference to the anisotropic Heisenberg model (44) with the following interaction:

$$J\sigma_{zi}\sigma_{zj}+J'(\sigma_{xi}\sigma_{xj}+\sigma_{yi}\sigma_{xy}). \qquad (59)$$

If $J'=0$, the model reduces to the simple Ising model in three dimensions for which γ had been estimated at 1.25, whereas if J' grows to J, the model becomes classical Heisenberg with corresponding estimate 1.38. What happens when $0<J'<J$? Conjecture 3 suggests that the change takes place discontinuously at $J'=J$, and that $\gamma\cong 1.25$ when $0<J'<J$. Likewise if $J=0$ the model is classical x-y with $\gamma\cong 1.32$; conjecture 3 suggests that if $J'>J$, γ retains the value 1.32.

Critical exponents for the three-dimensional Ising model lay between those for the two-dimensional model and those of classical theory. Thus, as the dimensionality increased, classical values were approached. However, increase in spin dimension generated a move away from the classical results. In keeping with this it was shown rigorously that the two-dimensional classical Heisenberg model has no ordered state except at $T=0$ and is in this respect similar to the *one-dimensional* Ising model.

3.5 Spherical and Gaussian Models

In 1952 Berlin and Kac discussed two new models for which they were able to calculate an exact solution in three dimensions in a nonzero field. The Gaussian model consists of independent spins with a nearest-neighbor Ising interaction, the magnitude of each spin being governed by a probability distribution

$$(2\pi)^{-1/2}\exp(-\sigma^2/2)d\sigma. \qquad (60)$$

The spherical model allows the spins to take any value subject to the overall restriction

$$\sigma_1^2+\sigma_1^2+\cdots+\sigma_N^2=N. \qquad (61)$$

Neither model is realized by any known physical system, and the solutions exhibit certain marked unphysical features.

For many years the models were regarded as of mathematical interest only. The discovery by Stanley in 1968 that the spherical model can be regarded as the limit of the classical vector spin model in which the *spin* dimension becomes infinite secured an important place for the model in the general pattern of critical behavior. The Gaussian model found its place as a first step in Wilson's application of the renormalization group (Sec. 5.4).

Like the Heisenberg model, the spherical model does not manifest critical behavior in two dimensions. In three dimensions Kac and

Berlin found that $\gamma=2$, and because of Stanley's result, the variation of γ as a function of spin dimension could be understood, starting with 1.25 for $n=1$, 1.32 for $n=2$, and 1.38 for $n=3$, and reaching 2 for $n=\infty$.

An important contribution of the spherical model to our understanding of critical behavior arose from the calculation by Joyce in 1966 of the properties of the model when the dimension $d \geqslant 4$. Joyce found that with the exception of logarithmic factors, all critical exponents attain their classical values when $d=4$ and retain them for higher dimensions. Joyce also calculated the properties of the model for long-range forces of the form $J(r) \sim 1/r^{d+\sigma}$ and found that for a sufficiently small σ, exponents attain classical values (even when $d=1$). In such a case a large number of neighbors effectively contribute to the interaction, so that the mean-field approximation discussed at the end of Sec. 2.1 gives the correct answer.

We shall see that these results are of great help in constructing an overall pattern of critical behavior.

3.6 Systems with Weak Long-Range Forces

In 1959 Kac introduced a one-dimensional continuum model with long-range forces that seemed to offer the possibility of exact treatment. The molecules interact with a hard-core repulsion of length b, and an exponential attraction $\lambda e^{-\lambda r}$. For this model he showed that the partition function can be derived as the maximum eigenvalue of a linear integral equation with a positive-definite Hilbert–Schmidt kernel.

The calculations were pursued by Kac, Uhlenbeck, and Hemmer in 1963. They first showed that for any finite value of λ the partition function is continuous, and there is no phase transition. However, in the limit of $\lambda \to 0$ there is a phase transition, and it can be evaluated in closed form. It gives rise, in fact, to the van der Waals equation [Eq. (4)] with the Maxwell construction automatically included. At the end of their paper, Kac, Uhlenbeck, and Hemmer discussed the three-dimensional model and advanced arguments to show that in this case also the attractive and repulsive parts of the potential make independent contributions to the free energy. In three dimensions the hard-sphere partition function is not known in closed form, but Monte Carlo estimates are available.

Calculations of a similar kind for the one-dimensional Ising model led to a Weiss type of solution [Eq. (7)]. In fact, it seemed that a mean-field solution will always be obtained for a model with a weak long-range attractive force of the form

$$J(r)=\lim_{\lambda\to 0} \lambda^{d} e^{-\lambda r}. \tag{62}$$

Classical theory was thus partially reinstated—it is a valid theory for long-range forces, but in practice intermolecular forces in nature are usually short ranged.

The work of Joyce on the spherical model indicated that a mean-field solution should result for models with forces of the form $J(r) \sim 1/r^{d+\sigma}$ for a sufficiently small σ.

3.7 Experimental Results

The experimental investigation of the behavior of a substance near a critical point is a matter of considerable difficulty. Very accurate temperature measurements are needed since small changes of temperature are accompanied by large differences in equilibrium values. Substances must be very pure; a small concentration of impurity can exercise a significant influence. As T_c is approached the time needed to reach equilibrium becomes large, so that a long time scale is needed for the performance of experiments. For fluids gravity must be taken into account. The theoretical values of several of the thermodynamic properties investigated become infinite at T_c. But such an infinity applies only to an unbounded sample; in practice the finite size of the sample becomes important since it provides a bound on the values that can be obtained. In solids this involves a consideration of grain boundaries.

The first suggestion that experimental results for real fluids deviated from the van der Waals picture came from Verschaeffelt at the end of the 19th century. Unfortunately his work was ignored by his contemporaries. In 1945 Guggenheim undertook a critical analysis of experimental data on the coexistence curves of a number of gases. According to van der Waals theory these gases should obey a law of corresponding states, i.e., if reduced units T/T_c and ρ/ρ_c are used (where ρ_c and T_c are the density and temperature, respectively, at the critical point), the coexistence curves for the different gases should fall on a single universal curve. Guggenheim found that the data provided good support for such a law of corresponding states (Fig. 8), but the form of the curve was cubic,

$$\Delta\rho \sim (-t)^{1/3},$$

rather than quadratic as required by van der Waals theory.

In 1954 Habgood and Schneider published precise measurements of the isotherms of xenon near the critical point. They found that the critical isotherm is much flatter than the cubic curve predicted by van der Waals (Fig. 9), and they suggested that the third and fourth derivatives of P with respect to ρ are zero at the critical point.

The theoretical developments described in Sec. 3.4 stimulated a new wave of precise experimental measurements, making use of new techniques and new magnetic materials to attain a much greater accuracy than had been available previously. We shall quote a few representative examples. In 1957 Fairbank, Buckingham, and Kellers published the result of a new investigation into the nature of the λ point of liquid ^{4}He. Improved low-temperature techniques enabled them to get very close to the λ point, and domains and

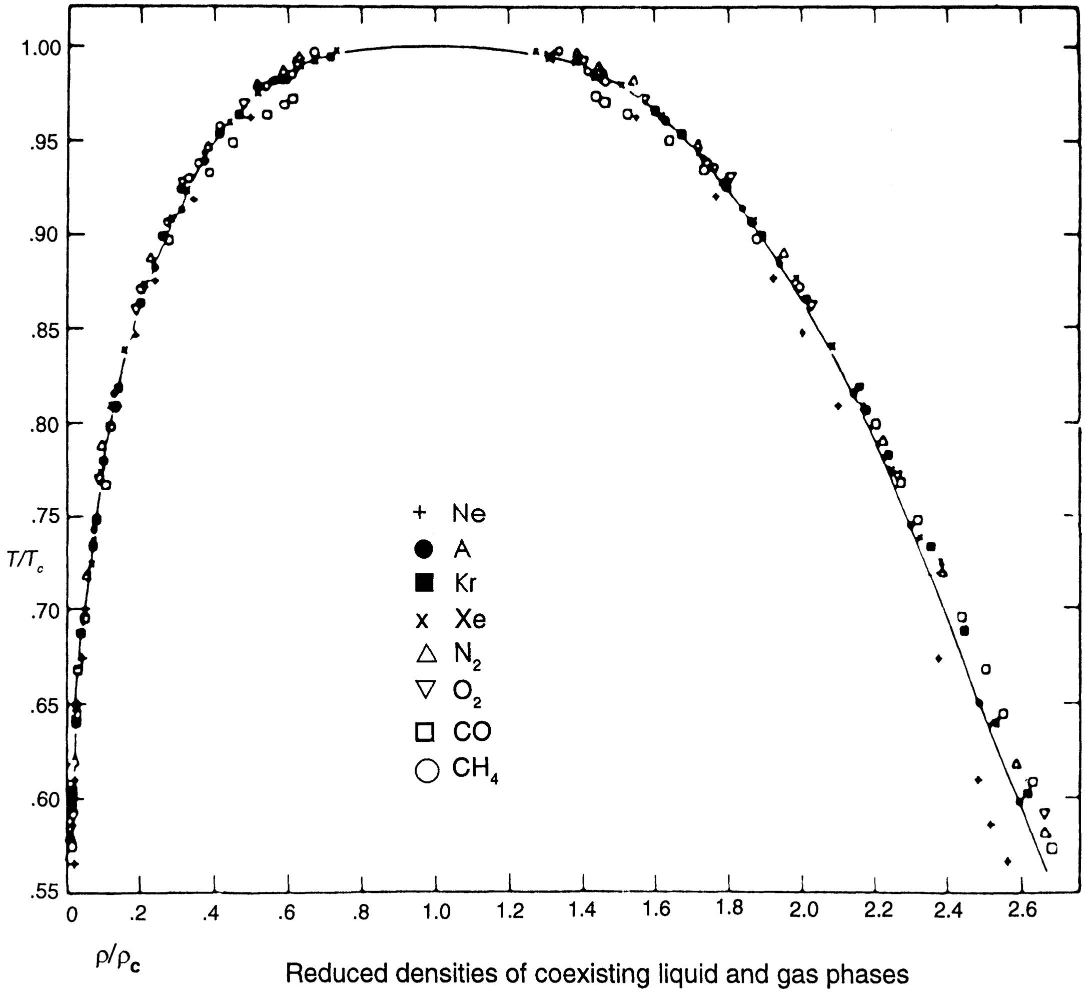

FIG. 8. Reduced densities of coexisting liquid and gas phases (T/T_c vs ρ/ρ_c). The data fit a law of corresponding states, but the resulting curve is cubic rather than quadratic as given by van der Waals's equation (after Guggenheim, 1945).

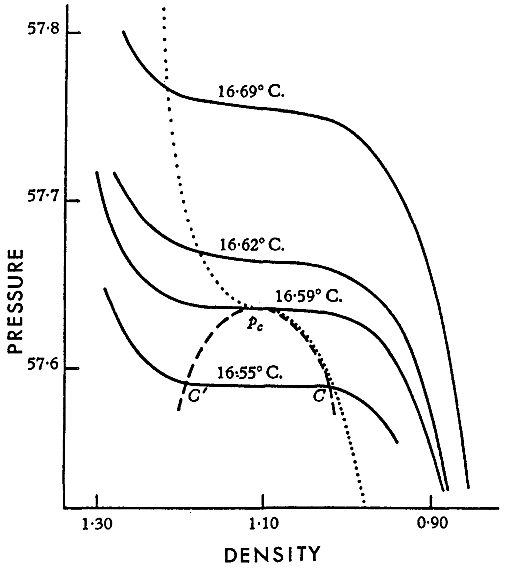

FIG. 9. Isotherms of xenon near the critical point. The dashed line marks the region of coexistent phases. The dotted line is the critical isotherm according to van der Waals's equation to be contrasted with the measured 16.59 °C isotherm (after Habgood and Schneider, 1954).

grain boundaries that limit the growth of specific heats of crystals are absent in liquid helium. They concluded that the specific heat is logarithmically infinite on both sides of the λ point (Fig. 10) and is in many respects similar to the Onsager specific heat depicted in Fig. 5. Of course they did not suggest that there was any basic reason for the similarity between a three-dimensional quantum fluid and a two-dimensional Ising ferromagnet, but at least they demonstrated that logarithmically infinite specific heats are a practical reality.

Conventional ferromagnets like iron, nickel, and cobalt have high Curie temperatures, and accurate measurements of critical behavior are difficult. However, new ferromagnets were discovered, such as europium sulfide ($T_c \sim 16.50K$), which are much more amenable to accurate measurements, and nuclear magnetic resonance can be used to measure the fraction of spins oriented in a particular direction at a given temperature and hence to deduce the spontaneous magnetization. Figure 11 is an example of such a measurement by Heller and Benedek in 1965 from which they deduced that the cube of the spontaneous magnetization is very nearly linear.

It is difficult to find a magnet that conforms satisfactorily to the Ising interaction. However, we have seen in Sec. 2.1 that an order–disorder transition in a binary alloy can also provide a realization of an Ising model. β-brass (CuZn) was chosen by Als-Nielsen and Dietrich for neutron-scattering experiments to test the theoretical predictions for the three-dimensional Ising model, and they estimated for the critical exponents $\beta = 0.30 \pm 0.005$ and $\gamma = 1.25 \pm 0.02$. These were in good agreement with the predictions of series expansions.

The new experimental results seemed to fit well to the theoretical calculations, even though the theoretical models were simple and crude,

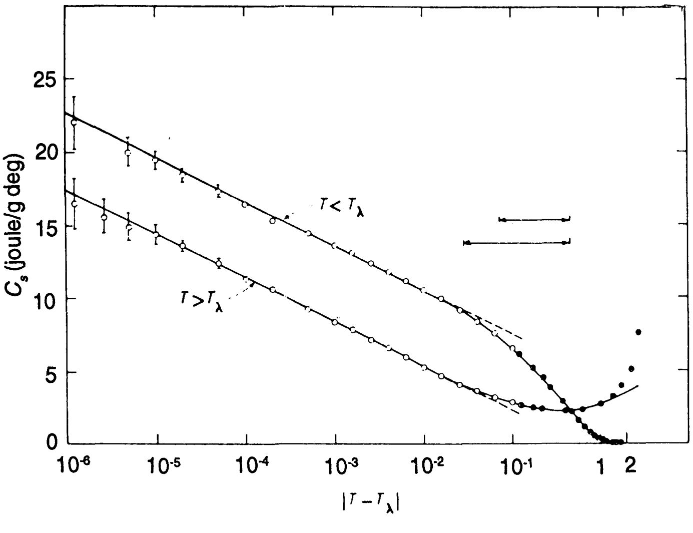

FIG. 10. Specific heat of liquid ^{4}He near the λ point. Accurate measurements by Fairbank, Buckingham, and Kellers in 1957 indicated a logarithmic curve of the type derived by Onsager for the Ising model.

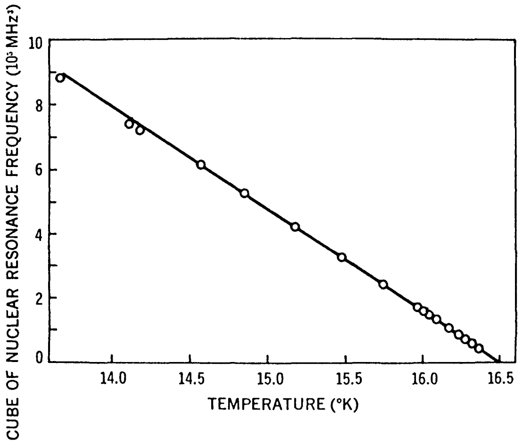

FIG. 11. Temperature dependence of the cube of the nuclear frequency of ^{153}Eu in EuS between 13.60 and 16.33 K. In this range the law $m_0 \sim Dt'^{1/3}$ is quite accurately obeyed (after Heller and Benedek, 1965).

and did not adequately map the true physical interactions. It seemed as if critical behavior was insensitive to the details of the interaction mechanism.

3.8 Conclusion

In this section we have described the chain of theoretical and experimental work set in motion by Onsager's solution. Agreement between theory and experiment was gratifying, but there was no coherent framework to replace the classical theory. In the next section we shall describe how such a framework was constructed.

4. SCALING AND UNIVERSALITY

4.1 Reconciliation

The first international conference devoted specifically to critical phenomenon took place in April 1965 in Washington at the National Bureau of Standards. It could reasonably be termed the founding conference of critical phenomena, since for the first time all the different strands of the subject were woven into a coherent fabric, and the major obstacles to progress were clearly delineated.

The keynote address was given by G. E. Uhlenbeck, and it is particularly fascinating now to quote the actual words of one of his concluding paragraphs:

> "If there is such an universal, but non-classical behaviour, then there must be a universal explanation which means that it should be largely independent of the nature of the forces. The only corner where this can come from is I think the fact that the forces are not long range. The Onsager solution gives I think a strong hint. It may well be so that away from the critical points the classical theories give a good enough description but that they fail close to the critical point where the substance remembers so to say Onsager. I think that to show something like this is the central theoretical problem. One can call it the reconciliation of Onsager with van der Waals."

Uhlenbeck was looking for a new type of universality for short-range forces that would replace the universality of the classical theories, which are valid only for very-long-range forces.

The first requirement in effecting the reconciliation was a coherent description of the "nonclassical universality" analogous to the van der Waals description of classical behavior. A preliminary attempt in this direction was the "droplet model" introduced by Essam and Fisher in 1963 and elaborated by Fisher a few years later. The model attempted to find an empirical approximation to $g_r(z)$ in Eq. (48) by analogy with droplet formation in a condensing gas. The resulting partition function depended on only two parameters and led to a relation between critical exponents,

$$\alpha'+2\beta+\gamma'=2, \qquad (63)$$

which was satisfied by the exact exponents for the two-dimensional Ising model. Rushbrooke noted that from thermodynamics alone one could derive an inequality

$$\alpha'+2\beta+\gamma'\leqslant 2. \qquad (64)$$

Rushbrooke's observation triggered off thermodynamic investigations that led to other inequalities of a similar kind. However, the heuristic droplet model had a number of unphysical features, and could not be regarded as providing a representation of the equation of state over the total range of the variables.

A satisfactory form of a nonclassical equation of state valid in the critical region emerged within a few months of the above conference.

It was suggested independently by three different groups: Widom (1965) in the U.S., who searched for a generalization of van der Waals's equation that could accommodate nonclassical exponents; Domb and Hunter (1965) in the U.K., as a result of an analysis of the behavior of series expansions of higher derivatives with respect to magnetic field at the critical point; and Patashinskii and Pokrovskii (1966) in the U.S.S.R., who considered the behavior of multiple correlations near the critical point.

Widom used fluid language in developing his ideas. Because of the exact symmetry $H \to -H$, $m \to -m$ in magnetic systems we shall find it convenient to reproduce the results in magnetic language. The transition to fluids is achieved by replacing H by $p-p_c$ and m by $\rho - \rho_c$.

4.2 Equation of State in the Critical Region: Scaling

The critical magnetic equation of state was derived from high-temperature series expansions of the form Eq. (45) and involved the plausible assumption (which was afterwards checked numerically) that the critical behavior of the rth field derivative of the magnetic susceptibility is of the form

$$\frac{d^r \chi_0}{dH^r} \sim t^{-\gamma - r\Delta}, \qquad (65)$$

where Δ was termed the gap exponent. This led to an equation of state of the form

$$m = t^{\beta} U(Ht^{-\Delta}). \qquad (66)$$

However, since one wishes to use the equation for positive and negative values of t, the form (66) is not very convenient, and Griffiths reformulated the equation so as to involve t only linearly,

$$H = m^{\delta} h(tm^{-1/\beta}). \qquad (67)$$

Equation (67) is correct only for positive H and m. By symmetry H and m can both be reversed without making any physical difference to the system. Therefore the general equation, valid for all m,H is

$$H = m|m|^{\delta-1} h(t|m|^{-1/\beta}). \qquad (68)$$

It is convenient to use Eq. (67) with the symmetry assumption latently understood.

There are two characteristic features of Eq. (67). First, all critical exponents depend on only two parameters, β and δ, and this is the basis for relations like Eq. (63) that are indeed satisfied exactly. The critical exponents of other thermodynamic quantities can be readily derived, and are reproduced in Table 2.

Second, critical data satisfy a *scaling relation*, i.e., if $Hm^{-\delta}$ is plotted against $tm^{-1/\beta}$, the two-dimensional data will fall on a single curve $h(x)$. As a result of the Yang–Lee theorem quoted in Sec. 2.5, $h(x)$ is analytic and the variable x ranges from $-x_0$, the zero of $h(x)$ (which corresponds to a spontaneous magnetization), to $x=\infty$. For a mean-field theory $h(x)$ is linear; as the dimension decreases and the spin dimension increases, $h(x)$ becomes more curved. $h(x)$ is termed the *scaling function.*

Patashinskii and Pokrovskii related susceptibility derivatives to correlation functions and were therefore able to relate the correlation exponent ν to Δ:

$$2\Delta = \gamma + d\nu. \qquad (69)$$

Such a relation was usually termed a *length scaling* relation as opposed to *thermodynamic scaling* relations of type (63).

These scaling relations were satisfied by the known exact exponents for the two-dimensional Ising model and for the spherical model (Table 2). For the three-dimensional Ising model, numerical estimates supported thermodynamic scaling, but there were small but persistent discrepancies in the length scaling relations, which will be discussed subsequently (Sec. 5.5). They were subject to experimental test for a large number of systems of fluids and magnets, and the results were very encouraging.

Similarly, the hypothesis of a scaling function $h(x)$ was tested for fluids and magnets, and a typical result using data for ^{4}He is reproduced in Fig. 12. It will be seen that the data fit well to a single curve.

4.3 Universality

Equation (67) says nothing about possible values of β, δ, and $h(x)$. We have already mentioned empirical information accumulating about regularities in the pattern of critical exponents. These were collected together in the *hypotheses of universality* put forward by

Table 2. Scaling relations between critical exponents.

Thermodynamic quantity	Exponent	Simple Ising model in two-dimensions	Mean field	Spherical model in three dimensions	Spherical model—long-range forces[a]
Spontaneous magnetization	β	$\frac{1}{8}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$
Magnetization vs field at T_c	δ	15	3	5	$(d+\sigma)/(d-\sigma)$
High-temperature susceptibility	$\gamma=\beta(\delta-1)$	$\frac{7}{4}$	1	2	$\sigma/(d-\sigma)$
High-temperature gap	$\Delta=\beta\delta$	$\frac{15}{8}$	$\frac{3}{2}$	$\frac{5}{2}$	$(d+\sigma)/2(d-\sigma)$
High-temperature specific heat	$2-\beta(\delta+1)$	0	0	-1	$(d-2\sigma)/(d-\sigma)$
Low-temperature susceptibility	$\gamma'=\gamma$	$\frac{7}{4}$	1	…	…
Low-temperature gap	$\Delta'=\Delta$	$\frac{15}{8}$	$\frac{3}{2}$	…	…
Low-temperature specific heat	$\alpha'=\alpha$	0	0	…	…
		Length scaling			
High-temperature coherence length	$\nu=\beta(\delta+1)/d$	1	$\frac{1}{2}$	1	$1/(d-\sigma)$
Low-temperature coherence length	$\nu'=\nu$	1	$\frac{1}{2}$	…	…
Spin pair correlation at T_c	$\eta=d(\delta-1)/\delta+1$	$\frac{1}{4}$	0	0	$2-\sigma$

[a] Force $J(r)\sim r^{-(d+\sigma)}$ in d dimensions $(1<d/\sigma<2,\ 0<\sigma<\min\{2,d\})$.

Kadanoff in 1970 at a summer school on critical phenomena; an analogous *smoothness postulate* was advanced independently by Griffiths. This nonclassical universality is more sophisticated than had been envisaged by Uhlenbeck; different classes are defined by the space dimension d and the spin dimension n, and within a given class critical behavior is universal. If a third parameter σ is introduced to take account of the range of the intermolecular forces, both classical and nonclassical behavior can be taken into account in a wider pattern of universality. Once d, n, and σ have been specified, the exponents δ, β, and the function $h(x)$ are determined, and the behavior is smooth and universal within the class. Changes in critical exponents with accompanying discontinuities occur in the *crossover* between one universality class and another (e.g., in the transition from a two-dimensional to a three-dimensional system by the introduction of a new interaction), and we shall now discuss this crossover behavior in more detail.

4.4 Crossover Behavior

It was noted by Hankey and Stanley in 1972 that scaling laws are closely related to homogeneous functions. A homogeneous function of degree p in two variables u,v is defined by the relation

$$g(\lambda u,\lambda v)=\lambda^p g(u,v) \qquad (70)$$

for all λ. But if we use Eq. (70) with the value $\lambda=1/u$, we deduce that

$$g(u,v)=u^p g(1,v/u)=u^p G(v/u). \qquad (71)$$

Hence a homogeneous function of two variables scales to a function of a single variable.

To take account of the types of exponent arising in relations like (66) or (67), Hankey and Stanley introduced the concept of a *generalized homogeneous function* that satisfies the relation

$$g(\lambda^a u,\lambda^b v)=\lambda g(u,v). \qquad (72)$$

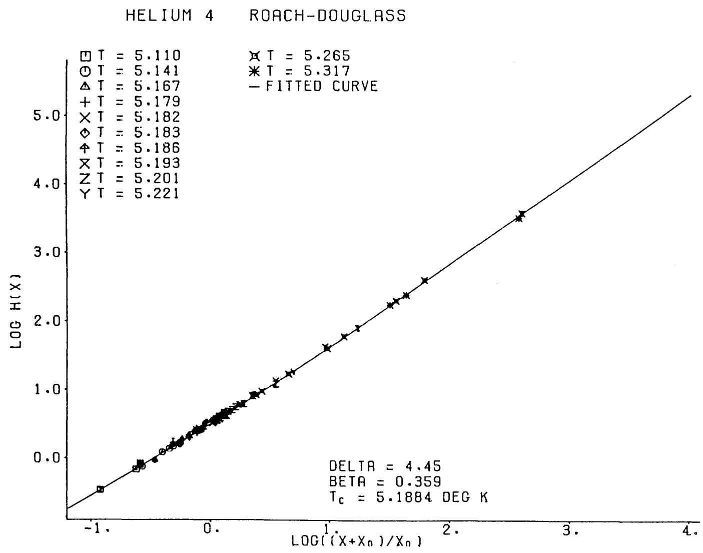

FIG. 12. Scaling relation for the fluid ^{4}He. Experimental data of Roach (1968) fitted by Vicentini-Missoni (1971).

A standard homogeneous function (70) corresponds to $a=b$. Taking λ to be $u^{-1/a}$ we find as a generalization of Eq. (71)

$$g(u,v)=u^{-1/a}g(1,v/u^{b/a})=u^{-1/a}G(v/u^{b/a}), \tag{73}$$

and this is of the same form as Eqs. (66) or (67). From (67), for example, we have

$$a=1/\delta, \quad b=-1/\beta\delta. \tag{74}$$

We have seen in Sec. 3.4 that critical exponents for a given model depend on dimension and not on lattice structure. If we consider a Hamiltonian of the form

$$\mathscr{H}=-J\sum_{\mathbf{i},\mathbf{j}}\sigma_{\mathbf{i}}\sigma_{\mathbf{j}}-gJ\sum_{\lambda,\mu}\sigma_{\lambda}\sigma_{\mu}=\mathscr{H}_0+g\mathscr{H}_1 \tag{75}$$

for a simple-cubic lattice, where $\mathbf{i},\mathbf{j}$ refer to nearest neighbors in horizontal planes, and λ,μ to nearest neighbors in the vertical direction, then for $g=0$ the behavior will be two-dimensional in character, but for $g\neq 0$ it will be three-dimensional. How does the transition or *crossover* depend on the parameter g when g is small? We shall investigate this example in detail as typical of the crossover from one universality class to another.

For the Hamiltonian (75), by analogy with Eq. (66), we postulate for the singular part of the free energy a generalized homogeneous function

$$f(g,t)=t^{2-\alpha_2}V(gt^{-\phi}), \tag{76}$$

where the subscript 2 is to remind us that we are dealing with the two-dimensional critical exponent, and ϕ is the new *crossover* exponent analogous to the gap exponent Δ in Eq. (66).

In presence of a magnetic field H, Eq. (76) would generalize to

$$f(g,H,t)=t^{2-\alpha_2}V(gt^{-\phi},Ht^{-\Delta_2}). \tag{77}$$

By differentiating Eq. (77) we conclude that thermodynamic quantities corresponding to the derivatives of the free energy with respect to H satisfy scaling relations similar to Eq. (76); for example, for the initial susceptibility we can write

$$\chi_0(g,t)\cong t^{-\gamma_2}Z(gt^{-\phi}). \tag{78}$$

However, there is an important difference between the scaling relations with respect to g and those with respect to H of Eqs. (66) and (67). For the latter the transition disappears when $H\neq 0$, whereas for the former a new transition point $T_c(g)$ appears with new critical exponents. For this to be possible the scaling function $Z(x)$ in Eq. (78) must have a singularity at some point x_c, and the singular behavior must be such as to enable the susceptibility when $g\neq 0$ to correspond to the three-dimensional Ising model:

$$\chi_0(g,t)\cong A(g)\dot{t}^{-\gamma_3} \quad [\dot{t}=T/T_c(g)-1]. \tag{79}$$

From this we first deduce that the new critical point is given by $gt^{-\phi}=x_c$, or

$$t_g = T_c(g)/T_c(0) - 1 = g/x_c^{1/\phi}. \quad (80)$$

To divide the crossover region more precisely into areas of temperature where the behavior is two-dimensional in character and those where it is three-dimensional, for a given g, we require knowledge of the scaling function $Z(x)$. But the general pattern of these areas can readily be outlined. Let us fix arbitrarily a percentage deviation p from two-dimensional behavior that we regard as significant, and let x_A be the value of x for which $Z(x_A)$ deviates from $Z(0)$ by p%. Then for $0 < x < x_A$ we can reasonably consider the behavior as two dimensional, i.e.,

$$t > (g/x_A)^{1/\phi}. \quad (81)$$

Let us now determine x_B at which the deviation of $Z(x)$ from its singular behavior is less than p%. For $x_B < x < x_c$ we can reasonably consider the behavior as three dimensional, i.e., for

$$(g/x_B)^{1/\phi} > t > (g/x_c)^{1/\phi}. \quad (82)$$

4.5 Kadanoff's Treatment

The progress described at the beginning of this section depended on an empirical and pragmatic approach. In a key paper published in 1966 Kadanoff tried to provide a theoretical basis for understanding the scaling properties that had been discovered in critical behavior.

Kadanoff noted that near T_c the coherence length ξ becomes very large, and hence it is possible to find a length L large compared with the lattice spacing but small compared with ξ. He then considered replacing the interaction of individual spins by the interaction of blocks of L^d spins. One might perhaps expect that in each block the spins would be nearly all up or nearly all down, and the original Ising model of spin σ and interaction J could then be replaced by a new model with block spin $\tilde{\sigma}$ and interaction $\tilde{J}$. If the new block spin model was effectively the same as the original model, the free energies would be related by

$$f(h,t) = L^{-d} f(\tilde{h},\tilde{t}) \quad (h = \beta H). \quad (83)$$

But how would $\tilde{h}$ and $\tilde{t}$ be related to h and t? Kadanoff suggested that

$$\tilde{h} = L^x h, \quad \tilde{t} = L^y t. \quad (84)$$

It is then easy to show that all the exponents (including ν) can be expressed in terms of x and y, that relations (63) and (69) are satisfied, and that a scaling-type equation of state (66) results.

Relation (69) is satisfied by the Ising model in two dimensions, but, as we have noted, numerical calculations for the three-dimensional model showed a small but persistent discrepancy. Also, there are several features of Kadanoff's argument that do not stand up to critical examination. However, his ideas stimulated the next major theoretical advance that completed the reconciliation sought by Uhlenbeck.

5. RENORMALIZATION GROUP

5.1 Background Ideas

The renormalization group (RG) was developed in the 1950s in connection with field theory (see PARTICLES, ELEMENTARY; QUANTUM ELECTRODYNAMICS), but it had no apparent practical consequences and had not been taken very seriously. Wilson saw that the theory was capable of providing an understanding of universality and a framework for the detailed calculation of critical behavior.

The RG does not produce exact solutions of the Onsager type, and its application involves quite drastic approximations, but it endeavors to retain all the essential physical characteristics of the problem near T_c, while rejecting those features that are not significant. No reliable method has been found of assessing directly the magnitude of the error at any stage of approximation of an RG treatment, and comparison with the results of exact solutions and series expansion estimates has played, and continues to play, a key role in the successful application of the RG.

Before discussing the RG approach we shall outline (following Wilson) the nature of the problem to be tackled in trying to account for critical behavior. We shall then give a qualitative account of how the RG deals with it.

If we consider the behavior of a fluid such as water, far from the critical point there are microscopic density fluctuations on an atomic scale (wavelengths ~1 Å). If the temperature and pressure are increased towards the critical point, fluctuations become important at longer wavelengths. Sufficiently close to T_c and P_c there are fluctuations on the scale of 1000–10 000 Å that scatter ordinary light and give rise to critical opalescence, making the water look milky. However, the microscopic fluctuations have not decreased in magnitude. Close to the critical point there are fluctuations at all wavelengths from 1 Å up to the correlation length, which tends to infinity at the critical point. The essence of the problem is how to deal with an assembly with so many scales of length.

The aim of the RG approach is to reduce in a systematic way the enormous number of degrees of freedom of the system, eliminating those that are irrelevant and do not contribute to critical behavior, and focusing attention on those which are relevant. A transformation is set up in the parameter space of the Hamiltonian,

$$\mathscr{H}' = \mathrm{R}\{\mathscr{H}\}, \tag{85}$$

which preserves the dimensionality and symmetries of the system and reduces the correlation length by a factor $b > 1$ and the number of degrees of freedom from N to $N' = N/b^d$. The transformation is chosen so that the partition function is preserved:

$$Z_{N'}(\mathscr{H}') = Z_N(\mathscr{H}). \tag{86}$$

A very wide choice of transformations is possible that can be characterized in *real space* or in *momentum space*. In real space the transformation usually follows the Kadanoff idea of introducing block-spin variables or eliminating some of the spins by partial summation (decimation transformation). However, the edge of the block is not long compared with the lattice spacing, but contains one or two lattice spacings; also the Kadanoff picture must be amplified, and the relation between the original spin and the block spin must be described precisely. In momentum space the aim is usually to eliminate high-momentum variables.

The transformation is iterated:

$$\mathscr{H}' = \mathrm{R}[\mathscr{H}],\ \mathscr{H}'' = \mathrm{R}[\mathscr{H}'],\dots . \tag{87}$$

A brief reference to the behavior of standard elementary iterative processes of the form

$$x_{n+1} = f(x_n) \tag{88}$$

will help to clarify the next step. It can easily be shown in Eq. (88) that the x_n tend to a limit x^* (fixed point), which is a solution of the equation

$$x = f(x). \tag{89}$$

If there are several solutions of this equation some may be *stable* (any deviation leads back to the fixed point) and others *unstable* with the opposite property. It can be shown easily that the fixed point is stable if $|f'(x^*)| < 1$ and unstable if $|f'(x^*)| > 1$. If $f'(x^*) = 1$ the fixed point is *marginal*, and we must proceed to higher derivation of $f(x)$ at x^*.

For iterative processes in s variables we can write Eq. (88) in the more general form

$$x_{(n+1)i} = f_i(x_{nj}) \quad (i,j = 1,2,\dots,s), \tag{90}$$

and fixed points x_i^* will be determined by solutions of the s equations

$$x_i = f_i(x_j). \tag{91}$$

The behavior at the fixed point is now governed by the eigenvalues of the matrix $|\partial f_i/\partial x_j|$ at x_i^*. If they are all less than 1, the fixed point is stable; if they are all greater than 1, it is unstable. But there are now other possibilities of partial stability; if t are > 1 and $s - t$ are < 1, we can describe the fixed point as t-unstable. In the theory of critical phenomena we are concerned with t-unstable fixed points with $t = 1$, 2, and perhaps 3.

The characteristic of a stable fixed point is that for a certain range of variables the solution is independent of the starting point. Each stable fixed point $x_i(r)^*$ has a *range of attraction*, and for any starting value within this range the limit will be $x_i(r)^*$. It is thus assumed in Eq. (87) that convergence takes place in the parameter space of the Hamiltonians to a fixed-point Hamiltonian, satisfying

$$\mathscr{H}^* = \mathrm{R}[\mathscr{H}^*], \tag{92}$$

and that critical properties are determined by behavior near the fixed point. Each fixed point has its own range of attraction, and all Hamiltonians within this range will have the same pattern of critical behavior (universality). All such Hamiltonians lie on the *surface of criticality* in the parameter space of Hamiltonians. But different fixed points in the parameter space give rise to different universality classes.

5.2 RG Derivation of Critical Behavior

Consider the partition function

$$Z_N = \langle \exp(-\beta\mathscr{H}) \rangle, \tag{93}$$

which is characterized by a number of coupling constants $K^{(1)}, K^{(2)}, K^{(3)}, \ldots$ that depend on $T, H, \ldots$ and can be conveniently written as a vector $\mathbf{K}$. Suppose that the correlation length associated with this Hamiltonian is $\xi(K)$. We now apply a block-spin or decimation transformation R_b to obtain a new set of parameters $\mathbf{K}'$ satisfying

$$\mathbf{K}' = \mathbf{f}(\mathbf{K}), \tag{94}$$

where the function will usually be nonlinear. Since we have reduced the unit of length by b we have the relation

$$\xi(\mathbf{K}') = b^{-1}\xi(\mathbf{K}), \tag{95}$$

and because of Eq. (86) we have for the partition function per particle $Z = (Z_N)^{1/N}$

$$[Z(\mathbf{K}')]^{N'} = [Z(\mathbf{K})]^{N} \tag{96}$$

and hence for the free energy per particle

$$\psi(K') = b^d\psi(\mathbf{K}). \tag{97}$$

Applying the transformation successively as in Eq. (87) in the form

$$\mathbf{K}_{n+1} = \mathbf{f}(\mathbf{K}_n), \tag{98}$$

we find that

$$\xi(\mathbf{K}_{n+1}) = b^{-1}\xi(\mathbf{K}_n) = \cdots b^{-n}\xi(\mathbf{K}_0). \tag{99}$$

Suppose now that $\mathbf{K}_n$ approaches a fixed point $\mathbf{K}^*$ satisfying

$$\mathbf{K}^* = f(\mathbf{K}^*). \tag{100}$$

It then follows from Eq. (99) that if we start at $\mathbf{K}_0$, then

$$\xi(\mathbf{K}_0) = b^n\xi(\mathbf{K}_{n+1}), \tag{101}$$

so that if $\xi(K^*)$ is not zero the correlation of the original system must be infinite, i.e., $\mathbf{K}_0$ must correspond to the critical point.

To obtain critical behavior near $\mathbf{K}^*$ we write

$$\mathbf{K}_n = \mathbf{K}^* + \mathbf{k}_n, \tag{102}$$

where $\mathbf{k}_n$ is small. Applying this to Eq. (98) we can develop an expansion and retain only linear terms, obtaining

$$\mathbf{K}_{n+1} = \mathsf{L}\mathbf{k}_n, \tag{103}$$

where relations (103) are linear so that L is a matrix. Let $\mathbf{l}_i$ be the eigenvectors and Λ_i the eigenvalues, satisfying

$$\mathsf{L}\mathbf{l}_i = \Lambda_i\mathbf{l}_i. \tag{104}$$

Expand $\mathbf{k}_{n_0}$ in the form

$$\mathbf{k}_{n_0} = \sum_i u_i^{(0)}\mathbf{l}_i \tag{105}$$

where n_0 is sufficiently large for Eq. (103) to be valid. We then have

$$\mathbf{k}_{n+n_0} = \sum_i \Lambda_i^n u_i^{(0)}\mathbf{l}_i. \tag{106}$$

Any eigenvalue Λ_i whose modulus exceeds 1 will grow in importance (*relevant*); one whose modulus is less than 1 will be *irrelevant*; an eigenvalue for which $|\Lambda_i| = 1$ is called *marginal*. The $u_i^{(0)}$ are called *scaling fields* (and we can drop the superscript); for example, u_1 is the temperature t, u_2 the magnetic field H, etc.

From Eq. (99) we have the relation for the correlation function

$$\xi(u_1, u_2, \ldots) = b^n\xi(\Lambda_1^n u_1, \Lambda_2^n u_2, \ldots) \tag{107}$$

while the corresponding relation for the free energy follows from Eq. (97),

$$\psi(u_1, u_2, \ldots) = b^{-n}\psi(\Lambda_1^n u_1, \Lambda_2^n u_2, \ldots). \tag{108}$$

When $H=0$ and the only relevant field is t we find from Eq. (107)

$$\xi(t, 0, \ldots) = b^n\xi(\Lambda_1^n t) \cong b^n(\Lambda_1^n t)^{-\nu}. \tag{109}$$

Hence we find that

$$b\Lambda_1^{-\nu} = 1 \quad \text{or} \quad \nu = \ln b / \ln \Lambda_1. \tag{110}$$

For the free energy we define scaling indices y_T and y_H by

$$\Lambda_1 = b^{dy_T}, \quad \Lambda_2 = b^{dy_H}, \tag{111}$$

and we then have, for all λ,

$$\psi(t, H) = b^{-dn}\psi(b^{ndy_T}t, b^{ndy_H}H), \tag{112}$$

i.e.,

$$\psi(\lambda^{y_T}t, \lambda^{y_H}H) = \lambda\psi(t, H) \tag{113}$$

where $\lambda = b^{dn}$.

The free energy is a *generalized homogeneous function* (Sec. 4.4). Take λ to satisfy

$$\lambda^{y_T}t = 1, \quad \lambda = t^{-1/y_T}, \tag{114}$$

and we have

$$\psi(t,H)=t^{2-\alpha}K(Ht^{-\Delta}), \tag{115}$$

where

$$2-\alpha=y_T^{-1}, \quad \Delta=y_H/y_T, \quad K(u)=\psi(1,u), \tag{116}$$

i.e., we have derived a relation analogous to Eq. (66). Finally we have the additional relation, from Eqs. (110) and (111),

$$\nu^{-1}=dy_T. \tag{117}$$

Hence *all* exponents are determined by y_T and y_H in agreement with Kadanoff, and in support of length scaling.

The extension to crossover behavior (Sec. 4.4) is immediate. One needs to use a scaling field g and to introduce a scaling index y_g satisfying a relation corresponding to Eq. (111), and this will lead to a free energy of the form (77).

5.3 Real-Space Renormalization

To give a specific illustration of the above ideas for real-space renormalization, we take an example used by Wilson in relation to the simple Ising model on the two-dimensional square lattice of lattice spacing a. The block spin relates to a 2×2 cell of the lattice that contains 9 spins. The value of the block spin is determined by a simple majority rule; if 5 or more of the 9 spins point upwards, the block spin has value $+1$, otherwise it has value -1. It is a straightforward matter with the help of a computer to transform any configuration of the original lattice to one of the transformed lattice. The 2^9 possible configurations of a cell in the original lattice are reduced to 2 in the transformed lattice, the value of b above is 3, and the new lattice has spacing $3a$. Speaking roughly, we can say that the transformation averages out fluctuations in spin direction whose scale is smaller than the block size $3a$. It is as if one looks at the lattice through an out-of-focus lens that blurs the smaller features but does not affect the larger ones.

When the transformation is applied for a second time, fluctuations in spin direction whose scale is smaller than 3^2a will have been averaged out. After n applications, fluctuations whose scale is smaller than 3na will have been averaged out. Eventually fluctuations at all scales up to the correlation length are averaged out.

Block spins do not have the same couplings as the spins in the original configuration lattice. In the original formulation, there is one nearest-neighbor interaction parameter. The first stage of the block spin transformation introduces a finite but substantial number of more distant neighbors and multispin couplings. If the second state is carried out exactly, a new round of coupling parameters will be introduced; if this is continued indefinitely an infinite number of coupling parameters will be required. An infinity of parameters is needed to furnish an exact solution. Wilson's crucial conjecture was that all but a finite and relatively small number of coupling parameters can be ignored without impairing the physical description of behavior near the critical point. He later tested this conjecture by performing a calculation for the simple Ising model on the simple quadratic lattice using a decimation transformation (developed by Kadanoff) and retaining 217 parameters! His conclusion is as follows:

"The dominant interaction at the fixed point is the nearest-neighbor coupling. For accurate calculations one must include many more; but for a qualitative picture the nearest-neighbor constant K plus perhaps the next-nearest-neighbor coupling L should be enough. The remaining couplings are at least a factor of 5 smaller than L.... Thus the old idea of Kadanoff that there would be effective nearest-neighbor Ising models for block spins is very close to the truth."

5.4 Momentum-Space Renormalization

For the use of the RG in momentum space it proved convenient to employ a continuous-spin adaptation of the Ising model. This enabled contact to be made with the Gaussian model (Sec. 3.5) which gives valid results for critical exponents when $d>4$; on replacing the lattice structure by a continuum (as for a fluid) the theory could be merged with the Landau–Ginzburg development (Sec. 1.5) and with the field theories with which the RG originated.

The partition function for the simple Ising model (24) can be written in the alternative form

$$Z^I=\int_{-\infty}^{\infty} d\sigma_1 2\delta(\sigma_1^2-1)$$

$$\times \exp\left(K \sum_{\mathbf{l},\mathbf{m}} \sigma_{\mathbf{l}}\sigma_{\mathbf{m}} + \beta\mu_0 H \sum_{\mathbf{l}} \sigma_{\mathbf{l}}\right) \quad (118)$$

with $\sigma_{\mathbf{l}}$ a continuous variable. Wilson replaced the function $2\delta(\sigma_{\mathbf{l}}^2-1)$ by the continuous function

$$w(\sigma_{\mathbf{l}}) = \exp(-\tfrac{1}{2}c\sigma_{\mathbf{l}}^2 - u\sigma_{\mathbf{l}}^4), \quad (119)$$

where u is a positive number. When $c=-4u$, $w(\sigma_{\mathbf{l}})$ has the form

$$w(\sigma_{\mathbf{l}}) = \exp[-u(\sigma_{\mathbf{l}}^2-1)^2+u], \quad (120)$$

which reproduces the simple Ising model when $u \to \infty$. For finite positive u, $w(\sigma_{\mathbf{l}})$ then has maxima at $\sigma_{\mathbf{l}} = \pm 1$, and if u is large, the probability function is sharply peaked at $\sigma_{\mathbf{l}} = \pm 1$. When $u=0$ Eq. (119) the Gaussian model is retrieved for positive c.

Following the idea of universality classes enunciated in Sec. 4.3 one might expect that any weighting function of the form (120) would belong to the Ising universality class. Wilson made the more daring suggestion that as long as $u>0$ *any* weighting function of the form (119) will correspond to the Ising universality class, i.e., that the only value of the parameters (c,u) giving rise to a change in behavior is $u=0$.

The transition to a continuum-space model can be achieved on replacing the $-\sigma_{\mathbf{l}}\sigma_{\mathbf{m}}$ in Eq. (118) by

$$\tfrac{1}{2}(\sigma_{\mathbf{l}}-\sigma_{\mathbf{m}})^2. \quad (121)$$

Since the lattice spacing is small and not expected to exercise a significant influence on critical behavior, the discrete σ is replaced by the continuous function $\sigma(x,y,z)$ and becomes

$$\tfrac{1}{2}(\nabla\sigma)^2. \quad (122)$$

To operate in momentum space it is convenient to introduce the Fourier-transformed spin variables

$$\hat{\sigma}_{\mathbf{q}} = \sum_{\mathbf{l}} \exp(i\mathbf{q}\cdot\mathbf{l})\sigma_{\mathbf{l}}. \quad (123)$$

For a lattice structure of spacing a, the momenta $\mathbf{q}$ are essentially restricted by $|q| \leqslant \pi/a$ (neglecting the shape of the Brillouin zone which, as one might expect, proves irrelevant). This cutoff is characteristic of the physics of condensed matter, and contrasts with quantum field theory where there is normally no natural cutoff and the momenta must be taken to infinity; the latter is therefore represented by zero lattice spacing. The RG transformation R of Eq. (85) is defined by averaging out all the $\hat{\sigma}_{\mathbf{q}}$ variables satisfying

$$b^{-1} < |q|a/\pi \leqslant 1. \quad (124)$$

This corresponds as before to a spatial rescaling factor b.

The first practical application by Wilson of the RG was in momentum space taking $b=2$. Severe approximations were required in evaluating the integrals to put the results into a form from which iterative recursion relations could be derived. They were solved numerically and gave fair values for the critical exponents.

In a subsequent paper by Wilson and Fisher the key suggestion was advanced that the appropriate expansion parameter for the critical exponent is $\epsilon = 4-d$ treated as a continuous parameter, and expansions to the first order in ϵ were derived for a number of models. Wilson then generalized the treatment to the n-vector classical Heisenberg model, using for the exponent in Eq. (119)

$$-\tfrac{1}{2} c_0 \sum_{i=1}^{n} \sigma_i^2 - u_0\left(\sum_{i=1}^{n} \sigma_i^2\right)^2. \quad (125)$$

For this model he used Feynman graph methods of field theory (see QUANTUM ELECTRODYNAMICS) to derive the following expansions:

$$\gamma = 1 + \frac{n+2}{2(n+8)}\,\epsilon + \frac{(n+2)(n^2+22n+52)}{4(n+8)^3}\,\epsilon^2 + O(\epsilon^3), \quad (126)$$

$$\eta = \frac{n+2}{2(n+8)^2}\,\epsilon^2 + \frac{n+2}{2(n+8)^2}\left(\frac{6(3n+14)}{(n+8)^2} - \frac{1}{4}\right)\epsilon^3 + O(\epsilon^4), \quad (127)$$

$$\phi = 1 + \frac{n\epsilon}{2(n+8)} + \frac{\epsilon^2(n^3+24n^2+68n)}{4(n+8)^3}\,\epsilon^2 + O(\epsilon^3). \quad (128)$$

Even though ϵ is assumed to be a small parameter, substituting $\epsilon=1$ gave results that compared surprisingly well with the series expansion estimates.

This seminal work initiated a new diagrammatic approach to the calculation of critical exponents, and powerful field-theoretical techniques were used to extend the ϵ expansion to higher orders, and to improve the accuracy of the critical exponent estimates.

5.5 Critical Exponents: Corrections to Scaling

Using the above techniques Nickel added several terms to the ϵ expansion, but the series was found to be divergent. However, Nickel and Lipatov showed how to calculate the asymptotic behavior of the general term in the expansion, and this enabled a Borel transformation to be used to convert the series into a convergent one. From this Le Guillou and Zinn-Justin in 1977 made the accurate estimates of the exponents of the simple Ising model with $\epsilon = 1$ as follows: $\gamma = 1.240$, $\beta = 0.325$, $\nu = 0.630$. Series expansions had favored $\gamma = 1.25$, $\beta = 0.3125$, $\nu = 0.64$. The differences, although relatively small, were beyond the expected error bounds. Of more fundamental importance was the failure of the second set of exponents to satisfy the length scaling (or hyperscaling) relation (69).

The key to the resolution of this discrepancy lay in the form of the correction terms to scaling. It is latently assumed in the ratio analysis, Eq. (55), that there is no *confluent singularity*, i.e., that the critical behavior of the thermodynamic function under consideration is of the form

$$t^{-h}G(t), \tag{129}$$

where $G(t)$ is analytic. However, Wegener showed in 1972 that the RG leads to the conclusion that there is a correction term

$$t^{-h-\Delta_1}G_1(t), \tag{130}$$

where Δ_1 need not be an integer. Moreover, it was possible to derive an ϵ expansion for Δ_1, and for $\epsilon = 1$ this gave $\Delta_1 \simeq \frac{1}{2}$.

In 1980 the discrepancy was resolved in a paper by Nickel presented at the International Conference on Statistical Mechanics in Edmonton, Alberta. Nickel added a significant number of new terms to the series expansion for the susceptibility of the bcc lattice and showed that with a correction term of the form (130) it was possible to achieve agreement between the series expansion and RG estimates with acceptable error bounds.

It is now generally assumed that the most accurate estimates of critical exponents in three dimensions are provided by the ϵ expansion. The results shown in Table 3 are taken from the final 1980 paper of Le Guillou and Zinn-Justin.

5.6 Conclusion

It is very gratifying that such good agreement should finally have been achieved between the two most accurate methods of estimating critical behavior. As regards the contributions to progress in the RG, real-space renormalization has proved useful for illustrating the general principles but has not proved very accurate in three dimensions. Momentum-space renormalization has surprisingly provided the most accurate estimates of three-dimensional critical behavior to date.

6. MISCELLANEOUS ADDITIONAL TOPICS

Although we have described in detail the mainstream developments in critical phenomena, a number of related topics have been passed over for lack of space. We summarize them briefly in this section.

Exact solutions have played a role of special importance in critical phenomena. We have seen that the modern era was initiated by Onsager's exact solution, which revealed the defects of the classical theories and served as a test for new techniques of calculation. For about 20 years after Onsager's work there were no new solutions for realistic interactions that differed in a substantial way from

Table 3. ϵ-expansion estimates of critical exponents, from Le Guillou and Zinn-Justin (1980).

that of Onsager. Then in 1967 Lieb produced a variety of new solutions for two-dimensional ferroelectric models. The critical behavior followed a completely different pattern from the Ising model, and it seemed that new ground was being broken.

Lieb was followed by Baxter, whose solution of another ferroelectric model, the eight-vertex model, gave rise to exponents that vary continuously with the strength of the interaction. This was a major challenge to the idea of universality, since the model is equivalent to an Ising model with a two- and four-spin interaction. The issue was resolved by an analysis by Kadanoff and Wegener in 1971, who indicated that the model possesses a special symmetry that gives rise to continuously varying exponents; this particular feature would not be expected to arise in normal physical systems.

Baxter subsequently derived a number of other new solutions and as a by-product extended very significantly exact series expansions for two-dimensional models which he was unable to solve exactly. (For more details of this exact work, see Baxter, 1982).

An interesting point that led to fruitful ideas is the behavior of two-dimensional models when $n=2$. Peculiarities in this model were noted some years ago, and their investigation by Kosterlitz and Thouless in 1973 has suggested a new type of critical phenomenon related to *topological order*. Experimental work has already confirmed some of the theoretical predictions.

Other problems in condensed-matter physics that have been profoundly influenced by progress in critical phenomena are the shape and size of polymer chains in solution (see, e.g., de Gennes, 1979), and percolation processes (see, e.g., Stauffer 1985). The model of a self-avoiding walk on a lattice (see, e.g., Domb, 1969) had for many years been regarded as a useful representation of a polymer chain with a realistic hard-core "excluded volume." It had been noted empirically that the properties of such self-avoiding walks paralleled those of the Ising model. The precise connection was revealed by de Gennes in 1972, who noted that the self-avoiding-walk configurations correspond to a ferromagnetic model with spin dimension n when n is allowed to take the value zero (see Table 3).

A theoretical model that burst into prominence after being ignored for nearly two decades is the Potts model. This was first suggested in 1952 as a generalization of the Ising model having q orientations but only two different energies of interaction; the critical point could be located exactly. At the Kyoto Conference on Statistical Mechanics in 1968, Kasteleyn and Fortuin showed that percolation processes associated with random mixtures that have applications to dilute magnets, amorphous semiconductors, and a number of other problems in condensed-matter physics correspond to the Potts model with $q=1$! A number of physical systems have been identified for which the Potts model is a reasonable representation, and the difference in symmetry between the n-vector ferromagnetic model and q-component Potts model gives rise to important differences in critical behavior. The literature on percolation and the Potts model has escalated sharply in the past few years.

GLOSSARY

Coherence Length: The range over which the behavior of atoms is significantly correlated.

Critical Exponents: Parameters that characterize the singular behavior of thermodynamic functions near a critical point.

Crossover: A change from one specific pattern of critical behavior to another.

Curie Temperature (Point): The temperature at which a ferromagnet loses its intrinsic magnetization.

Gaussian Model: A model of ferromagnetism in which the values of the atomic spins follow a Gaussian probability distribution.

Heisenberg Model: A model of ferromagnetism introduced by Heisenberg in 1928 with a quantum interaction between atomic spins.

Ising Model: A model of ferromagnetism suggested by Lenz to his student Ising in 1925 in which each spin has two values, up or down.

Lambda-Point Transition: A phase transition with no *latent* heat but with a *specific heat anomaly* in the shape of the Greek letter λ.

Lattice-Gas Model: A lattice model of a fluid in which each lattice cell is either occupied or unoccupied by a molecule.

Long-Range Order: Correlation of molecules or spins that extends to infinite range.

Mean-Field Solution: An approximation in the theory of critical behavior in which a fluctuating quantity is replaced by its average value.

Opalescence: Changes in color and appearance arising from light scattering.

Order Parameter: A key thermodynamic quantity identified by Landau that characterizes the critical behavior of a system.

Partition Function: A function constructed from the *microscopic* properties of molecules of a system from which *macroscopic* behavior can be derived.

Relevant (or Irrelevant) Fields: Interactions that do (or do not) significantly affect critical behavior.

Scaling Relations: Relations arising from a simplified equation of state in which two-dimensional data scale onto a single curve.

Universality: Systems of widely different origins whose critical behavior follows the same standard pattern.

INTRODUCTION

Cryogenics is the field of science and engineering that deals with the production of low temperatures. This subject includes the techniques needed to obtain low temperatures, the methods to measure low temperatures, and the study of the physics of matter at these temperatures. A quest for obtaining low temperatures followed the proposal of an absolute zero temperature by Guillaume Amontons in 1702. Progress accelerated after the middle 1800s when a series of experiments succeeded in liquefying the materials that were gases at room temperature. These were liquefied in the descending order of their boiling points—oxygen, nitrogen, hydrogen, and finally helium. In this article, we will briefly review the sorts of physical changes that take place in matter at cryogenic temperatures. Then we will discuss the techniques used to obtain these temperatures. After this we will introduce the very important subject of measuring temperature. Since the range of

temperature varies over a number of orders of magnitude, we will frequently refer to logarithmic graphs as shown in Fig. 1. Here, each factor of 10 in absolute temperature is one division on the scale.

1. WHAT HAPPENS AT LOW TEMPERATURES?

The understanding of absolute temperature, first postulated by Guillaume Amontons, was incorporated by William Thomson (Lord Kelvin), James P. Joule, Rudolf Clausius, and several other thermodynamicists into the laws of thermodynamics during the mid-1800s (Mendelssohn, 1977). The absolute temperature is zero when all thermal energy has been extracted from matter. Thus when a material is at zero temperature, only the quantum-mechanical zero-point motions remain.

As a material is cooled from room temperature many changes take place. Liquids freeze, and solids become stiffer and more brittle. Pure metals become less resistive, and many metals become superconductors. All of the gases that exist at room temperature eventually liquefy, and most of these also freeze into solids. At ordinary pressures, helium (the common isotope ^{4}He and the rare isotope ^{3}He) remains a liquid at absolute zero in temperature.

FIG. 1. Logarithmic temperature scale indicating significant events as the temperature is lowered from room temperature. The temperatures are on the kelvin scale.

The process of reducing temperature lowers the energy in materials. This is the energy that causes the random motions. For this reason, as the temperature is reduced, interactions between molecules, atoms, and even nuclei of neighboring atoms progressively become more important. We can substitute an energy scale, with ϵ being a typical single-atom or -molecule energy, for the temperature scale in Fig. 1 by using

$$\begin{aligned}\epsilon &= k_B T \\ &= (1.38\times 10^{-23}\ \mathrm{J/K})T \\ &= (8.63\times 10^{-5}\ \mathrm{eV/K})T. \qquad (1)\end{aligned}$$

As the temperature (or energy) is reduced below the interaction energy, important physical changes are likely to occur. These energies are small and become tiny when the temperatures are reduced. For this reason, cryogenics can be thought of as the physics of small energy.

A second way of thinking about low temperatures is to consider the entropy that is contained within materials (Kittel and Kroemer, 1980; Zemansky and Dittman, 1981). Entropy is a measure of disorder or randomness. The classical definition of entropy is written in terms of the number of ways that one can microscopically rearrange a system consistent with whatever physical constraints exist (e.g., temperature, energy, pressure or volume, magnetic field or magnetization). In usual systems, this number of rearrangements is a very large number, but the entropy is the logarithm of this number. If we use S for the entropy and Γ for the number of combinations we have

$$S = k_B \log \Gamma. \qquad (2)$$

When the thermal energy, as shown in Eq. (1), is smaller than interactions, the system goes into its ground (lowest-energy) state. The system becomes highly organized. Thus when a system is highly organized, the number of possible arrangements of particles Γ is small and S approaches zero. This corresponds to the low-temperature state of a system.

The universe has a background temperature of about 3 K due to the residue of radiation from the "big bang." Current measurements show this temperature to be 2.735 K (Mather, 1990). For this reason, there are no naturally occurring regions anywhere in the universe that have a temperature below this 2.7 K. Thus, with cryogenics, we are capable of producing unique states of matter (below 2.7 K) that are not duplicated in the natural world. By contrast, in other frontiers of technology (high energy, high pressure, high temperature, high magnetic fields, low pressure or high vacuum, etc.) manmade efforts are inevitably exceeded by nature.

At very low temperatures (below 1 K) the usual vibrations (phonons) in most materials become insignificant. Properties of materials are dominated by the interactions of electrons and magnetic spins, and eventually as the temperature is reduced, the magnetism of the nuclei becomes important. (Zemansky and Dittman, 1981; White, 1979; Lounasmaa, 1974).

2. PRODUCTION OF LOW TEMPERATURES

In 1877 L. Cailletet expanded high-pressure oxygen, which produced a fine mist of liquid (Mendelssohn, 1977). Simultaneously, R. Pictet had produced a similar result in another laboratory. After this, the race was on to liquefy all of the remaining gases. Sir James Dewar was the first to liquefy hydrogen in 1898; but, in the race to liquefy helium (the last natural gas), he was beaten out by Kamerlingh Onnes, who succeeded in 1908. Soon after this time, temperatures near 1 K were achieved.

As a by-product of the highly competitive effort to be the first to liquefy gases, several inventors worked to improve cryogenic refrigerators. The first patent for an expansion engine was given to Solvay in 1887. Hampson in England and Linde in Germany each filed a patent in 1895 for a process using a compressor, a counterflow heat exchanger, and a Joule–Thomson expansion valve to produce large quantities of liquid oxygen and nitrogen. Shortly after this, Claude filed a patent in France for a refrigerator that placed an expansion engine before the Joule–Thomson expansion valve in the Hampson–Linde refrigerator. An expansion engine greatly improves the refrigerator by letting the gas do work on a moving piston and thus lose heat energy. This staged approach to refrigeration is characteristic of low-temperature refrigerators.

Magnetic cooling was first proposed independently by William Francis Giauque and Peter Debye in 1926 (Mendelssohn, 1977). Giauque succeeded in reaching 0.25 K by 1933.

Currently, the production of low temperatures follows the techniques developed by the pioneers that we have mentioned above. Heat energy is extracted from materials with various methods of refrigeration depending on which methods efficiently remove entropy in the temperature range where the refrigerator is operating. Figure 2 shows, on a logarithmic temperature scale, the approximate temperature ranges in which these various techniques function best. As the temperature is reduced, the preferred method of cooling changes. For this reason, devices that produce or operate at low temperatures (cryostats) frequently employ a series of cooling techniques. This cascade approach is used in state-of-the-art cry-

ostats for obtaining microkelvin temperatures. These cryostats start with liquid helium at 4.2 K (a result of a cascade of mechanical coolers), then use an evaporation refrigerator to obtain 1 K; this is followed by a dilution refrigerator that can get to less than 10 mK. Next a nuclear cooling stage gets the temperature to well below 1 mK. Sometimes, a second nuclear cooling stage is added that can obtain a final (nuclear) temperature in the nanokelvin range.

2.1 Thermal Insulation

The production of low temperatures requires that we remove heat energy. Our ability to lower the temperature is ultimately limited by the amount of heat that leaks back in. For this reason, any low-temperature system needs to be surrounded by thermal insulation. This insulation can be in the form of materials that have low thermal conductivity, or a vacuum. Heat flows in three primary ways. First, there is diffusive conduction, which is usually high in pure metals and crystals and low in glasses and composite materials such as ceramics, plastics, and fibers (White, 1979; Powell and Childs, 1972). A second mode of heat flow is convection, in which heat is carried by a gas or liquid. A temperature inversion (hot region below the cold region) generally induces convection so that a fluid moves from a low-density hot region to a high-density cold region. Most gases are actually poor thermal conductors. However, in open regions, they can start a convective flow that transports much more heat than conduction. For this reason, many forms of insulation such as Styrofoam rely on trapping air in small cavities. The third common mode of heat flow is blackbody radiation. The heat flow due to radiation depends on the emissivity of the material and is proportional to T^4 (Stefan's law) (Kittel and Kroemer, 1980).

Containers for cryogenic fluids and equipment are referred to as Dewar flasks—named for James Dewar. Dewars rely on vacuum and reflective surfaces to minimize heat flow. In Fig. 3, we illustrate two types of Dewars. The first is the original vacuum flask. Here the walls are made from glass or stainless steel. Glass Dewars have a shiny metal film added to the walls to reduce radiation. (These Dewars are the same as the household Thermos™ bottles for holding coffee or cold drinks.) The second Dewar is an improved version that uses superinsulation in addition to the vacuum. Superinsulation is made of many layers of Mylar (polyester) film coated with a thin film of aluminum. The superinsulation then acts as a very efficient radiation shield since, going from higher temperature, each layer radiates less then the one outside. Also, residual gas in the vacuum space is trapped between the layers of the superinsulation. In modern Dewars, the neck, in which there is a rapid change in the temperature, is frequently made from an epoxy and fiberglass composite. For efficient storage of cryogenic liquids, the neck is usually kept small since much of the heat leaking into the Dewar is conducted down the neck. Dewars can be made in many shapes ranging from the simple cylindrical shapes shown here to large tank cars.

Many low-temperature devices use "heat switches," which are capable of turning on and off heat flow (White, 1978; Lounasmaa, 1974). Heat switches are used when there is a need to have parts of the cryogenic apparatus in close thermal contact at some times, and well isolated at other times. For example, a

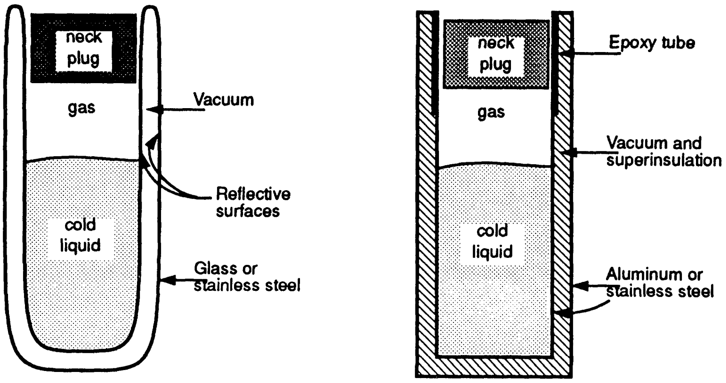

FIG. 3. Typical arrangements of Dewar flasks. The one on the left is close to the original design and uses a vacuum and highly reflective surfaces to insulate the liquid from heat coming through the walls. The walls are made from a poor heat conductor so that the top region, or neck, conducts very little heat. The Dewar on the right uses a more modern construction with the neck constructed of an epoxy tube (usually with fiberglass as a filler) and the walls filled with superinsulation.

heat switch can be used to allow cooling and later isolation of a material, the heat capacity of which is being measured. Such a switch can be a mechanical switch, or a system using a gas that can be later evacuated to exchange heat. At temperatures below 1 K, heat switches are most frequently made from pure superconducting metals such as Pb, Sn, In, and Al. (See the inset in Fig. 14.) When these metals are pure, their heat conductivity is very high in the "normal" state but very low in the superconducting state. A superconducting heat switch is made by surrounding the superconductor with a variable-field magnet. When the magnetic field is raised above the superconductor's critical field, the conductor becomes normal and switches from being a poor conductor of heat to a very good conductor of heat.

2.2 Cryogenic Refrigeration Using Fluids

All large-scale cryogenic refrigerators, and most small-scale refrigerators, use heat engines that have either a liquid, a gas, or a mixture of a liquid and gas as the refrigerant. These engines use the expansion of a compressed fluid as the cooling process. A few heat engines use magnetic or thermoelectric cooling. Graham Walker in his book on cryogenic heat engines (Walker, 1983) has coined the term "cryocoolers" to describe heat engines intended to produce cryogenic temperatures. In this section, we will briefly discuss three processes that can be used singly or in combinations to produce low temperatures. In practice, there are many variations of these processes named after different inventors. The three processes we discuss here illustrate the essential features that exist in all of these refrigerators.

In general, heat engines are devices that use heat to produce mechanical work. Examples of these would be steam turbines or gasoline and diesel engines. In Fig. 4 we have a schematic drawing of two heat engines, one running forward using high-temperature heat to produce work, and one running in reverse using work to remove heat. A forward-running heat engine is characterized by its efficiency ϵ in converting the high-temperature heat Q_h (that's what you pay for) into work W_{out}:

$$\epsilon = W_{\mathrm{out}}/Q_h. \tag{3}$$

Low temperature heat source

Forward running heat engine

Reverse running heat engine (cryocooler)

FIG. 4. Schematic diagrams for continuously operating heat engines. The forward-running heat engine uses heat Q_h to produce work W_{out} and rejects heat Q_c. The reverse-running heat engine uses work W_{in} to remove heat Q_c from a low temperature and adds heat Q_h to the high-temperature heat sink.

The first law of thermodynamics (energy conservation) requires that $W_{\mathrm{out}} = Q_h - Q_c$. The change in entropy due to heat flow is given by $\Delta S = Q/T$, which means that proportionately more entropy is carried away by the heat carried to the low-temperature reservoir. The second law of thermodynamics requires that the net entropy of the heat engine cannot decrease. Thus there is a maximum efficiency which is equal to $1 - T_c/T_h$ and can never exceed 1.

A cryocooler is a reverse-running heat engine, which can be characterized by the ratio of the extracted heat Q_c to the input work W_{in}. This ratio is called the coefficient of performance C,

$$C = Q_c/W_{\mathrm{in}} \tag{4}$$

Here, the second law of thermodynamics shows that the maximum value for C is $T_c/(T_h - T_c)$, which can exceed the value 1 (which occurs in common refrigeration devices such as room air conditions), while the first law requires that $W_{\mathrm{in}} = Q_h - Q_c$. (Note that the directions of heat flow and work in the cryocooler are reversed.)

An ideal heat engine follows a Carnot cycle. The Carnot cycle has four parts, which are illustrated in a *TS* plane in Fig. 5. This figure shows the heat engine going through a series of constant-temperature ($1 \rightarrow 2, 3 \rightarrow 4$) processes and constant-entropy processes ($2 \rightarrow 3, 4 \rightarrow 1$). These correspond to combinations of heating or cooling and compressing or expanding the fluid. In the Carnot cycle, the thermodynamic system plotted is usually a

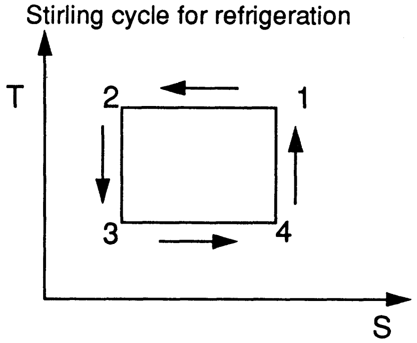

FIG. 5. The Stirling cycle as represented in a *TS* plane. The arrows indicate the direction taken when a Stirling engine is operating as a refrigerator.

single substance—often a gas. However, obtaining the heat switching necessary to have constant-entropy processes in a single substance is impractical.

2.2.1 Stirling Cryocooler. A Stirling heat engine uses a process approximating a Carnot cycle. In contrast to the Carnot engine, the Stirling engine uses two "working substances" that exchange heat between themselves so that the composite system follows a Carnot path. Figure 5 represents the ideal path for the refrigerator, but a real Stirling refrigerator relies on mechanical devices that only approximate the path. Also, friction and thermal gradients reduce the performance. Thus, the real coefficient of performance is less than $T_c/(T_h-T_c)$. Frequently, this cycle is shown in a pressure–volume (*PV*) plane; however, this presentation can be deceptive since a Stirling engine relies on a reversible heat source to produce adiabatic (constant *S*) changes in the temperature.

A still idealized model of a Stirling refrigerator using a gas is shown in Fig. 6. Here step 1→2 is accomplished by compressing the gas on the right (hot) side and simultaneously removing heat Q_h through a heat exchanger (not shown) to the high-temperature reservoir. The next step, 2→3, involves moving both pistons simultaneously with the gas delivering heat to the regenerator. Step 3→4 is the isothermal expansion of the left (cold) cylinder. Now, heat from the low-temperature side Q_c is absorbed.

In a real Stirling engine, the reversible heat source is called a regenerator and is typically made from an assembly of finely divided metal in the form of strips, wires, or tubes. This provides a large heat capacity, efficient heat exchange, and low heat conduction between the hot and cold ends. An actual Stirling engine only approximates the steps described in Fig. 6, since the mechanical linkages to produce these exact piston motions would be unnecessarily complex. On the other hand, smooth oscillatory motion of the pistons does not deteriorate the efficiency much. Stirling engines have a significant advantage in that they do not require valves, which makes them highly reliable. They are among the most efficient cryocoolers, and modern versions of these are used in both large-scale and small lightweight systems. Most modern military aircraft have Stirling cryocoolers on board to cool their infrared detection systems.

2.2.2 Joule–Brayton Recuperative Refrigerator. A Joule–Brayton recuperative cryocooler is very similar to a Stirling engine except in the manner in which the gas is precooled. The Joule–Brayton cryocooler uses a compressor, a counterflow (recuperative) heat exchanger, and an expander. A schematic diagram for this type of refrigerator is shown in Fig. 7. First the gas is compressed, which heats it up. The high-temperature heat exchanger brings the gas back to the temperature of the surroundings. The expander is a reversed compressor. Compressed gas is allowed to expand while doing work on the piston. The walls of the expander are poor heat conductors so that the process is adiabatic and nearly reversible. Thus the work done by the expanding gas on the piston in the expander removes internal energy from the gas, which results in a temperature drop in gas. After passing through the cold region, the returning gas flows through a counterflow heat exchanger which precools the incoming gas.

2.2.3 Joule–Thomson Refrigerator. The third refrigeration technique, the Joule–Thomson expansion, differs from the expander explained above because in this case the gas does no external work. Instead of the gas doing work on a piston, it does work on itself. This is the procedure that is most commonly used in air conditioning, home refrigerators, and freezers, where the working fluid is Freon 12 (a chlorofluorocarbon) or ammonia. A Joule–Thomson refrigerator uses a compressor to feed gas through a narrow

restriction. This narrow restriction can be made with a piece of fine capillary tubing or a fine porous material. In many cryogenic refrigerators, the restriction can be adjusted to fine tune the performance of the refrigerator. Thus this restriction is often called a Joule–Thomson valve. We can easily show that a thermodynamic potential called the enthalpy is the same before and after the gas passes through the restriction. The enthalpy is defined by $H = U + PV$, where H is the enthalpy and U is the internal energy. In general, a constant-enthalpy expansion can cause either cooling or warming depending on the sign of the Joule–Thomson coefficient $\mu \equiv (\partial T/\partial P)_H$. In general, gases have a negative μ at high temperatures and warm when expanded, but have an inversion point where μ goes through zero and becomes positive at lower temperatures. For gases at temperatures below the Joule–Thomson inversion point, the result is a reduction in temperature. The maximum inversion temperatures, which also depend on pressure, for N_2 and O_2 are about 621 and 764 K—above room temperature—while the inversion temperatures for H_2 and He are about 202 and 40 K.

Although Joule–Thomson expanders can reduce the temperature of a gas at any starting temperature below the inversion point, they are efficient refrigerators and liquefiers only if the gas going into the Joule–Thomson valve can be precooled to significantly lower temperatures. As a rule of thumb, starting the

expansion near the critical temperature of the liquid greatly increases the efficiency of the refrigerator.

A Hampson–Linde cycle (named for its inventors) uses a Joule–Thomson expansion and a recuperative heat exchanger. Figure 8 shows a schematic diagram of this cycle, and the path taken by the gas in a temperature–entropy diagram is shown in Fig. 9. The numbers in the *ST* diagram refer to the points in this Joule–Thomson refrigerator.

1→2 is a compression from the low-pressure side of the system at P_1 to the high-pressure side at P_2. This compression raises the temperature of the gas above the ambient (room) temperature, and as the gas is fed through the high-temperature heat exchanger, the temperature is returned to the ambient temperature, 2→3. Then the gas passes through the counterflow heat exchanger, where it is cooled by the returning gas, to point 4. The Joule–Thomson expansion, 4→5, follows a line of constant enthalpy and ends in the two-phase region. Thus part of the gas liquefies and can be removed with new make-up gas coming in at the intake of the compressor, or alternatively, the system can be used as a refrigerator using the latent heat of the liquid

FIG. 8. Joule–Thompson expansion refrigerator. Here, the compressed gas is first returned to close to room temperature and then further cooled by returning gas in the counterflow heat exchanger. The Joule–Thompson expansion results in a liquid–gas mixture if the inlet temperature to the Joule–Thompson valve is sufficiently low.

in the two-phase region, 5→6. If the precool temperature (corresponding to point 4) is not sufficiently close to the two-phase region so that the Joule–Thomson expansion does not reach the two-phase region, this system still operates as a refrigerator, but at a greatly reduced efficiency.

By itself, a Joule–Thomson refrigerator can be used for the liquefaction of air and other gases with the exception of hydrogen and helium. However, this process is usually coupled with one or more other expansion engines. For example, Collins developed a helium liquefier during the late 1940s that used two Joule–Brayton type expanders followed by a Joule–Thomson expansion stage. This three-stage liquefier is now common to low-temperature laboratories throughout the world.

2.2.4 Evaporative Coolers—1 K, 0.3 K. Apparatus that requires temperatures below 4 K usually use liquid helium (^{4}He, which boils at 4.2 K at atmospheric pressure) as a starting point. In most low-temperature experiments that use liquid helium, the liquid is produced elsewhere and then transferred via an insulated line to a Dewar. The process of producing lower temperatures involves adding stages to the refrigeration process. As a first stage in cooling below 4.2 K, a simple evaporative cooler can be used.

Figure 10 illustrates a simple pumped-^{4}He refrigerator. The main Dewar holds a supply of ^{4}He at atmospheric pressure. Inside the Dewar, there is a leak-tight container ("can") whose high vacuum acts as insulator. Inside the vacuum can, a container holding liquid ^{4}He is connected to a vacuum pump, usually located outside the Dewar. A small amount of liquid ^{4}He is allowed to trickle into the "1-K pot" through a tiny capillary. The pump reduces the pressure in the 1-K pot causing the liquid ^{4}He to boil, removing the latent heat of vaporization and cooling the remaining liquid. As the temperature is reduced, the ^{4}He vapor pressure is reduced, as shown on the left-hand side of Fig. 10. The lower vapor pressure in turn lowers the amount of ^{4}He that can be pumped away so that eventually a steady-state temperature is obtained that depends on the vapor pressure and the size of the vacuum pump. With a good vacuum pump and fast pumping lines, temperatures near 1 K (more frequently nearer 1.2 K) can be obtained this way.

^{3}He is a rare isotope of helium containing one less neutron than the common isotope ^{4}He. Isotopically pure ^{3}He has significantly different properties from ^{4}He at low temperatures. We have included a sketch of the ^{3}He vapor-pressure curve in Fig. 10. Since ^{3}He has a higher vapor pressure, we can reach lower temperatures (about 0.3 K) by substituting ^{3}He for ^{4}He in the cryostat. Of course, in that case we are very careful to recover the ^{3}He from the back of the vacuum pump since it is very expensive.

2.2.5 Dilution Refrigeration. Most cryostats that reach temperatures below 0.5 K use a dilution refrigerator as the next cooling stage below the 1-K pot. A dilution refrigerator uses a mixture of ^{4}He and ^{3}He. This mixture separates into two phases below 0.86 K. At low temperatures, one phase (the "concentrated" phase) is nearly pure ^{3}He and the other phase is mostly ^{4}He with about 6.4% ^{3}He (the "dilute" phase). When concentrated ^{3}He is diluted, latent heat is absorbed in a way very much analogous to the vaporization of a liquid (such as the ^{4}He discussed above). A dilution refrigerator can operate either by having ^{3}He circulate with ^{4}He remaining stationary or with ^{4}He circulating. Dilution refrigerators with circulating ^{3}He are the most common form of these refrigerators.

The essential parts of this type of refrigerator are shown in Fig. 11. The entire low-temperature portion of the refrigerator is

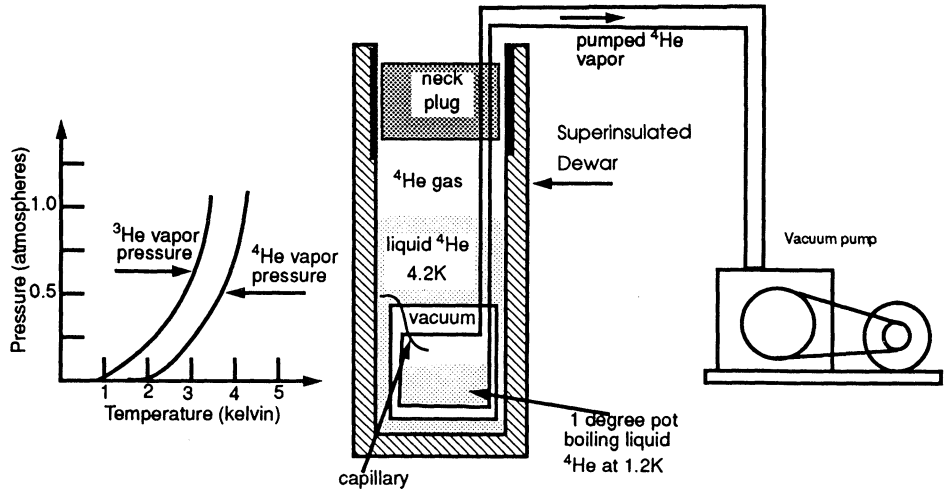

FIG. 10. A schematic diagram showing a Dewar with a 1-K refrigerator inside. The vacuum pump removes helium gas from the 1-K pot, causing cooling. The 1-K pot is refilled by a small capillary connected to the helium in the main Dewar. The inset on the left shows approximate values for the vapor pressures of ^{4}He and ^{3}He. When ^{3}He is used for refrigeration, a second ^{3}He pot is placed below the 1-K pot and the ^{3}He vapor is returned to the ^{3}He pot after passing through a series of heat exchangers.

surrounded by a vacuum can that is immersed in liquid ^{4}He in the same configuration as is shown in the ^{4}He refrigerator. With the dilution refrigerator, the cooling takes place in the mixing chamber, which has both concentrated and dilute phases in coexistence. The ^{3}He is moved through the refrigerator by pumping on the still, which is held near 0.8 K. In that temperature range, the vapor pressure of the ^{3}He is much greater than that of the remaining ^{4}He *even though the concentration of ^{3}He is small.* For this reason, the pump removes from the still almost pure ^{3}He, which is recovered and then returned. The continuous removal of ^{3}He from the still causes a depletion of ^{3}He in the mixing chamber, which in turn causes the concentrated ^{3}He to dilute continuously into the ^{4}He. This process is similar to evaporation, in which the concentrated ^{3}He is the liquid phase and ^{3}He in the dilute phase is analogous to a vapor. (Here the "vapor" phase lies below the "liquid" phase since liquid ^{4}He is denser than ^{3}He.) The temperature of the mixing chamber depends on how much heat it is removing, the size of the pumping system, and the efficiency of the heat exchangers that cool the returning ^{3}He. Dilution refrigerators with large pumping systems and very efficient heat exchangers are capable of reaching temperatures below 0.005 K (5 mK) at the mixing chamber, and some have even reached 2 mK.

Since the ^{3}He in both the concentrated and dilute phases is a Fermi liquid, a closer analogy can be drawn with the Peltier effect (Ebner and Edwards, 1971) in which current through a thermocouple junction cools (or heats). However, Peltier refrigerators do not function well much below room temperature because of the Joule (Ohmic) heating due to the electrical resistance of the wires.

2.3 Magnetic Refrigerators

2.3.1 Introduction to Spin Entropy and Adiabatic Demagnetization. Magnetic refrigerators take advantage of the heat energy associated with the magnetization of materials. These refrigerators are most easily understood in terms of entropy, with the heat required to raise the entropy being given by $\Delta Q = T\Delta S$. In the simplest case, a magnetic material can be thought of as a collection of small magnetic moments. With no magnetic field, the orientation of the spins is random. In a magnetic field, the individual moments have an energy given by

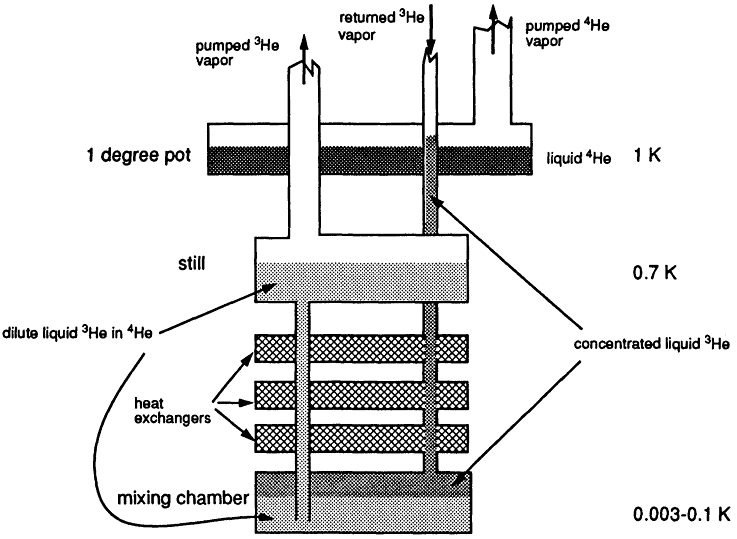

FIG. 11. A schematic diagram of a dilution refrigerator. The parts shown are placed inside a vacuum can that is inside a Dewar similar to that in Fig. 10. The still is connected to an external vacuum pump that removes mostly ^{3}He from the dilute liquid ^{3}He mixture. The 1-K pot acts as a precooler to condense the returning ^{3}He vapor. The heat exchangers further cool the returning ^{3}He. The mixing chamber removes the latent heat of mixing, which causes the mixing chamber to cool. Typical values for the temperatures of the various stages are indicated on the right.

$$\epsilon = -\mathbf{m}\cdot\mathbf{B}, \tag{5}$$

where **m** is the magnetic moment and **B** is the magnetic field. At high temperatures, where the thermal energy $k_B T$ is greater than ϵ, the orientation of the spins is almost random. In this situation, pictured in Fig. 12(a), the number of possible rearrangements of the spins having the same total magnetization is large. Thus according to Eq. (2), the entropy at high temperatures is large. At lower temperatures where $\epsilon \cong k_B T$, the individual moments are partially aligned, as shown in Fig. 12(b), and the entropy is reduced. At very low temperatures, the spins are almost completely aligned by the field, as shown in Fig. 12(c). Here there remain very few rearrangements of the spins consistent with the same magnetization and so the entropy is near zero. Figure 13 shows a sketch of the entropy versus temperature at two magnetic fields. For isolated spins, the entropy reduction is a function only of the ratio B/T.

2.3.2 Demagnetization of Paramagnetic Materials. Figure 13 shows a typical demagnetization cycle. In step 1→2 the material is magnetized in a large magnetic field. An external refrigerator connected to the sample through a "heat switch" removes the entropy. The magnetic material is then thermally isolated and the field reduced in step 2→3. Ideally, there is no heat flow, so that this step is adiabatic and we see that the temperature is reduced. Heat flowing into the material eventually warms it up, as indicated by step 3→4. Finally the magnetic field can be increased to complete the cycle, making a magnetic heat engine; however, most practical magnetic refrigerators act as "one-shot" systems only using steps 1→2 and 2→3.

Many materials can be used to make a magnetic refrigerator. The choice of material depends on the size of the magnetic moment and the strength of the residual interactions between the magnetic moments. If the magnetic moment is small, the entropy reduction during the magnetization is small, and the refrigerator will not be effective. Interactions between magnetic moments cause magnetic ordering (either ferromagnetic or antiferromagnetic), which reduces the entropy and makes the entropy independent of the magnetic field. Thus, very little magnetic cooling can occur at temperatures below which magnetic ordering occurs.

At high temperatures Gd is frequently used for magnetic refrigeration. Below 1 K a number of rare-earth salts are used. The most common of these in low-temperature laboratories is CMN (cerium magnesium nitrate). This salt orders ferromagnetically near 2 mK (0.002 K), and this sets the minimum temperature that it can achieve.

2.3.3 Nuclear Demagnetization. Nuclear demagnetization follows the same process as that for paramagnetic materials except that the magnetic moments that are used are the nuclear moments. While these moments are much smaller, the interactions between the

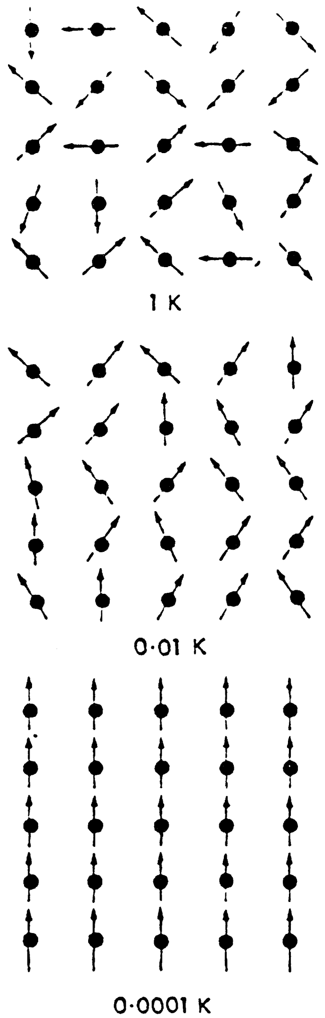

FIG. 12. Arrangements of magnetic spins at a high, intermediate, and low temperatures. The high-temperature arrangement is nearly random with a small total magnetization. There are many arrangements of spins with small magnetization causing a high entropy. At the intermediate temperature, the magnetic energy is approximately the same as $k_B T$. At low temperatures, the spins are aligned with a higher magnetization, but fewer possibilities. Thus the entropy is low. (Mendelssohn, 1977, p. 168.)

moments are also small. A nuclear demagnetization apparatus typically uses a dilution refrigerator to precool a sample such as copper in a high magnetic field (8 T or more) to temperatures near 10 mK. Sometimes, two stages of nuclear demagnetization are used with the first stage providing the precooling for the second. The entropy reduction may be less than 10% of the total entropy. Nevertheless, these refrigerators are capable of reaching extremely low temperatures because these systems, which have small interactions, do not order (ferromagnetically or antiferromagnetically) until the temperature is much smaller than in the case of electron paramagnetic materials. Nuclear demagnetization cryostats hold all of the current low-temperature records, as we will discuss in the last section.

A diagram of a nuclear demagnetization cryostat is shown in Fig. 14. The materials that can be used for nuclear demagnetization include In, Cu, Ag, and even Tl and Pt. Cu is used in the greatest number of nuclear demagnetization cryostats by far.

There is a group of metal alloys with rare earths that have a hybrid form of magnetic moment through which the atomic polarization enhances the field at the nucleus, which gives a larger effective moment. This is called Van Vleck enhancement of the nuclear moment, and these alloys can be very effective for nuclear demagnetization (Andres, 1978). The most effective of these Van Vleck alloys is $PrNi_5$, which can be used to reach temperatures in the range of 0.5 mK.

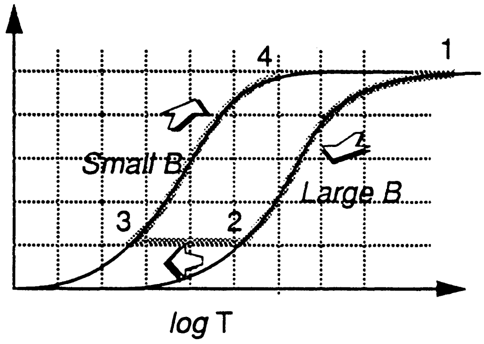

FIG. 13 The path taken in entropy-vs-temperature space for a magnetic refrigerator. The magnetic material is precooled in large magnetic fields (1 → 2), then demagnetized while it is thermally isolated (2 → 3). Heat is removed from the surroundings at low field (3 → 4), and finally the field is raised which increases the temperature (4 → 1).

3. MEASUREMENT OF LOW TEMPERATURES

3.1 Temperature Scales

3.1.1 The Absolute Temperature Scale. The definition of the true thermodynamic temperature is subtle and annoyingly unsatisfying. The intuitive sense of temperature, being what registers on a thermometer when it has come into thermal equilibrium with the material to be measured, is, however satisfying, insufficient to determine uniquely an absolute universal scale. A correct definition of temperature is that it is the quantity that connects entropy changes and heat exchanges in reversible processes:

$$dS = \text{đ}Q/T. \tag{6}$$

Equivalently, $1/T$ is the integrating factor that converts differential heat exchanges into a perfect differential, so that thereby entropy is a state variable.

Obviously, every practical thermometer does not immediately refer to this definition, but each does have a connection to it through whatever chain of calibrations establishes its accuracy.

The definition implicitly defines $T=0$ at the absolute zero of temperature, so that all that is required for a complete scale is an overall scale factor, set by defining one special temperature. That special place is chosen by in-

FIG. 14. Nuclear demagnetization. This cryostat combines the features of several refrigeration processes. The main components are indicated on the left. Three pumping lines are connected to external pumps and gas recovery systems as shown. The bold printed temperatures indicated along the right-hand side of the figure are typical operating temperatures of the various stages in the cryostat. Liquid ^{4}He is delivered to the main Dewar. A 1-K pot maintains 1.2 K. The dilution refrigerator provides precooling for the nuclear demagnetization stage, which is connected by a heat switch. When the demagnetization stage is isolated from the dilution refrigerator, the main magnet field is lowered, lowering the last stage to submillidegree temperatures. The inset shows a heat switch using a superconducting bridge between copper rods.

ternational convention to be the triple point of water (at which ice, water, and water vapor are simultaneously in equilibrium, $P=4.579$ Torr$\approx$6.1 mbar) and defined to be $T=273.16$ K, where K stands for the international unit of temperature, the kelvin (not degree kelvin). The Kelvin scale is used principally in scientific work, particularly at low temperatures.

3.1.2 Other Temperature Scales. There are three other temperature scales in common usage today. Each was originally defined by choosing two special points to define two temperatures. Each is thus linearly related to the Kelvin temperature scale. Closely connected to the Kelvin temperature scale is the Celsius scale, with temperature changes numerically equal in each. Today the definition is $T(^\circ\mathrm{C})=T(\mathrm{K})-273.15$. The original definition of this scale used the equilibrium temperature of melting ice at 1 atm as 0 °C, and the normal boiling point of water (where the pressure is 1 atm) as 100 °C. This exact 100 °C interval was preserved (to the then existing level of accuracy of experiments) by the specific choice of Kelvin scale factor given by choosing the triple point of water temperature given above. Accounting for the negative slope of the water–ice coexistence curve, the temperature of the normal melting point is about 0.003 °C. The Celsius scale, having zero closer to ordinary human conditions than the Kelvin scale, is the most commonly used temperature scale in the world, and is used in most scientific work near room temperature.

An earlier scale is the Fahrenheit scale, originally defined to be 0 °F at the lowest temperature then available (ca. 1700, with a salt–ice mixture) and 12 °F (carrying over a proposal by Isaac Newton) at normal human body temperature, later multiplied by eight to become 96 °F. (Nonlinearities in early thermometers led this number to differ from the now standard value 98.6 °F.) This scale is currently defined in terms of the Celsius scale as $T(^\circ\mathrm{F})=\frac{9}{5}T(^\circ\mathrm{C})+32$. It is the one most commonly used in the United States, but is (very) slowly being displaced in favor of the Celsius scale.

Finally, analogous to the relationship between the Kelvin and Celsius scales, in which the size of a unit temperature change is the same but with a zero offset, is the relationship between the Fahrenheit and Rankine scales. The Rankine scale is an absolute Fahrenheit scale and defined equivalently by either $T(^\circ\mathrm{R})=T(^\circ\mathrm{F})+459.67$, or $T(^\circ\mathrm{R})=\frac{9}{5}T(\mathrm{K})$.

3.1.3 International Temperature Scale of 1990 (ITS-90). The current international temperature scale, ITS-90, was established at the 17th session of the Consultative Committee on Thermometry (CCT) in September 1989 (Preston–Thomas, 1990). The CCT is one of eight Consultative Committees of the International Committee of Weights and Measures, which is, in turn, a committee of the General Conference of Weights and Measures, the authority, by international agreement, for the International System of Units (SI). The CCT is composed of representatives of national standards laboratories throughout the world and of other laboratories concerned with the accurate definition of temperature.

ITS-90 establishes temperatures down to 0.65 K. It also defines overlapping ranges and the functions to be used in calibrating the various thermometers used in each range. (See Fig. 15.) From 0.65 to 5.0 K, temperature is defined as a specified function of the vapor pressure of each of the helium isotopes in separate subranges. From 3.0 to 24.5561 K and from 13.8033 to 1234.93 K the scale is defined in terms of, respectively, a constant-volume gas thermometer using each of the helium isotopes and a platinum resistance thermometer. Up to room temperature each

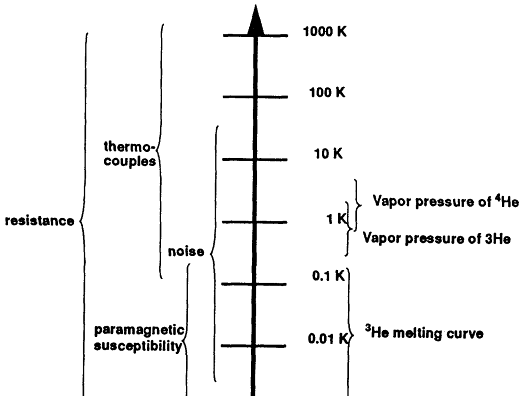

FIG. 15. A logarithmic temperature scale indicating the various types of thermometry that are used.

Table 1. Summary of classes of thermometers for use at cryogenic temperatures.

Class	Theoretical foundation	Examples	Usability	Range	Accuracy	Sample-to-sample reproducibility
Primary	Rigorous, absolute	Ideal gas law, 2nd law, nuclear orientation	Generally poor	Limited	High	Excellent
Secondary	Strong	NMR, noise	Poor to good	Limited	Needs calibration point	Good
Tertiary	Weak	Resistance, diode voltage, thermocouples	Good	High	Needs calibration curve	Poor
Transfer standards	None	Vapor pressure of ^{3}He and ^{4}He, solidification pressure of ^{3}He	Poor	Limited	High	Excellent
Transfer standards	None	Triple points, superconducting transitions	Poor	None	High	Excellent

thermometer is calibrated at the triple points of hydrogen (with equilibrium ortho–para ratio), neon, oxygen, argon, mercury, and water at 13.8033, 24.5561, 54.3584, 83.8058, 234.3156, and 273.16 K, respectively.

ITS-90 superseded the previous temperature scale, known as ITPS-67(75), by extending its lower bound below the triple point of H_2 and changing temperatures below the triple point of H_2O by a mean amount of 10 mK. It also provides better agreement with thermodynamic values than the 1976 Provisional 0.5 K to 30 K Temperature Scale (EPT-76).

3.2 Classes of Thermometers

All thermometers operate by measuring some physical property of a material that changes with changing temperature. Every thermometer can be classified on the basis of its ability to define the absolute temperature. The classification scheme given here is consistent with general use, although there is no universally recognized definition. Examples of each class of thermometer will be given in the following section. These classes are summarized in Table I.

A primary thermometer is one that is capable of defining the temperature by itself, without reference to any other device. It must therefore be grounded in a rigorous thermodynamic principle. For example, a gas thermometer measuring the pressure P of a fixed amount of gas and comparing it to the pressure when in equilibrium with water at its triple point, P_{tr}, would define temperature as

$$T = 273.16 \lim_{P_{\text{tr}} \to 0} \left(\frac{P}{P_{\text{tr}}} \right), \tag{7}$$

where the limiting process successively reduces the amount of gas in the volume to eliminate the effect of intermolecular interactions. The reliance on the ideal gas law and the experimental production of an ideal gas (through the limiting process) makes this a good primary thermometer, although in practice it is rather limited. In general, the reliance on thermodynamic principles renders primary thermometers independent of the working substance, so that reproducibility from sample to sample (and, more importantly, from laboratory to laboratory) is excellent.

A secondary thermometer is one in which an absolute temperature can, in principle, be measured (at least in some approximation) but for which technical difficulties prevent absolute calibration. For example, the nuclear susceptibility in platinum (far from any ordering temperature) to a high accuracy obeys a Curie law with a known coefficient. The difficulty, however, is that an absolute calibration would require an accurate knowledge of the coupling of the platinum nuclei to the thermometer's electronics. Usually the process of determining this coupling is foregone in favor of calibrating at some known point. In principle, a single calibration point is sufficient to define a secondary thermometer's entire absolute scale.

All other thermometers without simple connection to fundamental thermodynamic principles, which includes almost all thermometers in use, are classified as tertiary. Certainly the physics of their operation is well known, but difficulties in a first-principles calculation prevent their being classified as secondary. For example, the voltage developed by a thermocouple arises from the temperature-dependent chemical potential of the two involved materials, but this is exceedingly difficult to evaluate even for simple metals, let alone the metal alloys usually used in practical thermocouples.

Finally, we mention the role of transfer standards and fixed points. These provide an excellent mechanism to transfer temperature scales between laboratories. These are exclusively associated with phase transitions (fixed points simply being the intersection of at least two phase transitions) and are thus not calculable from first principles without a known equation of state, which we do not have. These transitions can be used either directly, as in the case of ^{3}He melting-curve thermometers in the low-millikelvin regime, or indirectly, to calibrate other, potentially more convenient, thermometers such as by using the pressure-dependent superfluid transition temperature in ^{3}He, $T_c(P)$, which establishes a reliable scale from 0.9 to 2.5 mK (Greywall, 1986).

3.3 Practical Thermometers

A good thermometer should have high sensitivity, short internal thermalization time constants (so that the thermometer itself will have a well-defined temperature), good thermal contact with the system, and negligible total heat capacity so as not to load thermally the system it is measuring (which may be achieved simply by making the thermometer physically small), and should introduce negligible heat to the system through its operation. It should furthermore be insensitive to all environmental influences other than temperature. A good thermometer for one measurement may be a poor one under different conditions. We summarize here some of the thermometers used in cryogenic measurements. The ordering of these thermometers generally follows their useful temperature range, in decreasing order.

3.3.1 Constant-Volume Gas Thermometer. As mentioned above, the pressure of a fixed amount of an approximately ideal gas can be used, although corrections for nonideality are important. This thermometer can be used until the pressure becomes so small that thermomolecular corrections become significant. This limits its practical range to that above several kelvins. For precision metrology there is also a significant problem associated with adsorption of the gas on its container's walls. Even for the noble gases, the binding energy for initial layers to surfaces is 100 K or more, which can significantly affect the inferred molar volume if the surface-to-volume ratio is not negligible.

3.3.2 Thermocouples. Thermocouples have a long history of importance, being used in the definition of the Kelvin scale until the advent of the current scale, ITS-90. They have the advantage of simplicity, but the disadvantage of relatively small voltage signals which vanish as $T \rightarrow 0$. Below 10 K they are generally not useful, although special Kondo-enhanced thermocouples (see HEAVY-FERMION PHENOMENA) have been demonstrated to work in a limited range around 10 mK.

3.3.3 Cryogenic-Liquid Vapor Pressure. The vapor pressure of cryogenic liquids can be used as a thermometer. The ITS-90 is, in fact, *defined* in terms of the helium liquid vapor pressures from 0.65 to 5.0 K. This technique has a range limited from above by the liquids's critical point and from below by the rapidly vanishing vapor pressure, decreasing as $\exp(-\Delta/k_BT)$, where Δ is a constant (at low temperatures) proportional to the latent heat of vaporization. Even using ^{3}He, with its small latent heat of vaporization, the lowest measurable temperatures with this technique are only 0.3 K.

3.3.4 Resistance Thermometers. One of the simplest tertiary thermometers to use is a resistance device. Any material with a temperature-dependent resistance can be used. Typical materials are carbon (including ordinary carbon composition resistors), germanium, platinum, and numerous alloys. All resistors exhibit some degree of magnetoresistance so that calibrations are distorted by modest (few teslas) magnetic fields, but most resistors retain sensitivity to thermal changes, which may be sufficient in a given application. Off-the-shelf carbon resistors are convenient, but vary in their characteristics from batch to batch and may show significant irreproducibility during the first few thermal cyclings.

The low-temperature limit is set by different effects for different materials. For carbon resistors, the resistance of which climbs with decreasing temperature, the low-temperature limit is set by the maximum resistance measurable without significant interference from spurious effects, such as leakage resistance. A typical maximum resistance is 1 MΩ. For commercial thermometers the low-temperature limit is around 1 K, although uncalibrated carbon resistors routinely used in ultralow-temperature laboratories can be used down to a few millikelvins. Carbon resistors generally also have a problem with internal thermalization in the millikelvin regime because they are poor thermal conductors.

Platinum resistors decrease in value with decreasing temperature. Their practical low-temperature limit is about 10 K, which arises from their vanishing temperature coefficient at low temperatures and the power dissipation from the temperature-independent part of the resistance.

3.3.5 Diode-Voltage Thermometers. Closely connected to resistance thermometers are diode thermometers. The difference between diodes and resistors is only in the diode's nonlinear current–voltage relationship. For a fixed current, as is used conventionally, the two are identical. Driven with 10 μA forward current, silicon diodes yield a sensitivity of 2–3 mV/K from room temperature down to about 30 K when the carriers begin to freeze out and the sensitivity increases to 50–100 mV/K. GaAs diodes have a similar sensitivity at high temperatures, but this sensitivity decreases below about 20 K. The low-temperature limit is about 1 K, set by the rather large power dissipation of 10 μW.

3.3.6 Capacitance Thermometers. Capacitance thermometers use the temperature dependence of the dielectric susceptibility of ferroelectric (and other ordered) crystals. They have the advantage of insensitivity to magnetic fields and are used principally to regulate temperatures as magnetic fields are applied. Capacitance thermometers utilizing $SrTiO_3$ exhibit a nonmonotonic temperature dependence, peaking around 65 K. They also suffer from irreproducibility when thermally cycled.

3.3.7 Ferromagnetic and Antiferromagnetic Frequency Shifts. The resonance frequency of nuclei in solids depend sensitively upon the internal magnetic fields. Therefore there have been a number of proposals to measure temperature via nuclear frequency shifts in magnetically ordered materials. By choosing the appropriate ferromagnet or antiferromagnet, essentially any temperature interval can be covered. The disadvantages of this technique are the sensitivity to sample preparation and the narrow temperature interval over which this technique has high sensitivity.

3.3.8 Electron Paramagnetic Susceptibility. The magnetic susceptibility of electrons in paramagnetic salts provides a convenient thermometer at low temperatures. For example, by choice of a material with a suitable magnetic ordering temperature (and by use of a large measuring field), temperature resolution of 1 nK near the λ point of ^{4}He can be achieved (Chui and Lipa, 1984; Steinberg and Ahlers, 1983; Marek, 1987). Below 1 K a convenient material is cerous magnesium nitrate (CMN), which has a large susceptibility, but a relatively low ordering temperature of 1.8 mK. In the low-millikelvin regime it is much more common to dilute the magnetic Ce ions with nonmagnetic La in a 1:19 ratio. This material is conventionally named LCMN. The temperature dependence of the susceptibility of LCMN is accurately given by a Curie–Weiss form, $\chi \propto 1/(T-\Delta)$, down to 0.3 mK, although this needs to be checked for each sample, given that the randomness of the La-for-Ce substitution means that there must exist CMN regions which are ordered.

3.3.9 Nuclear Susceptibility. Analogous to the magnetic susceptibility of electrons, the nuclear susceptibility also makes a convenient thermometer that is very common in ultralow-temperature laboratories. Because of the much smaller magnetic moments of nuclei relative to electrons, the susceptibility is smaller, pushing down the upper temperature limit of usability to a few tens of millikelvin. Also because of the reduced moments, the nuclear interactions are smaller than electronic ones, suppressing the ordering temperatures and pushing down the low-temperature limit of usability. As long as the temperature is significantly above 1 μK, well above the nuclear ordering temperatures, the susceptibility is accurately described by a Curie form, $\chi \propto 1/T$. For purposes of measuring temperatures in the low-millikelvin regime, the most commonly used material is platinum, which has a spin-lattice relaxation time of about (30 mK)/T s. As usually implemented, pulsed NMR spectrometers show pulse-to-pulse amplitude reproducibility of only about 1%, requiring considerable averaging for high accuracy.

3.3.10 ^{3}He Melting Pressure. An interesting thermometer used in several ultralow-temperature laboratories uses the melting pressure of ^{3}He directly as a thermometer. All that is needed to measure temperature is an accurate calibration of a pressure gauge. Zero offsets can be eliminated by adoption of the A transition of superfluid ^{3}He as the reference point. The melting curve is roughly independent of magnetic field for small fields ($B \leqslant 0.5$ T). This thermometer suffers from a rather large thermal load, but this is not significant for experiments studying superfluid ^{3}He or using it in an auxiliary role. This thermometer loses sensitivity at the low end below about 1 mK, where the solid orders magnetically. It is also insensitive at temperatures approaching the minimum in the melting curve around 0.3 K.

3.3.11 Noise Thermometry. Thermal noise (known as Johnson noise or Nyquist noise) is a limiting factor in resistance thermometry. However, this noise can itself be used as a thermometer directly. The maximum available noise power per unit bandwidth of any device is k_BT. In the case of a pure resistor of value R, at temperature T, thermal fluctuations of local charge density produce an effective voltage source in series with the resistor with mean square amplitude in a frequency interval Δf of $V^2 = 4k_BTR\Delta f$. The fundamental difficulty at low temperatures is efficient coupling of the noise into a detector that itself has a noise temperature small compared to that being measured, for which several solutions have been attempted. With commercial rf superconducting quantum-interference devices (SQUIDs), detector noise temperatures of order 1 mK have been demonstrated in noise thermometers. In principle, this thermometer could be a primary thermometer, but difficulties in precisely specifying the system transfer function over the entire bandwidth for which noise contributes power has limited devices to date to secondary status, requiring one calibration point to fix the temperature.

3.3.12 Nuclear Orientation. Nuclear orientation thermometry is a primary thermometer in that all of its parameters can be specified by studies of radioactive decay modes. The fundamental idea is that γ rays associated with a chain of radioactive decays are not emitted isotropically, but rather have a calculable probability of being emitted at any specified angle with respect to an axis easily defined by an applied magnetic field. The radiation pattern is isotropic at high temperatures and is maximally anisotropic at $T=0$. By measuring the anisotropy one can deduce the temperature. This thermometer suffers from self-heating associated with the nuclear decay by-products. Reducing the activity of the source to reduce the heating increases the time required to count decays. Furthermore, the accuracy of this device is not high, limited by instrumental difficulties to about 1%. Although there is no shortage of nuclei and hosts to consider, it appears unlikely that nuclear orientation will be a useful primary thermometer below several millikelvin.

3.3.13 Quasiparticle Damping Thermometry. A unique thermometer developed at the University of Lancaster, United Kingdom, measures the damping of a wire vibrating in liquid ^{3}He. At the lowest temperatures, the damping arises from individual quasiparticles being scattered from the wire. Since the number of quasiparticles as a function of temperature is known, this can be a good secondary thermometer. At temperatures above about 500 μK the damping becomes dominated by ordinary hydrodynamic viscosity, but this device is still useful as a tertiary thermometer. Since the ^{3}He itself is the thermometer, this avoids problems of thermal contact between ^{3}He and some other thermometer. This device has been used to measure the lowest temperatures in ^{3}He and has been used in dilute mixtures with some attendant controversy.

3.3.14 Nuclear Quadrupole Thermometry (NQT). A speculative technique being investigated by several laboratories uses a small Zeeman splitting (see ZEEMAN AND STARK

EFFECTS) of nuclear quadrupole levels to establish a primary thermometer. Nuclear resonance measures transitions between different quadrupole levels, with slightly shifted frequencies arising from the Zeeman fine structure. The ratio of the spectral weights of the different transitions depends upon relative populations of different energy levels E_i, which are determined by a Boltzmann factor $\exp(-E_i/k_BT)$. The possibility of such a thermometer has been demonstrated using a variety of nuclei at temperatures from 10 mK to 1 K.

3.3.15 Second-Law Thermometry. Finally, at the coldest temperatures yet reached, none of the above thermometers is reliable. Fortunately, the second law of thermodynamics can be used directly. The basic idea is to measure some thermometric property (such as magnetization) from which we can deduce the entropy while injecting a known amount of heat $\text{đ}Q=TdS$. The temperature is then immediately deducible.

4. HOW LOW CAN WE GO?

The second and third laws of thermodynamics state that the entropy of any system at zero temperature is zero, but the efficiency of removing entropy also approaches zero at zero temperatures. For this reason, $T=0$ stands as one of Nature's ultimate limits, much like the speed of light in a different context.

4.1 Negative Temperatures

In any discussion of low-temperature limits, it is natural to consider the possibility of exceeding the ultimate limit. While it is impossible to achieve negative temperatures solely by exchange of heat between reservoirs, it is possible to produce negative temperatures by nonthermal means.

In a discussion of *low*-temperature limits, it may appear odd to discuss negative temperatures because, simply put, negative temperatures are hotter than positive temperatures. However, the theoretical considerations involved in producing negative temperatures are identical to those in producing the current ultralow-temperature limits.

The range of systems in which negative temperatures can be achieved is quite limited. Consider an ensemble of two-state systems with energy levels $E_i = \pm\Delta/2$, as shown in Fig. 16, such as a spin-$\frac{1}{2}$ system in a magnetic field where $\Delta=\mu B$. In thermal equilibrium, the probability of level i being occupied is proportional to the Boltzmann factor $\exp(-E_i/k_BT)$. At ordinary (positive) temperatures this is consistent with the usual perception that lower-energy levels are more populated than higher-energy levels, as shown in Fig. 16(a).

If, however, by some means, such as magnetic resonance or rapidly reversing the field direction, the upper level can be made more populated, then the effective temperature describing this situation would be negative, as shown in Fig. 16(b). In fact, exactly this procedure of rapidly (quasiadiabatically) reversing the field direction has demonstrated negative temperatures in silver nuclei and their ferromagnetic tendency in the *minus* 10-nK temperature range.

What was required for this description to work? The obvious requirement was that the spectrum of energy levels needed to be bounded from above. Otherwise, at negative temperatures, the levels at infinitely high energy would be infinitely occupied. This is why a classical gas with translational kinetic energy (unbounded above) cannot exhibit negative temperatures. Since energy levels are

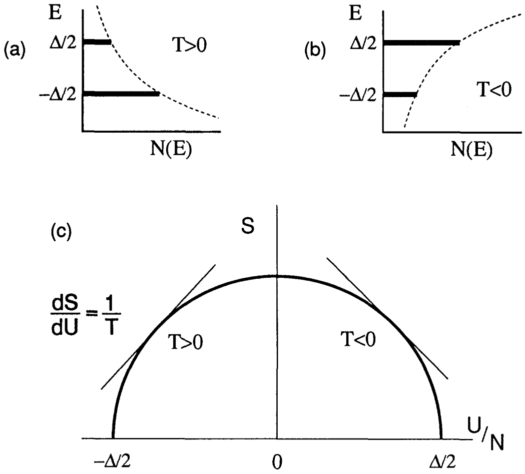

FIG. 16. Negative temperatures. The relative occupation probability of different energy levels in thermal equilibrium defines a temperature which can be (a) positive or (b) negative. In (c) the same problem is viewed from the perspective of the entropy, suggesting an alternative scale of temperature.

always bounded below, there is no converse argument against positive temperatures.

A more subtle requirement is that the system itself must be in thermal equilibrium. That is, there is a hierarchy of characteristic times that must be properly ordered. The characteristic time for the energy in the system to distribute itself thermally must be short compared to the time scale on which temperature is being defined by the experimental measurement, which in turn must be short compared to the time scale on which external influences change the system's temperature. This is analogous to the requirements given earlier for a thermometer to measure accurately the temperature of its environment.

The requirement of fast internal equilibration is somewhat obscured in the two-state example because any ratio of occupation probabilities uniquely defines some temperature, $N(E_1)/N(E_2)=\exp[(E_2-E_1)/k_BT]$. In an N-state problem, however, there are $N-1$ independent ratios of occupation probabilities, all of which must be derivable from one unique temperature if that quantity is to make sense. Given an arbitrary nonthermal disturbance of population levels, these $N-1$ ratios will not yield a unique temperature during an initial time interval before energy can be exchanged within the system.

An entirely equivalent description of negative temperatures is given in Fig. 16(c), where the entropy of the ensemble is shown as a function of its total internal energy. The derivative of this function is, by definition, the inverse of the temperature. The evolution of the temperature as a function of increasing energy can be read off easily. When the energy is minimum, the slope dS/dU is infinite, so that $T=0$. As the energy increases, the (positive) slope decreases until it reaches 0, at which point $T=+\infty$. Further increases in the energy cause the slope to decrease so that the temperature continuously evolves from $-\infty$ to -0, at which point the energy is a maximum.

This leads naturally to the frequent suggestion for an alternative scale of temperatures given by the negative slope $-dS/dU=-1/T$. This scale, called the "minus beta" scale ($-\beta=-1/k_BT$) or names equally unpoetic, satisfies the intuitive sense that it increases with increasing energy, and has the further advantages of correctly ordering negative and positive temperatures, and providing a ready answer to the question of why absolute zero is unattainable: you cannot reach infinity.

4.2 Present Ultralow-Temperature Limits

Finally, we summarize the current state of the art in achieving low temperatures. A logarithmic temperature scale showing the present limits of low-temperature technology is shown in Fig. 17. This is a dynamic field, and by the time this article appears in print some of the records listed here will be out of date. Nonetheless, here is a snapshot of the lowest records known to us as of August 1991.

The reason that there is more than one record is that for different systems there are different tradeoffs. For example, when trying to reach the lowest temperatures in a nuclear system, it is advantageous to leave the electrons at an elevated temperature to act as a larger buffer against heat leaks from the outside. The thermometers used at the end of the temperature scale here are also working at their limits, so that some revision in the reported temperatures is to be expected.

The lowest temperature achievable in a continuous mode is approximately 2 mK (Frossati, 1978). Short of mechanical failure or conscious decision to stop, this temperature could be maintained indefinitely. All of the remaining records listed use one or more stages of nuclear refrigeration, and so are intrinsically limited in duration, though, as mentioned earlier, this duration can be on the order of weeks at temperatures only fractionally above the low limit.

The lowest temperature at which a metal is known to become superconducting is 325 μK for rhodium (Buchal *et al.*, 1983) as discovered in the laboratory of F. Pobell, now at the University of Bayreuth in Germany.

In trying to establish a low temperature, both a low specific heat and low thermal boundary resistance are desirable. Dilute solutions of ^{3}He in ^{4}He do not have either of these advantages. The lowest measured temperature in these dilute mixtures is about 220 μK (Owers-Bradley *et al.*, 1983), although this measurement was limited by thermal contact to the thermometer so that the actual temperature may well be considerably lower.

Moving to ^{3}He lowers the boundary resistance, but increases the problem of high spe-

cific heat. In superfluid ^{3}He-A, with a specific heat varying as T^3, the current record is about 140 μK, while in superfluid ^{3}He-B, with specific heat decreasing faster as $\exp(-\Delta/k_BT)$, the record is just under 100 μK (Carney *et al.*, 1989). Both of these records were established at the University of Lancaster in the United Kingdom, and were measured via the quasiparticle damping of a vibrating wire immersed in ^{3}He-B. Much earlier measurements in Lancaster using a platinum NMR thermometer showed that ^{3}He-B could be cooled to about 110 μK.

Solid ^{3}He, with its much lower heat capacity for T less than 1 mK, has been cooled to about 40 μK (Takano *et al.*, 1985; Mamiya *et al.*, 1990).

Moving to metals considerably reduces the specific heat, and consequently gives the lowest achievable temperatures. Both of the groups in Lancaster and in Bayreuth have demonstrated temperatures in copper of 12 μK as measured by a platinum NMR thermometer in good thermal (i.e., electrical) contact with the copper (Gloos *et al.*, 1988).

Finally, we consider the temperature of the nuclear system in a metal. Here we gain the advantage of measuring the temperature of the actual refrigerant and not that of a material cooled by it. At the very lowest temperatures, the time constants for nuclear thermalization with the electronic system in the same block of metal can be made quite long, on the order of hours. Since the internal thermalization time within the nuclear system is much shorter, typically milliseconds, it makes good sense to define separate temperatures for the nuclear and electronic systems, even though they are physically inseparable (cf. the discussion above, regarding negative temperatures).

In copper, the nuclear ordering temperature is 58 nK. Since most of the nuclear entropy is removed in the vicinity of the transition, its cooling power rapidly diminishes, limiting the lowest temperature in copper nuclei to 30 nK, established at the Helsinki University of Technology in Finland (Huiku *et al.*, 1986). (At the same time, it should be noted that the electronic system in the same sample is maintained at about 50 μK, i.e., about a thousand times hotter.)

Silver, with much weaker nuclear interactions than copper, allows a much lower temperature to be reached. Using silver, the Helsinki group established the current nuclear low-temperature record of 560 pK (Hakonen *et al.*, 1991), 9 orders of magnitude below the bottom end of the International Temperature Scale of 1990.

ACKNOWLEDGMENTS

We wish to thank W. J. Gully, G. R. Pickett, and P. J. Hakonen for useful comments on this manuscript. Much of the research by the authors has been supported by the National Science Foundation Low Temperature Program.

GLOSSARY

Antiferromagnetism: A state of magnetic order in which alternate individual spins have opposite orientations, resulting in a reduced total magnetization.

Blackbody Radiation: Electromagnetic radiation coming from a heat source.

Carnot Cycle: A thermodynamically reversible closed cycle consisting of two adiabatic (see entropy) and two isothermal processes.

Compressor: A machine that uses mechanical energy to do work on a gas by reducing its volume.

Convective Flow: A spontaneously circulating flow caused by a gravitational instability associated with a hot, low-density fluid placed below a cold, higher-density fluid.

Counterflow Heat Exchanger: A device that allows heat to flow between two fluids that are moving in opposite directions.

Dewar Flask: Originally, a double-walled glass container with a vacuum between the walls and reflecting surfaces that provides thermal insulation. Currently applies to any well thermally insulated container. This term is often shortened to Dewar.

Dilution Refrigerator: A refrigerator that obtains cooling by diluting ^{3}He into a mixture of ^{3}He and ^{4}He.

Enthalpy: A thermodynamic potential obtained by subtracting the mechanical term ($-pV$) from the internal energy, i.e., $H=U+pV$.

Entropy: The thermodynamic variable that measures the quality of thermal energy. From a statistical-mechanics view, entropy measures the degree of disorder in a system.

Evaporative Cooler: A simple refrigerator that cools by evaporating a liquid.

Expansion Engine: The reverse of a compressor. Here, a high-pressure gas does work on a moving piston, thereby removing thermal energy.

Ferromagnetism: A state of magnetic order in which the individual spins have the same direction, resulting in a high total magnetization.

Heat Switch: A device that can interrupt heat flow. These are often made from superconducting metals, where the thermal conductivity is high in the normal state and low in the superconducting state. Other heat switches have been made from movable mechanical contacts and gas-filled containers.

Joule–Thomson Coefficient: The rate of cooling or heating caused by adiabatic (Joule–Thomson) expansion of a gas.

Joule–Thomson Expansion: An adiabatic expansion of gas through a restriction such as a small tube, a porous plug, or an adjustable valve (Joule–Thomson valve). This is a constant-enthalpy process.

Joule–Thomson Inversion Point: A temperature point in a phase diagram where the Joule–Thomson coefficient changes sign. These points depend on pressure and volume, and thus form a line in a phase diagram.

Latent Heat: The heat of vaporization or melting. This corresponds to the change in enthalpy in going from one phase to another.

Magnetic Ordering: An increase in the organization of magnetic spins as temperature is lowered. The magnetic order can be either ferromagnetic, ferrimagnetic, or antiferromagnetic and is accompanied by a reduction in the entropy.

Magnetic Refrigerator: A refrigerator that uses a magnetic material as the working substance and a magnetic field to provide the external work.

Nuclear Demagnetization: A refrigeration technique that uses the magnetic moments of nuclei at the magnetic material. (See Magnetic Refrigerator.)

Paramagnetic Material: A material that has no magnetic order.

Phonons: Lattice vibrations in a solid. Formally, phonons form a basis set to describe lattice deformations and are thus pseudoparticles.

Recuperative Refrigerator: A refrigerator that regains cooling by the use of a counterflow heat exchanger to precool returning gas.

Regenerator: Formally, an ideal heat source and sink. In heat engines, a regenerator temporarily stores heat during part of a cycle. An efficient regenerator can maintain a thermal gradient so that heat can enter and leave at a series of different temperatures.

Stirling Engine: A heat engine that follows the Stirling cycle, which is equivalent to a Carnot cycle using a gas plus a regenerator. Often, any heat engine that uses a regenerator is referred to as a Stirling engine.

Superinsulation: A highly effective cryogenic insulation made from multiple layers of aluminized polyester film. It operates in a vacuum. Frequently, the layers are spaced by a web of plastic fiber. This insulation works as an effective radiation shield because of the layers of reflective aluminum. The polyester and other plastics are poor thermal conductors. Also, the multiple layers trap any residual gas atoms or molecules.

Working Substance: The part of a heat engine that undergoes mechanical (pressure, volume, magnetization, etc.) and thermal (temperature, entropy) changes during a cycle. Typically, this is a gas, liquid, or magnetic material.

Zero-Point Motion: The minimum motion of atoms and molecules about their equilibrium position that is required by the wave nature of these particles. The energy associated with this motion cannot be removed even at $T=0$, and thus is not part of the thermal energy.

INTRODUCTION

Single crystals consist of a highly ordered atomic assembly. They can be produced in highest purity or with defined impurity (dopant) concentrations to have various important properties of scientific and technological interest. For these reasons crystals are produced in two scales: large crystals (e.g., 1.5-m-long silicon crystals) grown at industrial sites for technical applications and smaller crystals at laboratories for research (e.g., 10^{-3} m for structure analysis and 10^{-2} m for optical investigations).

Extensive study of crystal growth from solutions started in the late 19th century. Historical reviews are given by van Hook (1961), Buckley (1951), and Bohm (1985). The essential crystal-growth techniques which are used at the present time were developed between 1900 and 1960. In the last 30 years these methods have been enormously improved by the realization of control of heat, mass flow, and crystal form through electronic instrumentation. In recent years, experimental investigations of crystal-growth systems in space together with extensive numerical investigations of heat and mass flow have given sufficiently quantitative analyses of some crystal-growth systems that their state of art is now transforming to a state of science. The invention dates of the most important techniques are listed in Table 1.

In this article, the fundamentals of various growth methods of bulk crystals are emphasized with the goal of giving a general insight into the various procedures and their functions. Hence the common properties of different techniques are identified to improve understanding of particular procedures. In

addition, the advantages, disadvantages, and economic aspects of each method are pointed out. The basic physical processes of crystal growth, namely, mass transfer, heat transfer, incorporation of crystal species, and impurity segregation are undoubtedly rather complex and are therefore presented only by very simple quantitative relations. Crystallization is not considered that which is commercially applied to the production of sugar, salt, and fertilizer as reviewed by Mullin (1985). Also, electrocrystallization is ignored which is described, e.g., by Bockris and Razumney (1967).

Section 1 deals with physical and technical principles of crystal growth to the extent that they are needed to comprehend at least qualitatively the crystal-growth procedures, which consist of a controlled change of a mobile phase into a solid. The conduction of the crystal species through the fluid phase to the crystal interface by a suitable temperature field appears as the most important principle of crystal-growth processing in a monocomponent system. In a multicomponent system, change of the composition is an additional way of processing.

In Sec. 2 the basic components which are common to most crystal-growth systems are outlined. The components are essentially heat sources, fluid containers, and particular crystal environments.

The growth methods are described in Sec. 3 and are classified by the kind of mobile phase: crystal growth from the vapor phase in Sec. 3.1, from the melt in Sec. 3.2, from the solution in Sec. 3.3, and from the solid phase in Sec. 3.4. The particular techniques of each category are essentially characterized by technical aspects such as support, attachment, and geometry of fluid and crystal. Additional categories are obtained from physicochemical aspects such as the change of a temperature distribution or composition of the fluid phase (solution).

Since thin films are grown by the same physicochemical principles as those of bulk crystals, layer deposition techniques are briefly discussed in Sec. 4.

Some essential points of crystal characterization such as growth form, impurity segregation, and point, line, and two-dimensional defects are discussed in Sec. 5.

Section 6 closes the article and gives some examples of sophisticated applications of crystal-growth methods.

1. PHYSICAL AND TECHNICAL PRINCIPLES

1.1 Driving Force, Undercooling, and Supersaturation

From the view of thermodynamics, crystal growth consists of the change of a fluid phase into a solid phase which represents the crystal. The transition requires a driving force which is given by the difference in chemical potential $\delta\mu = \mu_f - \mu_c < 0$ between the species in the fluid (f) and crystalline (c) phase. Measurable thermodynamic quantities such as temperature T, vapor pressure p, and concentration C are preferred for the description of practical crystal growth. In particular,

1. the undercooling $T_m - T_c = T_m \delta\mu / H_m$ is used for a melt monosystem where T_m is the melting point and H_m the heat of fusion;
2. the supersaturation $p_f - p_c$ with $\ln(p_f/p_c) = -\delta\mu/kT$ for a vapor monosystem; and
3. the supersaturation $C_f - C_c$ with $\ln(C_f/C_c) = -\delta\mu/kT$ for a solution.

1.2 Formation of an Initial Crystal

The formation of an initial crystal is for all self-seeding techniques an important procedure. The creation of only one nucleus can be achieved by a sufficiently slow undercooling or supersaturation of the fluid in a cone or capillary. When the particular seeding area is idealized by a small circular cavity, the formation of a single seed can be explained by the thermodynamic approaches described by Sigsbee (1969) and Walton (1969). For an arbitrary cylindrical cluster of height h, the Gibbs energy of formation G_i results in

$$G_i = ivG_v + iv(\sigma_{12} + \sigma_{13} - \sigma_{23})/h + 2(\pi v h)^{1/2} \sigma_E\, i^{1/2}, \qquad (1)$$

where i is the number of cluster members; v the solid volume per monomer; G_v (<0) the difference in Gibbs energy between solid and fluid (driving force); σ the surface Gibbs interfacial energy among cluster (1), fluid (2), and wall (3); and σ_E the edge Gibbs energy. The energy G_i assumes a maximum value G_i^* at

$$i^* = -\pi h \sigma_E^2 v^{-1} [G_v + (\sigma_{12} + \sigma_{13} - \sigma_{23})/h]^{-2}.$$

The size i^* is denoted as critical since clusters smaller than i^* are unstable while those greater than i^* form growing nuclei. An increased possibility of nucleation exists for the cavity since the edge free energy σ_E is reduced through the reaction with the wall. The preferred nucleation is schematically illustrated in Fig. 1. Curve (1) represents the derivative of the interfacial energy of G_i as a function of the size i for a cluster on a plane crucible wall. Curve (2) shows the derivative for that cluster in a cavity of matching radius. For the actual cavity where the radius is in accordance with the cluster size i_c^* a nucleus is formed as soon as the driving force reaches vG_{vc}. The formation of other nuclei is unlikely since clusters of improbable sizes larger than i^* are required.

1.3 Crystal Growth

Crystal growth occurs through the transport of crystal species from the fluid phase to the crystal interface followed by incorporation of these species into the crystal. The incorporation is accompanied by chemical reactions at the surface if the fluid species differ from the structure units of the crystal, e.g., in the cases of chemical transport and associative and dissociative sublimation. In the case of a multicomponent system additional chemical reactions can happen in the fluid. When the reactions in the fluid can be ignored the three processes

1. mass transfer,
2. chemical reactions at the interface, and
3. incorporation

are sequentially coupled so that one of these determines the growth rate.

1.3.1 Mass Transfer of Crystal Species and their Incorporation. A quantitative description of the motion of fluid species is very complex since four conservation laws have to be considered—namely, conservation of momentum (Navier-Stokes), chemical species (transport), mass (continuity), and energy (heat flow). General treatments are presented by Bird *et al.* (1960), Hershey (1973), and Peube (1977). In general, mass transport controls the growth rate through volume diffusion for most multi-component systems. In comparison to a purely monocomponent fluid, here diffusive fluxes, caused by thermal (Soret effect) or concentration gradients, are superposed to the convective flux of the species as discussed by Wilcox (1971), Faktor and Garrett (1974), and Rosenberger (1979). A one-dimensional steady-state approximation for the two-component nonviscous fluid leads to the velocity

$$V_{cf}=(D/\delta)\ln[(C_t-C_{cf})/(C_t-C_f)] \qquad (2)$$

of the crystal species in the fluid, where D is the binary diffusion coefficient and C_t the total concentration, assumed to be spatially constant. The concentrations C_{cf} and C_f are those of the crystal species at the interface and at the

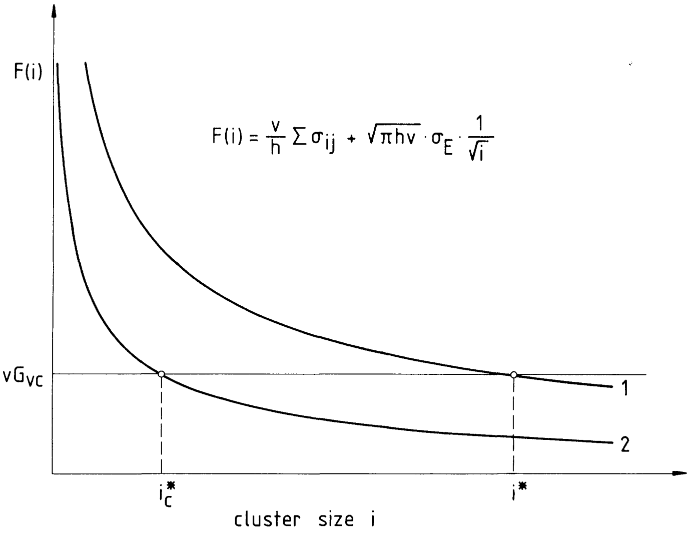

FIG. 1. Formation of an initial crystal. (See text.)

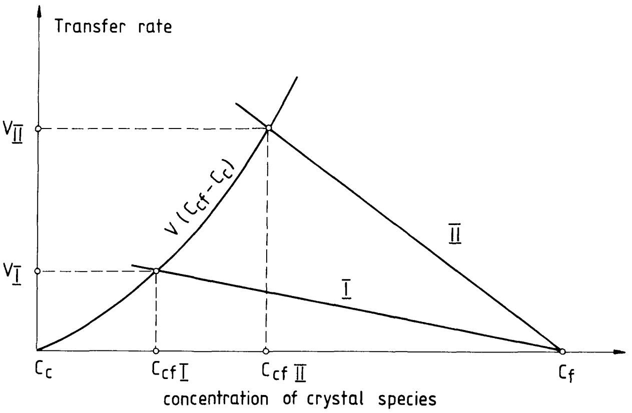

FIG. 2. Stationary crystal growth at the rates V_I and V_{II} for two different transport conditions. The mass transfer rates I and II equal the incorporation rate at $C_{cf\,I}$ and $C_{cf\,II}$, respectively. In both cases the saturation concentration difference $C_f - C_c$ is the same.

effective distance δ (see Sec. 5.2.1) from the interface, respectively. The concentration distribution, and thus the thickness δ, are strongly affected by convections resulting, e.g., from stirring, buoyancy, or tension gradients of wall-free fluid surfaces (Marangoni convection); therefore, the same total driving force $C_f - C_c$, where C_c is the saturation concentration of the crystal, can lead to different growth rates as illustrated in Fig. 2. Curve $V(C_{cf} - C_c)$ represents the surface reactions which are driven by the supersaturation $C_{cf} - C_c$. Curve I decribes the mass transfer for a convectively undisturbed flux. The intersection of the two curves determines the growth rate V_I. By pumping the fluid at a high speed towards the crystal, the effective diffusion zone δ becomes small resulting in curve II and thus in an increased growth rate V_{II}.

The growth is denoted as interfacial kinetics controlled if $C_{cf} - C_c \gg C_f - C_{cf}$ and mass transfer controlled if $C_f - C_{cf} \gg C_{cf} - C_c$. The growth rate V_c and fluid mass velocity V_{cf}, normal to the interface, are linked by the conservation relation

$$\rho_c V_c = \rho_{cf} V_{cf}\,, \qquad (3)$$

where ρ_c and ρ_{cf} are the densities of crystal and fluid, respectively, as shown by Wilcox (1971).

The interfacial processes are mainly affected by the surface structure, i.e., by the number of available bonds per approaching crystal-growth unit. The actual structure is between atomically rough and atomically smooth as schematically shown in Fig. 3. In the first case nearly every surface site has sufficient free bonds to bind an incoming growth unit, so that the growth occurs continuously normal to that interface. Rough interfaces achieve the highest incorporation rates and may appear close to the melting point or at high supersaturation as described by Jackson (1975) and Bennema and Gilmer (1973).

In most cases smooth plane as-grown surfaces are observed which run parallel to (low-

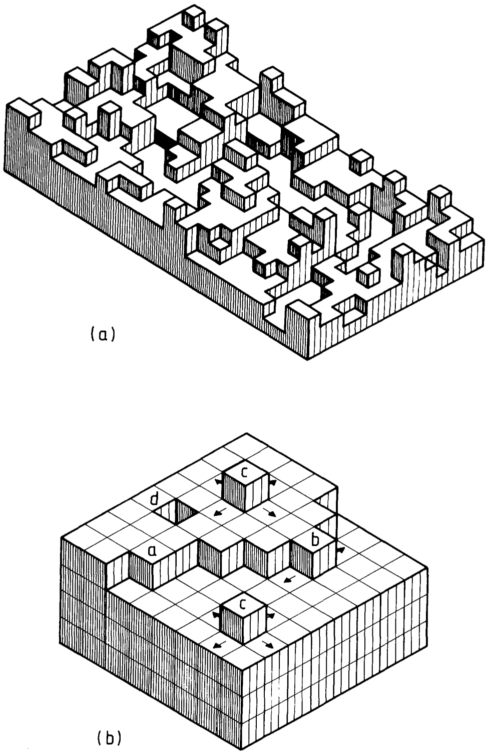

FIG. 3. Crystal surface models. (a) Rough surface. (b) Kossel-Stranski surface (Kossel, 1927; Stranski, 1928) characterized by some particularities: An atom is in a kink position (*Halbkristallage*) at *a*, at a ledge at *b*, and adsorbed at *c*. A hole (*Lochkeim*) is formed at *d*.

index) crystallographic faces (singular faces) of low surface energy. They grow layer by layer through the capture of growth units in kinks along monomolecular steps (ledges). The energy of kink formation is very low, about a tenth of the heat of evaporation, so that the growth rate is mainly determined by the creation of steps. Sources of ledges are screw dislocations (BCF theory) as discussed by Burton, Cabrera, and Frank (1951), Strickland-Constable (1968), Mutaftschiev (1980), and Chernov (1984) and two-dimensional seeds as described by Voronkov (1983). Screw dislocations continuously provide the surface with self-perpetuating spiral steps. In contrast to the free energy of a two-dimensional seed, the free energy of the first ledge winding around a screw dislocation is so low that the growth along the spiral step occurs at nearly zero driving force without observable critical behavior. In cases of growth from vapors and solutions, the kinks are mainly fed from adsorbed species so that the ledge spreading is strongly affected by the average surface diffusion length and desorption probability of the adsorbed species. At low supersaturations the distance between steps is much greater than the diffusion path and the growth rate becomes proportional to the square of the driving force. At high supersaturations the step density of the spirals becomes high and the growth rate linearly proportional to the driving force. When, in addition, heterogeneous reactions are involved the surface processes become very complex as described by Jones and Shaw (1975).

Surface nucleation models, which explain the growth of perfect crystals, lead to exponential, linear, or more complex relations between growth rate and driving force as, e.g., discussed by Brice (1973).

1.3.2 Mass Transport through Chemical Reactions. Chemical vapor transport is extensively discussed by Schäfer (1964) and Faktor and Garrett (1974). Transport of a solid in the vapor phase requires the presence of a volatile product of the solid. In the simplest case the volatile product is formed by the reaction of the solid with a gas (transporting agent), e.g., $M(s)+X_2(g)=MX_2(g)$, where M is a divalent metal, X a halogen, and MX_2 the volatile reaction product. When thermal diffusion and any kind of sublimation is excluded, the one-dimensional stationary flux J_i of the vapor species i is expressed by

$$J_i=\frac{D}{RTd}\,\frac{p^*(d)p_i(0)-p_i(d)p^*(0)}{p^*(d)-p^*(0)}\times\ln\frac{p^*(d)}{p^*(0)}, \tag{4}$$

where T is the average temperature between crystal (at the location 0) and source (at d). The average diffusion coefficient is given by

$$D=D_0(T/T_0)^n(p_0/p) \tag{5}$$

with $T_0=273$ K, $p_0=1$ Pa, $p=\Sigma p_i$ (total pressure), and $1.5 \leqslant n \leqslant 1.8$. The standard diffusion coefficient D_0 varies between 1.2×10^{-4} and 0.01×10^{-4} m^2/s. The mass velocity of the total vapor is

$$V_t=(D/d)\ln[p^*(d)/p^*(0)].$$

The stoichiometric average pressure, $p^*=\Sigma a_j p_j$, follows from the condition of insolubility ($J_j=0$) of the transporting agent j in the solid. The coefficients a_j are the stoichiometric ones of the gaseous transport agent compounds j. Transport of species i occurs from hot to cold places for

$$p^*(d)p_i(0)>p_i(d)p^*(0)$$

and from cold to hot for

$$p^*(d)p_i(0)<p_i(d)p^*(0).$$

In the example $M(s)+X_2(g)=MX_2(g)$ one has $D=D_1=D_2$, $p_1=p_{X2}$, $p_2=p_{MX2}$, and $p^*=p_{X2}$.

1.3.3 Heat Transfer into the Crystal. The balance of heat at the crystal interface leads to a quantitative description of crystal growth. In the case of growth in one dimension x the crystal-growth rate becomes

$$V_c=[k_c(dT_c/dx)-k_f(dT_f/dx)]/(\rho_c H_c), \tag{6}$$

where k_c and k_f are the heat conductivities, dT_c/dx and dT_f/dx the temperature gradients of crystal (c) and fluid (f), ρ_c the crystal density, and H_c the heat of phase transition. When A is the cross section of crystal and fluid, $Ak_f(dT_f/dx)$ is the heat transfer rate from the fluid into the crystal, and $Ak_c(dT_c/dx)$ the heat removal rate from the crystal. Most of the crystal-growth procedures consist of controlling these rates. A complete heat-flow description of a crystal fluid system leads to the Stefan problem as described, e.g., by Parker (1970) and Crank (1988).

1.3.4 Growth Rates from Theoretical Models. Maximum crystal-growth rates for a monocomponent system can be estimated from basic physical relations.

1. For the melt, from the Wilson-Frenkel relation

$$V = a\alpha \exp\left(-\frac{H_0}{RT_c}\right)\exp\left(-\frac{H_m}{RT_m}\right) \times\left[1-\exp\left(-\frac{H_m}{R}\frac{T_m-T_c}{T_m-T_c}\right)\right], \tag{7}$$

where a is the interatomic distance (10^{-10} m), α the lattice vibration frequency (10^{13} Hz), H_0 the activation enthalpy of self-diffusion in the melt as discussed by Jackson (1975), H_m the heat of fusion, R the gas constant, T_m the melting point temperature, and T_c the temperature of the crystal.

2. For the vapor, from the Hertz-Knudsen relation

$$V = \frac{M_f}{\rho_c(2\pi M_f RT_c)^{1/2}}(p_f-p_c), \tag{8}$$

if every atom is incorporated which hits the (rough) interface. In this expression, M_f is the molar mass of the vapor, ρ_c the density of the crystal, p_f the vapor pressure in front of the crystal interface, and p_c the saturation pressure of the crystal.

3. For the vapor in a cylindrical ampoule with interfacial equilibrium, from the Hagen-Poiseuille relation

$$V = \frac{M_f a_d^2}{16\rho_c \eta LRT}(p_f^2-p_c^2), \tag{9}$$

where η is the dynamic viscosity, a_d the ampoule diameter, p_f the vapor pressure of the source, L the distance between crystal and source, and T the average temperature of crystal and source.

4. For the vapor with an additional inert component A, from

$$V = \frac{M_{fc}D}{\rho_c LRT}\ln\left(\frac{p_t-p_c}{p_t-p_{fc}}\right), \tag{10}$$

where M_{fc} is molar mass of the crystal species of the vapor phase, D the binary diffusion coefficient defined in Eq. (5), $p_t=p+p_A$ the constant total pressure, p_{fc} the partial vapor pressure of the crystal vapor species at the distance L in front of the crystal, and T an average temperature.

Growth rates described by the relations (7)–(10) are shown in Fig. 4.

1.4 Principles of Crystal-Growth Procedures

1.4.1 Crystal Growth in Monocomponent Systems. In monocomponent systems, crystal growth is generally forced by adjusting a temperature distribution across the interface in such a way that heat is continuously flowing from the hotter fluid into the colder crystal. The growth rate is essentially determined by the rate of heat flow according to Eq. (6). Continuous growth in one direction toward the fluid is maintained by two principal techniques:

1. A temporary constant temperature distribution is slowly shifted toward the fluid by moving the crystal or in a few cases by the moving of the heater.
2. The container and heater are kept in a fixed

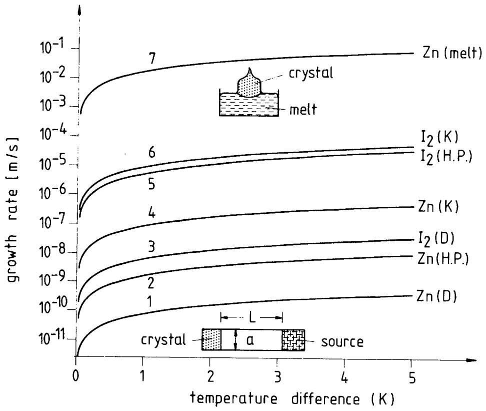

FIG. 4. Various growth rates from theoretical models for different monocomponent systems as a function of undercooling. *Curve 7:* Growth of Zn from the melt according to Eq. (7), H_0 = 21.31 kJ/Mol (from Ramachandrarao, 1978). *Curves 1–6:* Crystal growth rates of Zn and I_2 from vapor phase as a function of temperature difference between source and crystal. The parameters are T_c = 410 °C, $D_0=10^{-5}$ m²/s for Zn, and T_c=40 °C, $D_0=5\times10^{-6}$ m²/s for I_2. The common parameters are L=0.15 m, $a=2\times10^{-2}$ m, η = 2×10^{-4} P, and P_A = 133 Pa. Curves 1 and 3 represent Zn and I_2 crystal growth by diffusion through argon according to Eq. (10). Curves 2 and 5 represent crystal growth of Zn and I_2 by a pure viscous flow according to Eq. (9). Curves 4 and 6 represent Zn and I_2 incorporation according to Eq. (8).

position while the temperature of the heater is slowly lowered.

In a few cases crystals are isothermally grown from supercooled melts by extremely slow cooling rates as described by Scheffen-Lauenroth *et al.* (1981).

The shape or the temperature distribution of the fluid near the interface affects the stability of the interface, particularly if the fluid contains impurities or dopants. The possibility of parasitic nucleation is reduced by a strong normal temperature gradient through superheating the fluid in front of the interface.

1.4.2 Crystal Growth in Multicomponent Systems. In principle, the methods for crystal growth from a monocomponent system (melt) can be transferred to a multicomponent system. In that case the drive rates have to be reduced by a factor between 10^4 and 10^5 since the growth rate is essentially determined by the mass transfer according to Eq. (2) or by surface reaction kinetics.

In addition to the selection of the temperature, the choice of fluid composition is possible. Hence crystal growth can be carried out under isothermal conditions. Four principal isothermal procedures may be employed:

1. slow cooling (or heating) of the fluid-crystal system;
2. slow enrichment of the fluid with crystal species, e.g., by evaporation of the solvent or by injection of an additional fluid;
3. continuous supply of a supersaturated nutrient into the isothermal environment of the crystal (temperature difference technique); and
4. decomposition or heterogeneous chemical reaction in an isothermal environment.

1.5 Selection of Crystal-Growth Method

The choice of crystal-growth method depends on

1. external aspects such as desired size, shape, purity, doping, and perfection of the crystal;
2. economics;
3. available equipment; and
4. thermodynamic behavior.

The thermodynamic properties such as structural change below the melting point, peritectic reaction, decomposition, sublimation, reaction of the melt with the environment, and solubility in a suitable solvent exclude or indicate the applicability of a particular fluid and therefore determine the growth method.

In particular, the structural change limits heating to below the transition temperature so that solvents, reactive vapors, or eventually sublimation have to be employed. If an incongruent melting compound A_mB_n, e.g., forms solid A and a liquid at the peritectic temperature T_p, then crystals of A_mB_n can be grown below T_p from a solution which is obtained from a relevant mixture of B and A_mB_n. Materials which decompose into one or more (e.g., into two in the case of CdS) volatile components can be grown from the melt in closed containers or by encapsulation in a suitable liquid. Crystal growth through sublimation is possible at reasonable rates for vapor pressures higher than 100 Pa.

2. BASIC COMPONENTS OF CRYSTAL-GROWTH EQUIPMENT

2.1 Containers

In most crystal-growth methods containers are used to hold the fluid. Commercially available containers are often made of fused silica, sintered alumina, graphite, tungsten carbide, platinum, and iridium. It is necessary that the container material does not contaminate the fluid and does not react with the ambient atmosphere. In addition, when the crystal reacts with the crucible wall, the contact between crystal and wall must be prevented. For many substances these conditions of compatibility are hard to fulfill.

The principal designs of containers can be classified as regular crucibles, boats, tubular crucibles, and ampoules as shown schematically in Figs. 5(a), 5(b), 5(c), and 5(d), respectively.

2.2 Heating Apparatus

2.2.1 Resistance Heater. Resistance furnaces are employed for the heating of fluids; therefore, most heaters consist of tubes which closely surround the crucibles or ampoules. Ceramic tubes wound with NiCr or AlFe alloy wires and SiC resistor tubes are commonly

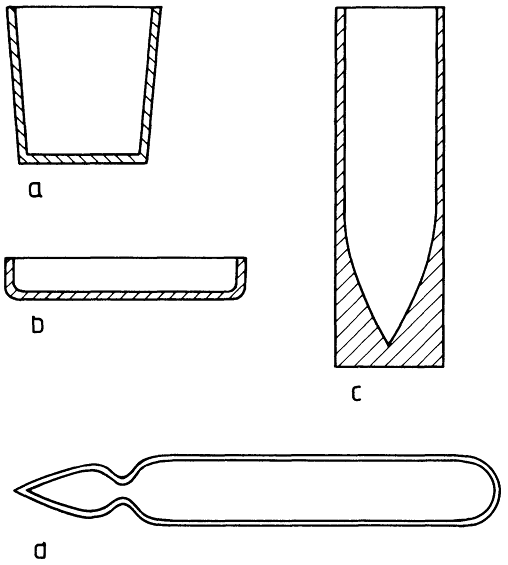

FIG. 5. Principal container designs for crystal growth. (a) Regular crucible, (b) boat, (c) tubular crucible, and (d) ampoule.

used in air. They are enclosed in an insulating housing to reduce the heat loss. Lengthwise-sliced cylinders of graphite or high-melting metals surrounded with metallic heat shields are preferred in oxygen-free equipment. Distinct temperature distributions are obtained through separate heating elements along the furnace axis. Chamber furnaces are mainly employed for growing crystals from high-temperature solutions through slow cooling. The available temperature of a resistance furnace depends on the corrosiveness of the ambient atmosphere. Temperatures up to 1800 °C can be reached in air with rhodium or $MoSi_2$ heaters. In vacuum and noble gases, temperatures up to 3000 °C are obtainable with tungsten, while in nitrogen, noble gases, and vacuum, graphite can be heated up to 2600 °C.

Advantages: Except those with noble-metal wiring, resistance furnaces have a low initial cost. Their temperature can be easily controlled. *Disadvantages:* In general, a desirable high temperature gradient cannot be achieved.

2.2.2 Induction Heater. An induction heater consists of a water-cooled copper coil which is supplied with an alternating voltage at a frequency between 100 kHz and 13.6 MHz. A body within the coil is heated by an induced current if the electrical conductivity of the body is sufficiently high and if the distance between coil and body is sufficiently small. Thus conductive fluids can be directly heated without using a container. Metal and graphite crucibles as well as any appropriately shaped conducting part (susceptor) can be inductively heated, while the surrounding wall can be kept cool with water [Fig. 6(a)]. Moreover, direct heating of a corrosive fluid is possible in a cold-wall boat [Fig. 6(b)], obtained by indenting a copper tube, or in a cold-wall crucible [Fig. 6(c)] described, e.g., by Aleksandrov *et al.* (1978). In both cases the melt is held by a shell which is formed between melt and crucible.

Advantages: Inductive heaters offer the possibility of directly heating the fluid and susceptors at higher temperatures than those which can be reached with resistance heaters. *Disadvantages:* High-frequency generators have a high initial cost, high consumption of cooling water, and difficulty in making an efficient power transfer.

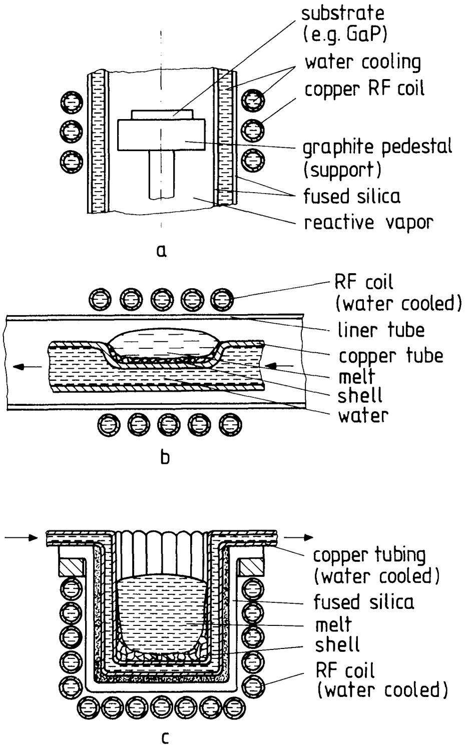

FIG. 6. Cold-wall heating designs. (a) Substrate heating enclosed in a cold-wall tube. (b) Cold-wall boat. (c) Cold-wall crucible.

2.2.3 Other Heat Sources.

The temperature of flames is difficult to control. They are used for the Verneuil method only.

Very high temperatures at an optimal efficiency can be obtained by electron bombardment; its application is preferred for floating-zone crystallization of conductive materials with a high melting point and low vapor pressure, as reviewed by Shah and Wills (1975). In the simplest assembly the fluid acts as an anode which is surrounded by a negative tungsten glowing filament. The method requires a vapor pressure less than 10^{-2} Pa of the environment and material. Insulating materials can be bombarded using a water- cooled slitted-ring anode.

Pure optical radiation is suitable for formation of molten zones in nonmetallic rods. The highest temperatures can be obtained by irradiation with a CO_2 laser beam. The light from the filament of a halogen lamp or arc of a xenon-tungsten lamp can be transferred by imaging with elliptical reflectors.

Heat pipes consist of a closed double-wall cylinder. The space between the walls is partly filled with a liquid. Heat is steadily transferred by boiling the fluid at some points and condensing it at others by placing the tube in a resistance furnace. Heat pipes provide an extremely spatially constant temperature distribution. Detailed descriptions are given by Chisholm (1971) and Winter and Barsch (1971).

Fluid baths are preferred for heating or cooling of tanks used for crystal growth from low-temperature solutions. The baths are heated with immersed resistance elements.

Other heating methods such as gas discharge arcs and plasmas are of minor importance. They have been reviewed by Shah and Wills (1975).

2.3 Temperature Control

To grow high-quality crystals and films it is very important to provide fluid and crystal with a temperature distribution according to a prescribed function of time. This is achieved with commercially available closed-loop control systems (personal computer). In general, the input function of the control system is a voltage which results from the difference between prescribed (set point) and measured (actual) temperatures. Temperature sensors are usually thermocouples. Platinum resistors and thermistors are frequently used at low temperatures ($<200\,^\circ C$) and pyrometers at very high temperatures ($>1500\,^\circ C$). The output function of the controller is a voltage which drives the power of the heat source, e.g., the current of the resistance element through a thyristor or the power of a high-frequency generator through the gate of the oscillation tube.

2.4 Growth-Rate Control

Growth-rate control is required for optimal crystal perfection and dopant distribution. With respect to process parameters (input functions), which can be varied during processing, the growth systems can be classified into two groups: (1) systems which are driven with one input function and (2) those with several input functions.

1. When only one input function is needed, the control of growth rate is reduced to control of that function (open-loop system). For optimal operation the functional relation between input and crystal shape have to be known. In all cases the input rates have to stay below a critical amount to prevent degeneration of the crystal interface. Bridgman, liquid-zone, and Pizzarello techniques are examples where the input is the displacement velocity between the temperature distribution and the fluid. These systems are approximately linear when the crystal grows at a constant diameter and can be described by the governing equation

   $$\beta d(t) = a(t) + \tau \frac{da(t)}{dt}, \tag{11}$$

   where $\beta \approx 1$ is the transition factor describing the temperature change through the crystal, $d(t)$ the input function (ampoule displacement), $a(t)$ the response (crystal length), and τ the time constant. The relaxation time is a function of kinetics, mass, and heat transfer. Figure 7 shows solutions of Eq. (11) for a ramp input.

   Other examples of linear behavior are solvent evaporation, where the input function is the evaporation rate, and solution cooling (with a linear relation between saturation and temperature) where the input is the cooling rate. Both systems are approximately linear when the rate of crys-

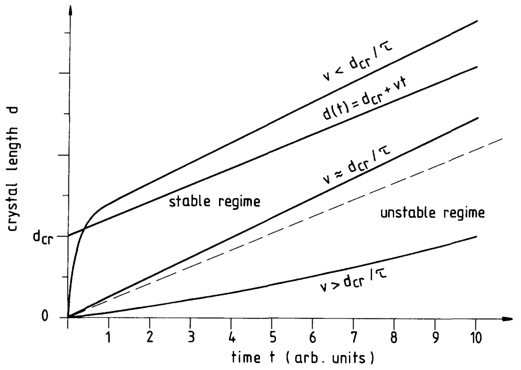

FIG. 7. Crystal lengths in response to different drive rates v as functions of time, according to Eq. (11), using the ramp function $d(t)=d_{cr}+vt$ as an input function. The drive length d_{cr} determines the critical undercooling of seed formation. Crystal growth degenerates for too high drive rates $v>d_{cr}/\tau$.

tallized mass is considered as the response. The growth rates are therefore monotonic and not constant for constant input rates.

2. For complex systems with more than one input possibility, closed-loop systems (or the skill of the crystal grower) have to be applied, where the shape of the crystal is measured and compared with a prescribed one. The Czochralski method is an example where the change of the melt temperature and pulling rate are two independent input functions. Two types of sensors, namely, a video camera for measuring the crystal diameter [described by Draper (1975)] and a balance for weighing the crucible [described by Bardsley *et al.* (1977) and Mecseki *et al.* (1987)], are preferably employed. The signals of the sensors are used to control the heating rate at a prescribed pulling rate.

2.5 Environment

The environment around the crystal and fluid may have different purposes:

1. to prevent contamination of the crystal, e.g., by oxidation,
2. to protect the laboratory from poisoning,
3. to reduce evaporation of the fluid, and
4. to stabilize decomposing compounds.

In most cases the crystal-fluid assembly is therefore enclosed in a modified housing which can be supplied with vacuum, static, or flowing high-purity inert gas. From the kind of heating design two types of housings can be classified: hot wall and cold wall. The hot-wall housings are heated by a resistance furnace from the outside. They are generally simple in design, i.e., consist, e.g., of sealed silica ampoules. Cold-wall housings are either heated inductively from the outside or enclose (in a more or less sophisticated manner) the heating elements.

The purest available environment is a vacuum. It can be applied to techniques of crystal growth from the melt if the vapor pressure of the melt is sufficiently low.

Slight evaporation of the fluid from open crucibles is reduced through heavy ambient inert gases (N_2, Ar, and Kr) at pressures of about 10^4 Pa. Strong evaporation of fluids at pressures $> 10^4$ Pa can be suppressed by covering the fluid with an inert liquid and applying a sufficiently high ambient gas pressure. The liquid must be of a lower density than that of the fluid and must also adhere to the crucible and crystal.

The decomposition of a fluid A_mB_n into a liquid phase and vapor component B [e.g., $2Li_3N(l)=6Li(l)+N_2(g)$] is prevented through an excess vapor of B (e.g., N_2 atmosphere).

3. TECHNIQUES OF CRYSTAL GROWTH

3.1 Techniques of Crystal Growth from the Vapor Phase

3.1.1 Pizzarello Method. A fused silica ampoule is supported with source material either together with a transport agent or a high vacuum ($<10^{-2}$ Pa), then sealed off and hung in a vertical two-zone furnace. The growth method, reviewed by Schönherr (1980), is illustrated in Fig. 8. The upper end of the ampoule is distinctly shaped with a pointed tip and a neck [Fig. 9(a)] or capillary [Fig. 9(b)] for seeding. Starting with the upper seeding end in the middle of the upper heating zone (Fig. 8), the ampoule is slowly ($\approx 2\times 10^{-8}$ m/s) pulled upwards so that the upper end becomes cooler than the source. After a crystal is formed its growth velocity matches the drive rate after an initial high speed as shown in Fig. 7.

The mounting of a seed is possible in similar designs as illustrated in Fig. 9(c).

According to Eq. (10), small amounts of an impurity vapor reduce the mass transfer rate

dramatically. Foreign vapors are removed by using "almost-closed" crucibles with a small hole ($\approx 0.1 \times 10^{-3}$ m) [Fig. 10(a)], or with self-sealing ends [Fig. 10(b) and 10(c)] which are enclosed in an evacuated tube as described by Faktor and Garrett (1974). In particular, partial pressures of materials which dissociate into two vapor components [e.g., $2CdS(s) = 2Cd(g) + S_2(g)$] can be adjusted to the stoichiometric ratio through almost closed ampoules.

Advantages: The Pizzarello technique is achieved with low-cost equipment. The easy processing only requires a constant temperature distribution and a constant drive rate. High crystalline perfection and high chemical purity usually result. *Disadvantage:* The crystals grow at low rates of about 10^{-8} m/s.

3.1.2 Temperature Gradient Technique. This technique is used for growing large crystals from the vapor phase at low temperatures ($\approx 120\,^{\circ}C$), e.g., HgI_2 crystals as described by Kaldis *et al.* (1987). The principle of the method is shown in Fig. 11. A seed crystal is mounted on a coolable pedestal at temperature T_c in the center of a cylindrical, evacuated, sealed glass container. The source material initially deposited at the upper part of the container wall is held at a temperature T_s higher than T_c of the pedestal. A heating ring at the bottom at a temperature T_r higher than T_s of the source prevents parasitic nucleation on the container bottom and pedestal wall. Crystal growth is forced by lowering the bottom temperature T_r while the pedestal T_c and source temperature T_s are kept constant.

Advantages: The low-cost equipment offers the possibility of growing crystals with high crystalline perfection and high chemical purity. A seed crystal may be easily supported. Although low linear growth rates of 10^{-8} m/s result, a large total crystalline mass is condensed because of radial growth. *Disadvantage:* The processing is rather complicated since a variation of source and crystal temperature are required to control the crystal growth.

3.1.3 Temperature Difference Technique. For synthesis of new compounds through chemical vapor transport, an ampoule is filled with source material together with an appropriate reaction agent and sealed at sufficiently low pressure. Then the nutrient is distributed at one end of the capsule. After that procedure the ampoule is placed in a horizontal two-zone furnace which heats the ampoule ends to different constant temperatures. The furnace is tilted slightly to increase the fluid velocity by gravitational convection. Numerous small crystals are formed opposite the source since no single distinctly supersaturated small area can be achieved.

Advantage: The technique needs very low-cost equipment only. *Disadvantage:* A single crystal cannot be achieved.

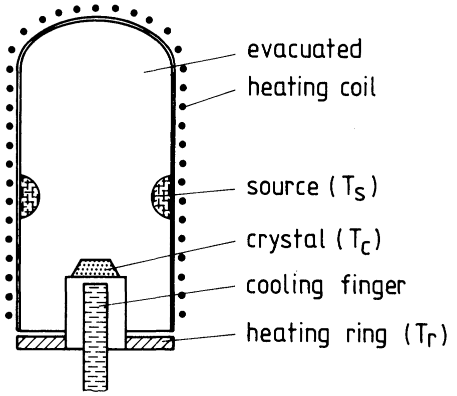

FIG. 11. Design of a closed vessel for crystal growth from vapor phase. (See text.)

3.2 Techniques for Crystal Growth from the Liquid Phase

3.2.1 Czochralski Technique. The modern Czochralski technique (Fig. 12) results from the ideas of Nacken (1915), Czochralski (1918), and Kyropoulos (1926). The primary steps are

1. the melting of the source material in a crucible,
2. the preheating of a seed by holding it close above the melt,
3. touching the melt with the seed,
4. slight backmelting of the seed to achieve coherent growth,
5. pulling of the seed with decreasing diameter (necking) to reduce or eliminate structural faults (e.g., grain boundaries and dislocations) of the seed, and
6. pulling with increasing diameter until the desired radius is reached. The crystal shape is controlled by variation of the melt temperature and pulling rate. The crystal and crucible are rotated in opposite directions at 5–40 rpm to achieve a radially symmetric temperature distribution.

Quickly evaporating materials can be crystallized by the liquid-encapsulation technique where the melt is covered with a suitable liquid and the vessel filled with an inert gas of sufficiently high pressure. The Czochralski technique is also employed for growing crystals from solution, as described by Elwell and Scheel (1975).

Advantages: Fast crystal-growth rates of between 10^{-6} and 10^{-5} m/s are attainable. Very large crystals (e.g., silicon 2.2 m in length and 0.16 m in diameter) can be grown. Crystals of highest perfection (e.g., dislocation-free silicon) can be obtained. *Disadvantages:* Medium- to high-cost equipment is required.

The crystal growth has to be continuously controlled since the heat-flow conditions change with crystal length.

3.2.2 Bridgman Technique. In the Bridgman method, crystallization of a melt is carried out in a boat [Fig. 5(b)], vertical tubular crucible [Fig. 5(c)], or ampoule [Fig. 5(d)]. Tubular containers are designed with a seeding end at the bottom similar to that shown in Figs. 9(a) and 9(b), while boats can have a seed installed at one end [Fig. 13(a)]. Figure 14 displays the principle of the vertical technique. The container is initially hung in the upper hot zone of a furnace for complete melting of the source material. Then the crucible is moved down into the cooler furnace zone, where an initial nucleus is formed in the seeding end. The growth of the nucleus is achieved by a sufficiently low drive rate. Alternatively, the heater can be moved while the container is held in a fixed position. Quickly evaporating materials can be processed in closed hot-wall containers (Fig. 14). Decomposition of a compound which forms a volatile constituent B can be prevented by an excess of B in a closed container at a sufficiently high wall temperature. Crystals of lower density than that of their melt (e.g., Ge) are processed in horizontal boats with a trapezoidal cross section where the upper side is greater than the bottom side.

Advantages: In general, low-cost equipment is sufficient. Medium growth rates between 10^{-7} and 10^{-6} m/s are reached. The processing is very simple, since it employs a constant temperature distribution and constant drive rate. The method offers the possibility of

1. crystal growth from solution, e.g., growth of peritectically melting compounds,

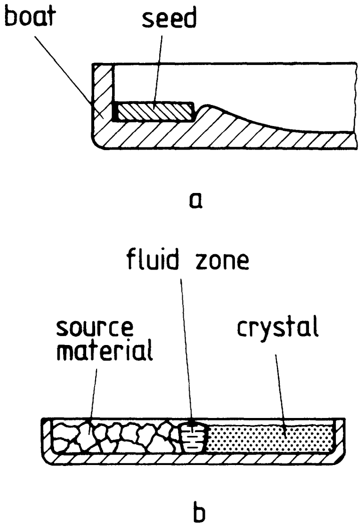

FIG. 13. Use of a boat for zone melting. (a) Seed mounting. (b) Crystal-growth method.

2. crystal growth of volatile or decomposing materials, and
3. doping with volatile elements.

Disadvantage: Dislocations may be formed if the thermal expansion of the container differs from that of the crystal.

3.2.3 Temperature Gradient Technique. The temperature gradient technique is, in principle, a modified vertical Bridgman method, where the crucible is always maintained at an initially fixed position in a particular furnace. The temperature of the heater locally decreases from the upper crucible part to the seeding end. Nucleation and crystal growth is forced by slow cooling of the furnace while the slope of the temperature distribution stays approximately constant.

Advantage: No movable mechanical parts are required. *Disadvantages:* The disadvantages are the same as those of the Bridgman techniques.

3.2.4 Liquid-Zone Techniques

3.2.4.1 Liquid-Zone Techniques with Crucible. The liquid-zone techniques are very similar to those of Bridgman with one difference: Only a small portion [Fig. 13(b)] of the source material is melted by heating with a short resistance oven or a short induction coil around the container. Crystal growth is achieved by driving the fluid zone from the seeding end to the opposite end by moving the container or heater. The method is widely applied for material refining through the use of a multi-heating-cooling zone assembly.

Advantage: A nearly constant (macroscopic) doping distribution may be obtained as shown in Fig. 22 (Sec. 5.2.2). *Disadvantages:* The disadvantages are the same as those of the Bridgman techniques.

3.2.4.2 Floating-Zone Methods. In the floating-zone techniques the melt hangs on a vertical feed rod (or crystal) and is supported by the vertical crystal (or feed rod) below without use of a container. The zone is achieved by heat sources, modified for particular materials as described in Sec. 2.2.3. The liquid is held in position by the surface tension σ which compensates for the weight. The resulting maximum crystal radius is given by

$$r_{\max}=0.92\sigma^{1/2}(\rho_f g)^{-1/2}, \tag{12}$$

where ρ_f is the density of the melt and g is the acceleration due to the gravity, as described by Brice (1965). The method is mainly applied to industrial production of silicon crystals of low oxygen content (Sec. 6.2).

Advantages: The method provides the fluid and crystal with the purest environment. The highest growth velocities (e.g., 10^{-4} m/s for silicon) can be achieved. *Disadvantage:* A

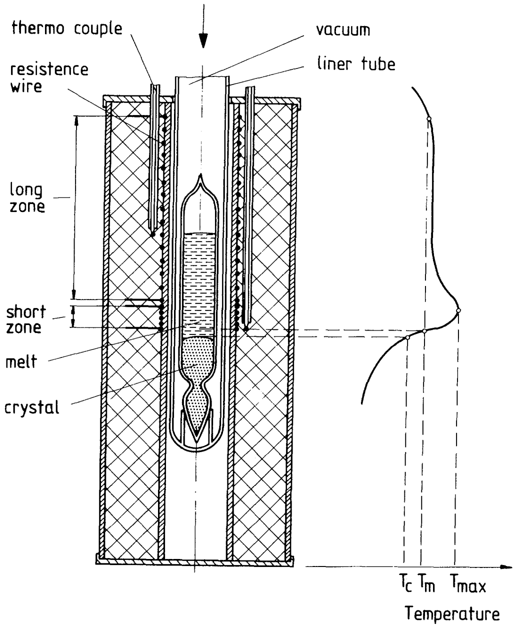

FIG. 14. Vertical Bridgman apparatus.

complex growth control is required by setting power, movement rate, and zone length. A suitable temperature distribution has to be applied for sufficient structural perfection.

3.2.4.3 Verneuil Technique. The Verneuil technique, described, e.g., by Falkenberg (1978), consists in passing powdered source material through a flame downwards to the top of a crystal on which a thin molten feeding zone is formed by the heat of the burner (Fig. 15). Crystal and flame are surrounded with an insulating ceramic tube to reduce heat loss. Oxygen and powder [(60–125)$\times10^{-6}$ m in diameter] are conducted through the center tube and hydrogen is passed through the outer tube. The powder chamber is divided by a fine-mesh screen into an upper large part which contains the powder source and a lower tapered part through which oxygen is conducted. The powder is mixed with the oxygen flow through the screen by tapping the chamber at a frequency of about 45 taps/min. Crystal growth from the thin molten zone is achieved by lowering the crystal while preserving the distance to the burner. Higher temperatures than those of a oxygen-hydrogen burner are obtained with an induction-coupled plasma as reviewed by Brice (1973) and Laudise (1970).

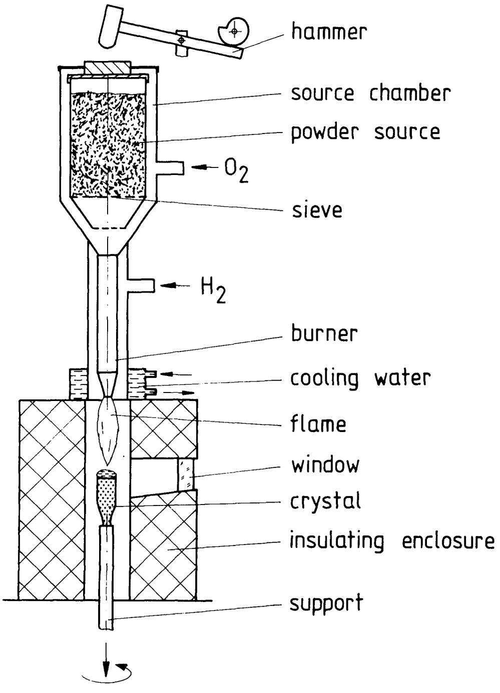

FIG. 15. Verneuil technique.

Advantages: Only low-cost equipment is needed for crystal growth of high melting oxides at temperatures below 2800 °C. *Disadvantages:* The heat control of the burner is difficult. The growth control is complicated, requiring variation of powder supply and crystal movement.

3.3 Techniques of Crystal Growth from a Solution

3.3.1 Solvent Evaporation. In general, a solute crystallizes from a solution at the container wall by slow evaporation of the solvent. A single crystal can be grown if one of the deposited crystals is selected and suspended in that (saturated) solution. The solvent evaporation is controlled by effusion through a hole in the closing top plate. The method requires a solvent whose vapor pressure is much greater than that of the solute. Therefore, the procedure is mainly restricted to low-temperature solvents, e.g., water. The technique is improved by temperature control, stirring, and feedback of the solution. Feedback is achieved by placing a sieve plate together with solute material between the top plate and the solution surface. The evaporating solvent condenses at the cooled top plate, flows back, and is saturated by solute material on the sieve.

Advantages: The method can be carried out with equipment of lowest cost. Large crystals can be grown by very simple processing. *Disadvantages:* The reachable growth rates are low (10^{-9}–10^{-7} m/s) and the optimum growth rate is difficult to control.

3.3.2 Temperature Difference Techniques

3.3.2.1 Normal Solution Conditions. In the temperature difference techniques a saturated aqueous solution, together with a great excess of solute material (nutrient), is maintained in a tank at the temperature T_s. The solution is continuously pumped through pipes to a second tank and back to the source tank. To grow a crystal the temperature T_c of the second tank is held lower than that of the source tank. The principle of the method is illustrated in Fig. 16. Here, in addition, the saturated solution first passes an overheated tank at the temperature T_u on the way to the

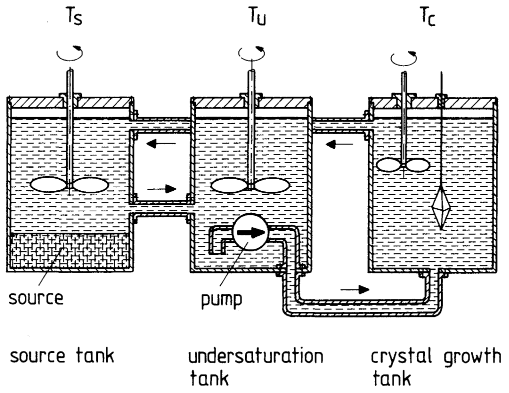

FIG. 16. Three-tank technique for growth of large ADP ($NH_4H_2PO_4$) crystals from aqueous solution, after Walker and Kohman (1948).

growth tank. Thereby residual floating nuclei of the source solution are dissolved.

Advantages: Isothermal crystal growth can be achieved at a constant supersaturation $C(T_s)$–$C(T_c)$. The growth rate is easily controlled by adjusting the temperatures. *Disadvantages:* The attainable growth rates are low (10^{-9}–10^{-7} m/s).

3.3.2.2 Hydrothermal Solution Conditions. Aqueous solutions under hydrothermal conditions (i.e., at temperatures higher than 100 °C and pressures greater than 10^5 Pa) are industrially applied to the growth of β-quartz crystals. The method requires a high-pressure autoclave as, e.g., described by Laudise (1970) and depicted in Fig. 17. The autoclave, of special steel (up to 1 m in diameter and 4 m in length), contains in the lower part a grit of natural quartz as source material (nutrient) and in the upper part suspended single-crystalline quartz seed plates. Nutrient and crystals are separated by a baffle plate with a small opening (5%) to reduce convective instabilities. For crystal growth the nutrient is held at 400 °C and the crystals at 380 °C (temperature difference technique). An 80% (at room temperature) filling with water results in a pressure of about 1.4×10^8 Pa. The solubility of quartz is increased by adding NaOH. A growth rate of 10^{-8} m/s is obtained with a 1.0 M NaOH solution. A review of hydrothermal synthesis of other materials is given by Rabenau (1985).

Advantages: Low-cost equipment is sufficient for synthesis of small crystals of new materials. *Disadvantages:* The costs for safe processing increase enormously with increasing autoclave volume.

3.3.3 Techniques with Gel Media. Most kinds of fine-crystalline precipitation in solutions at room temperature can be directed to single-crystal growth by precipitation in a gel as described by Henisch (1988) and Arora (1981). The possible chemical processes are, e.g., the formation of a reaction product, reduction of a compound, decomplexing of complex compounds, or outsalting. Water glass (sodium metasilicate solution), agar (carbohydrate polymer), and gelatin (protein) are the most commonly used gels which sufficiently reduce the nucleation frequency.

Figure 18 shows two principles of reaction-product precipitation in a silica hydrogel. The gel is prepared from Na_2SiO_3, H_2O, and a suitable acid at a *p*H value between 6 and 8. In Fig. 18(a) the gel contains the acid (here 2 M $C_4H_6O_6$) as one reactant. The other reactant (here 1 M $CaCl_2$) is dissolved in water which is placed above the set gel. Crystals of the solid reaction product (here $CaC_4H_4O_6$) are formed in the gel. In the U-tube method [Fig. 18(b)], the gel contains a minimal amount (here 0.2

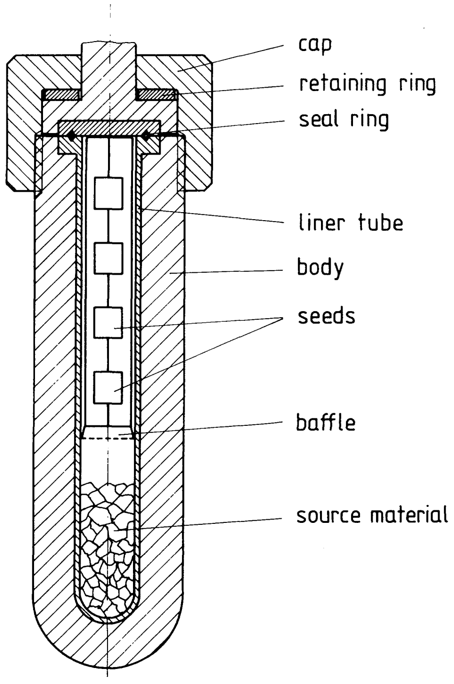

FIG. 17. Autoclave for quartz growth under hydrothermal conditions.

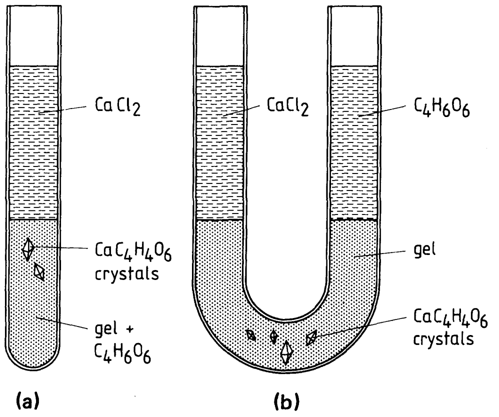

FIG. 18. Crystal growth in gel.

M $C_4H_6O_6$) of acid, which is sufficient forsetting. The reactants (here 1 M $CaCl_2$ and 2 M $C_4H_6O_6$) are placed on opposite sides of the set gel.

Advantages: Crystal growth in gels is one of the cheapest methods. *Disadvantages:* The attainable growth rates are very low (10^{-9}–10^{-8} m/s) and crystals above 10^{-2} m are hard to obtain.

3.3.4 Slow-Cooling Techniques. Growth of crystals by slow cooling is widely applied with aqueous, metal, and fluxed melt solutions. Tanks of glass enclosed in fluid baths and equipped with stirrers, and rotatable seed holders are used for aqueous solutions. Molten salt solvents with fluoride constituents are mainly employed for growth of oxide crystals. Detailed descriptions are given by Elwell and Scheel (1975) and Wanklyn (1975). High-temperature solutions are contained in crucibles of noble metals (platinium, iridium, etc.). They are sufficiently closed to release the pressure without noticeable solvent evaporation. The growth procedure is composed of several steps and illustrated in Fig. 19, where $LiAlSiO_4$ is used as a typical example.

1. The procedure is started by slowly heating (e.g., at 50 °C /h) the source materials in a chamber furnace to the soaking temperature T_{soak}. This temperature is preset 20–50 °C above the saturation temperature T_i.
2. The soaking temperature is held between 2 and 24 h for complete dissolution.
3. Then follows a fast cooling (e.g., at 100 °C /h) to the initial cooling temperature T_i, and

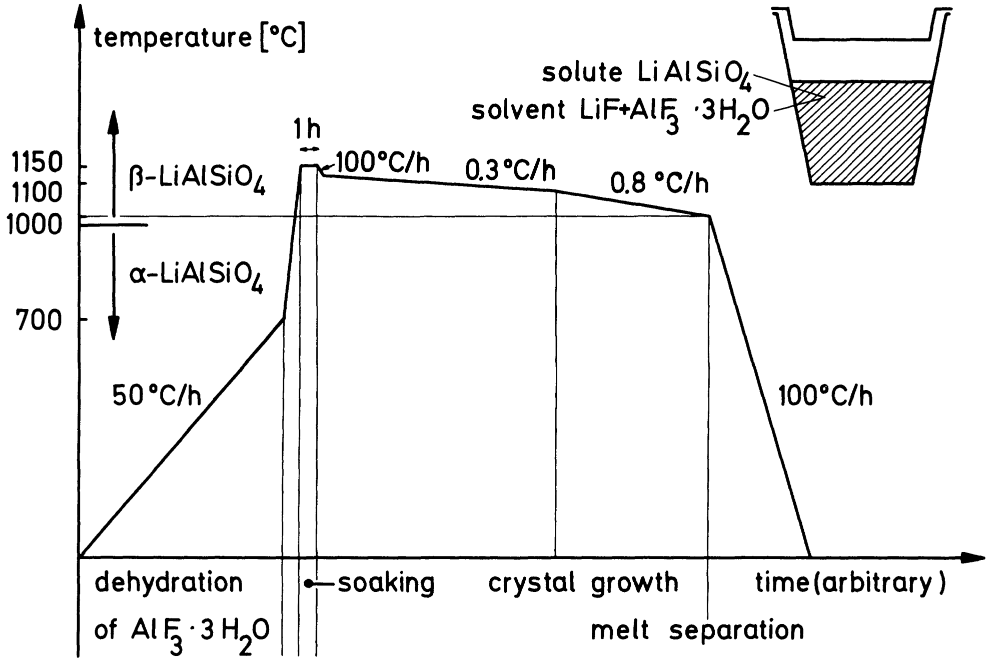

FIG. 19. Growth of eucryptite from fluoride flux as an example of the high-temperature solution technique (see text).

4. a slow cooling (e.g., at 0.3 °C/h) over several days. The slow cooling achieves a low number of nuclei and their undisturbed growth.
5. The slow cooling is continued at an increased rate (e.g., at 0.8 °C/h) since the normal growth rates decrease with the cube root (for linear solubility) of the cooling rate.
6. The crystal growth is terminated by decanting the solution from the crystals.
7. A slow cooling (e.g., at 20 °C) to room temperature prevents mechanical damage of the crystals.

A sophisticated example (growth of $Y_3Fe_5O_{12}$ crystals) with a preset seed is described by Tolksdorf and Welz (1978).

Advantages: The method is easily carried out and generally requires low-cost equipment. *Disadvantages:* The properties of fluid, conditions of surface reactions, and incorporation of the crystal species change with decreasing temperature.

3.4 Techniques of Crystal Growth from the Solid Phase (Recrystallization)

It is fundamentally difficult to grow a single crystal from a solid phase since the mobility of the crystal-forming species is strongly restricted. Precipitation of a dissolved phase or devitrification of glass leads to very small crystals in general. Only materials of high dislocation mobility, like metals, can in some cases be transformed by recrystallization into single crystals. The process consists of the release of Helmholtz free energy through migration of grain boundaries, i.e., through the growth of large grains by the consumption of adjacent small ones. The procedure is achieved in two steps: the sample is (a) loaded with high free energy by straining and (b) either annealed in a homogeneous temperature field or moved through a temperature distribution in the direction of increasing temperature (in contrast to the Bridgman technique). The methods are described in detail by Laudise (1970) and Burgers (1963).

Advantage: The method generally requires low-cost equipment. *Disadvantages:* The method is restricted to materials of high dislocation mobility. Large single crystals are hard to obtain.

4. TECHNIQUES OF THIN-FILM GROWTH

Thin ($<100\times10^{-6}$ m) crystalline layers of various materials are of great importance for modern electronic devices. Crystalline films are grown by deposition or precipitation of the film species on a particular plate, called the substrate. The procedure is called (homo)epitaxy if the film consists of the same material as the substrate, heteroepitaxy if not (see HETEROSTRUCTURES AND SUPERLATTICES, METALLIC; HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR; THIN FILMS, NONELECTRONIC PROPERTIES). The control of layer thickness requires sufficiently low growth velocity, which is obtained by using a low-density fluid. Therefore layers are grown from a solution, i.e., by the technique of liquid-phase epitaxy, and from various kinds of vapor phases for which the techniques of chemical vapor epitaxy [see CVD (CHEMICAL VAPOR DEPOSITION)] and molecular-beam epitaxy (*q.v.*) are most widely used. Methods with low growth rates, low processing temperatures, and fast exchangeable fluids are applied to produce technologically important multilayers which consist of a periodic sequence of very thin ($<0.1\times10^{-6}$ m), variably doped semiconducting films.

4.1 Liquid-Phase Epitaxy

Liquid-phase epitaxy is mainly applied to layer growth of III-V compounds (e.g., GaAs) using the metal of the compound as a solvent. The methods are characterized by the procedure of attachment between substrate and solution:

1. Tipping: The solution and substrate are separately placed in a modified (graphite) boat. The solution is tipped over the substrate by tilting the boat.
2. Dipping: Similar to the Czochralski technique, the substrate attached to a rod is immersed into the solution.
3. Sliding: The substrate is held in a tray of a horizontal (graphite) plate. A second plate on top of the support plate contains a sufficiently large bore filled with solution and is slid over the substrate. Multilayers can be grown using a support plate with several solution chambers.
4. Centrifuging (especially designed for grow-

ing multilayers) as described by Bauser (1987): A rotating vertical graphite cylinder holds the solution at low revolution rates in two opposite inner tanks around a rotation axis, and at high revolution rates in two opposite outer storage channels. The substrates are mounted in radially connected channels between inner and outer storage chambers. The solution comes in contact with the substrate when the initially low revolution rate is increased.

In each method the layer growth is achieved either

1. by cooling, i.e., a saturated solution is brought in contact with the substrate and is cooled by a linear or sudden temperature change, or
2. by isothermal growth, i.e., a supersaturated solution is brought into contact with the substrate on which the crystal then grows at constant temperature by the consumption of the supersaturation.

4.2 Chemical Vapor Epitaxy

In most cases epitaxial layer growth through a heterogeneous chemical reaction is achieved in an open transport system (reactor), i.e., in a fused silica tube or vessel which contains the substrate and eventually source materials. The reactor is fed by appropriate vapor species (precursor molecules) in an H_2 or He carrier gas through a pipework which controls the flow rate. The various reactor designs are directed to different purposes—e.g., a laminar gas flow over the substrate, small exchangeable gas volume for multilayers, and high mixing of the vapors for homogeneous growth. The simplest type consists of a horizontal chamber with an obliquely mounted substrate or a vertical tube with the substrate attached to a horizontal pedestal. Two different principal reactor types result from the means of heating: namely, the cold-wall reactor where only the substrate support is (inductively) heated [Fig. 6(a)], and the hot-wall reactor where the substrate is heated by a resistance furnace outside of the reactor.

Three different thermochemical processes —pyrolysis, pyrolytic synthesis, and chemical transport—are employed for epitaxial deposition.

1. Pyrolysis (thermal decomposition) is preferred for deposition of elements and is achieved in a cold-wall reactor. An example is silicon epitaxy from a $SiHCl_3$-H_2 feed which decomposes at 1100 °C, i.e.,

$$2SiHCl_3(g) \rightarrow 2Si(s) + H_2(g) + 3Cl_2(g).$$

2. Pyrolytic synthesis consists of the layer formation from a reaction of at least two introduced vapor compounds. An example is the MOVPE (metalorganic vapor-phase epitaxy) of III-V compounds from a metal alkyl and phosphine in a cold-wall reactor, e.g., indium phosphide according to the reaction

$$(C_2H_5)_3In(g) + PH_3(g) \rightarrow InP(s) + 3C_2H_6(g)$$

at about 550 °C.

3. Chemical transport is a reversible process. It additionally requires a heated source chamber. Hot-wall reactors are preferred. An example is the chloride procedure according to the (simplified) reaction

$$2GaP(s) + 2HCl(g) \\ = 2GaCl(g) + P_2(g) + H_2(g)$$

at about 850 °C. The deposition rate is adjusted by the H_2 flow rate, chlorine/hydrogen concentration ratio, and temperature difference between source and substrate.

4.3 Molecular-Beam Epitaxy

A molecular-beam apparatus consists of a very sophisticated assembly (see MOLECULAR-BEAM EPITAXY). It achieves precisely controlled epitaxial layer growth by incident fluxes [molecular beams, 10^7–10^8 molecules/(cm^2 s)] of atoms and molecules in an ultrahigh vacuum ($<10^{-8}$ Pa). Compound layers, e.g., $Ga_{1-X}Al_XAs$, are synthesized by the appropriate fluxes of Ga, Al, and As_2 species. Each species is evaporated from a particular Knudsen effusion cell. Monolayers of monatomic height are obtained by closing and opening the cells with specific shutters. Several apparatus are integrated such as

1. a mass spectrometer to control the vapor phase,
2. an electron gun to analyze the surface structure by angle-resolved photoelectron emission spectroscopy and reflection high-energy electron diffraction, and

3. an ion gun to determine chemical composition by secondary-ion mass spectroscopy.

5. CHARACTERIZATION OF CRYSTALS

5.1 Morphology

Depending on the growth procedure, a single crystal can display rounded or flat as-grown faces. Primarily, the morphology of growing crystals, i.e., the macroscopic shape, is determined by the density of free bonds at the surface or alternatively by the number of periodic bond chains (PBC) in different directions parallel to the interface within a distinct slice. According to the PBC theory, which is discussed by Hartman (1973), three types of interfaces can be classified—namely, kinked, stepped, and flat faces. Kinked (*K*) faces contain no PBC and are therefore rough, hence fast growing and unlikely to appear. Stepped (*S*) faces contain one type of PBC and provide the surface with parallel growth steps. Flat (*F*) faces contain at least two types of PBC, need step sources, grow slowly, and are therefore most likely to appear. In general, *F* faces have the highest lateral atom density, lowest Miller indices, and lowest surface energy. Reaction of free bonds with impurities or formation of surface bonds from neighboring free bonds (reconstruction) can lead to other faces as the PBC analysis predicts.

The formation of rounded faces depends on the temperature, the form of the fluid isotherms, and fluid composition. Strong rounding is not observed in crystal growth far below the melting point. In the case of crystal growth from solution or reactive vapor (e.g., chemical transport), the final morphology is strongly polyhedral: composed of *F* faces and eventually *S* faces. When the crystal is dissolved the morphology becomes different from that of growth in general. While the growth morphology consists of slowly growing faces, the solution morphology is preferably composed of fast-growing faces.

In the case of growth from a nonisothermal melt or vapor the crystal form approaches the surrounding isotherms. Faceting is pronounced by the presence of impurities in the fluid. Figure 20 illustrates an example. The faceting and rounding of the crystal interface are represented by interface contours. The sample, an iodine crystal, was grown by the Pizzarello technique (Fig. 8) from iodine vapor which contained a small amount of krypton. The initial (F_i) and final (F_f) interfaces were obtained by holding the ampoule at fixed positions x_i and x_f, respectively. The sequential growth contours from F_i to F_f result from a sudden ampoule displacement from x_i to x_f. Only rounded faces are observed for backsublimation where the interface moved from F_f to F_i after the reverse displacement from x_f to x_i.

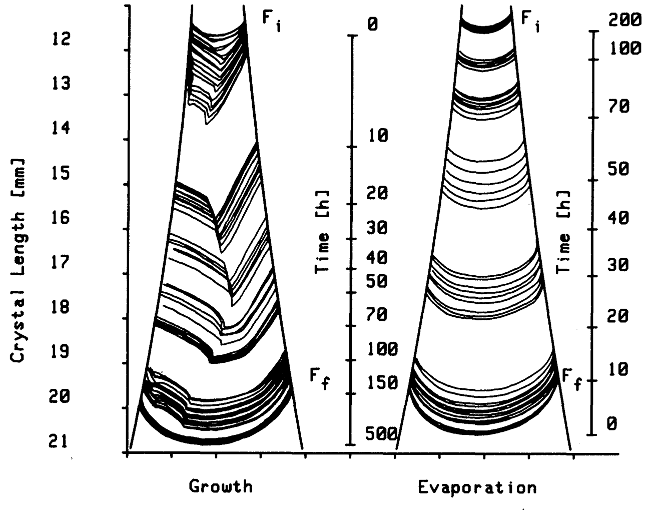

FIG. 20. Vapor-solid interface contours of iodine in the presence of krypton (400 Pa) at different times: growth at about 62 °C through sudden ampoule displacement; backsublimation (evaporation) after sudden reverse displacement.

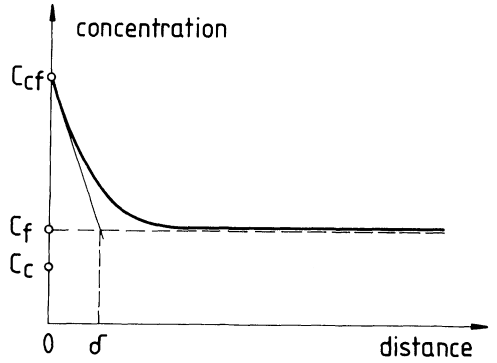

FIG. 21. Impurity distribution in front of a crystal growing from a melt. C_c is the concentration of the solute in the crystal, C_{cf} at the interface, and C_f in the melt at a large distance from the interface. δ is defined as the width of the boundary where transport of melt is achieved by diffusion.

5.2 Segregation of Impurities

5.2.1 Segregation Coefficients. In general, impurities dissolve in the coexisting melt and solid phases at different concentrations. The ratio $k_{\text{eq}}=C_{ce}/C_{fe}$ of the crystal impurity concentration (C_{ce}) to that (C_{fe}) of the melt is called the equilibrium segregation (or distribution) coefficient. The coefficient is obtained from the appropriate binary phase diagram. If $k_{\text{eq}}<1$ the impurity becomes enriched in front of the growing crystal interface as illustrated in Fig. 21 and discussed, e.g., by Pfann (1952, 1966), Carruthers (1975), and Brice (1965, 1973, and 1986). The impurity enrichment leads to surface concentration C_{cf}. The local (exponential) change of the impurity concentration in the fluid is approximated by a linear change which leads to the thickness δ of the so-called solute boundary layer. Two additional segregation coefficients are defined: the interfacial $k^*=C_c/C_{cf}$ and the effective $k_{\text{eff}}=C_c/C_f$ where C_c is the impurity concentration in the crystal near the interface and C_f the concentration in the bulk fluid. Under steady-state conditions the two coefficients are related by the crystal-growth rate V_c and diffusion coefficient D through

$$k_{\text{eff}}=k^*/[k^*+(1-k^*)\exp(-V_c\,\delta/D)]. \qquad (13)$$

The concentration distribution of the crystal is thus severely affected by fluctuations of the growth rate V_c and boundary-layer thickness δ. Fluctuations of both parameters are caused by fluctuations in the fluid which may arise from stirring or gravity-driven convection. If free-fluid surfaces are exposed to thermal gradients additional, irregular convection (Marangoni convection) appears driven by the difference in surface tension. The fluctuating impurity incorporation leads to changes of impurity densities perpendicular to the growth fronts, i.e., striations parallel to the interface, which can be revealed by a suitable etchant.

5.2.2 Impurity Distribution through Zone Refining. The difference in impurity concentrations in coexisting fluid and solid phases is used for purification through sublimation, distillation, and zone refining. For zone refining the principles of floating-zone techniques used for crystal growth are applied. A high efficiency is maintained by designs with several heating zones. Techniques are described by Pfann (1966) and Parr (1960). When a single melt zone of a width L is passed through a solid rod the concentration profile of the ingot assumes the form

$$C_c(x)=C_i[1-(1-k_{\text{eff}})\exp(-k_{\text{eff}}x/L)] \qquad (14)$$

[after Pfann (1966)], where C_i is the initial mean concentration of the ingot (molten zone) and k_{eff} an effective segregation coefficient. In the Bridgman and Czochralski processes the solute concentration of the crystal of a total length L_t is given by

$$C_c(x)=k_{\text{eff}}C_i(1-x/L_t)^{k_{\text{eff}}-1} \qquad (15)$$

for complete solidification of the melt and a constant crystal cross section. Concentration

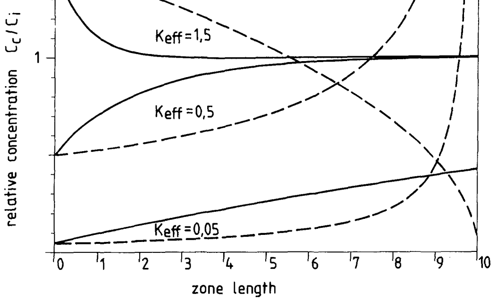

FIG. 22. Impurity distribution in a crystal for different segregation coefficients. Solid line for zoning. Dashed line for Bridgman procedure.

profiles according to Eqs. (14) and (15) are shown for different segregation coefficients in Fig. 22.

5.2.3 Precipitation. When the solubility of a solute decreases with decreasing temperature the solute may be precipitated in the crystal as small particles. Transparent crystals become opaque by this process. Preferably precipitation occurs along dislocations and grain boundaries.

5.3 Structural Defects

There are three classes of structural defects—

1. point defects,
2. line defects, and
3. two-dimensional defects—

that are or may be formed during crystal growth. Their formation is discussed by Vere (1987) and Chernov (1984). (See also IMPERFECTIONS IN CRYSTALS.)

5.3.1 Point Defects. The requirement of a minimum value of the Helmholtz free energy leads to some disorder of the structure above $T > 0$ K. There are two types of disorder:

1. vacant lattice sites, the so-called vacancies or Schottky defects, and
2. interstitials (Frenkel defects) which occupy sites other than those of the perfect structure.

Other point defects are formed by impurities which can occupy vacancies or interstitials. Point defects mainly influence the electrical and optical properties.

5.3.2 Line Defects. Line defects are called dislocations. They cannot terminate within the crystal, and so they either run between two surfaces, form a closed loop, or form a branch of another dislocation. A dislocation is characterized by the direction of its axis and Burgers vector. The vector results from comparison of the perfect structure with the actual structure around the dislocation. The defect is called a step dislocation when the Burgers vector runs perpendicular to the dislocation axis and a screw dislocation when the vector runs parallel to the axis. The screw dislocations serve as growth centers.

In Czochralski or floating-zone techniques, dislocations usually originate from the seed. If the dislocations are sufficiently strongly bonded by the lattice (e.g., silicon) they can be eliminated by growing a neck after seeding. During the crystal growth additional dislocations can be formed by shear strains which may result from

1. radial temperature gradients in the crystal,
2. precipitated impurities,
3. trapped impurity particles, or
4. sticking of the crystal to the container wall.

The formation of new dislocations is enhanced by multiplication of already existent dislocations as described by Hull (1975) and Friedel (1964).

5.3.3 Two-Dimensional Defects. Essentially there are three types of two-dimensional defects: (a) grain boundaries, (b) twins, and (c) stacking faults.

(a) Low-angle grain boundaries are mainly formed by multiplication of dislocations due to a straining stress field. Therefore, in the simplest case, low-angle boundaries consist of an array with parallel dislocations. For example, one family of step dislocations forms a pure tilt grain boundary where the dislocation axis is parallel to the tilt axis, while a family of screw dislocations forms a pure twist grain boundary where the dislocation axis is perpendicular to the boundary plane. The structure of high-angle boundaries is complex. They arise from intergrowth of differently oriented grains or from noncoherent nucleation on the growing surface (see GRAIN BOUNDARIES).

(b) Twin boundaries form a mirror plane where the structure is reflected. These particular faults originate either from a noncoherent nucleation or from mechanical deformation. Twinning is frequently observed for III-V and II-VI compounds which crystallize in the sphalerite structure. Here a twin is formed by a 180 °C rotated nucleus on a {111} plane. In contrast to grain boundaries, these twins are unmovable during heat treatment. Multiple twinning is caused by a too high supersaturation. Particular multitwin structures lead to dendritic growth as described, e.g., by Lindberg and Faust

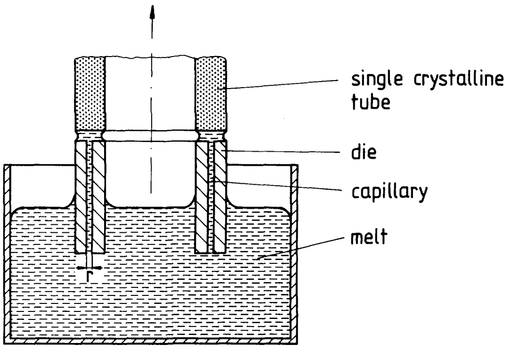

FIG. 23. Growth of a tube by the edge-defined film-fed method.

(1962).

(c) Stacking faults are mainly formed by precipitation of vacancies or interstitials so that either an atomic layer (intrinsic) is left out or an additional one (extrinsic) is inserted. Stacking faults are often observed on {111} planes of the sphalerite and diamond structures. Stacking faults extend within the crystal over a limited area, in contrast to twins, grain boundaries, and dislocations. More or less periodically different stacking (polytypism) of crystallographic planes occurs in some layered structures. The particular stacking faults are caused by dislocation movements. The faults are described by Trigunayat and Verma (1976) and Farkas-Jahnke (1983).

6. EXAMPLES OF APPLICATIONS

6.1 Czochralski Techniques

6.1.1 Edge-Defined Film-Fed Growth. Particular shapes of cross sections can be made through the Czochralski technique by placing a wettable die with pores between the melt and the crystal interface as illustrated in Fig. 23 and described by Ciszek (1981) and Wald (1981). The crystal is supplied with melt through a thin layer on top of the die. The layer is fed by the fluid which creeps through the pores if the die thickness is less than $2\sigma_f \cos(\phi)/\rho_f gr$, where σ_f is the melt surface tension, ϕ the wetting angle, ρ_f the melt density, g the acceleration due to the gravity, and r the radius of the capillary bores. Preferably, the method is applied to the growth of thin sheets (e.g., Si with a graphite die) and tubes (e.g., Al_2O_3 with a Mo die).

6.1.2 Dendritic Silicon Web Growth. Dendritic Si webs, candidates for solar cells, are grown by the Czochralski technique as indicated in Fig. 24. The sheets contain at least two coplanar twin planes parallel to the wide (111) sides; in addition, they are bounded by two [112] dendrites and grown in the [112] direction where the particular structure of two neighboring twin boundaries acts as a reentrant corner for the Si incorporation. The growth of the webs is started with a thin dendritic [112] seed (10^{-3} m diameter) from a melt of asymmetric temperature distribution. A review is given by Seidensticker (1982).

6.2 Float Zoning of Silicon

Figure 25 shows the principle of (a) normal and (b) pedestal zoning of silicon with inductive heating at a frequency between 3 and 5 MHz as reported by Keller and Mühlbauer (1981). A solid wedge-shaped coil (pancake coil with inner diameter of 35×10^{-3} m) with bores for water cooling (10^3-A current) superposes on the surface tension an electrodynamical force. In this way, a five times larger diameter (10^{-1} m) than that given in Eq. (12) can be achieved. The feed rod and crystal rod are oppositely rotated and displaced with respect to the fixed coil. The procedure of seeding and necking for disloca-

tion-free growth is, in principle, equal to the Czochralski method.

6.3 High-Pressure Technique of Diamond Growth

Diamonds of one carat (5×10^{-3} m in diameter) can be grown within a week from graphite dissolved in nickel at an external pressure of 6 GPa and a temperature of 1400 °C. The principle of this highly sophisticated method has been reviewed by Bundy *et al.* (1973), Wentorf (1974), and Nassau and Nassau (1979), and is schematically illustrated in Fig. 26. (See also DIAMONDS AND DIAMONDLIKE CARBON; HIGH-PRESSURE EFFECTS IN SOLIDS; HIGH-PRESSURE TECHNIQUES.) Two sections of a graphite heating tube are filled with a mixture of nickel and graphite powder. For better pressure control a diamond grit (synthetic or natural) is preferred instead of graphite powder. The two mixture compartments are lined with pyrophyllite $[Al_2Si_4O_{10}(OH)_2]$. The particular material is insulating and plastic at the employed high pressures and temperatures. A small seed plate of diamond is placed at the upper and lower pyrophyllite covering. The graphite tube is closed with nickel plates for current transfer and placed in a special belt press. The pestles and inner ring are made of cobalt-bonded tungsten carbide (carballoy: about 90% WC+10% Co). Both are surrounded by several belts of special steel. The free space between the tapered pistons and spheroid belts as well as that between the inner belt and graphite tube are insulated by pyrophyllite. By applying an electric voltage between the pistons the graphite tube is resistively heated slightly hotter at the middle than at the ends. Therefore the diamond grit dissolves in the middle and precipitates epitaxially at the seeds mounted at the tube ends (temperature difference technique).

Small diamond particles of about 0.25×10^{-3} m in diameter are crystallized within a short time (a few minutes) in a pyrophyllite

tube from a nickel graphite solution as shown in Fig. 26. The graphite is completely converted into diamond since the solubility of graphite is higher than that of diamond.

Advantages: Diamond grit can be fabricated at reasonable costs, and the grains are more suitable for tools than crushed natural diamond since they are free from cracks. *Disadvantage:* The fabrication of large crystals of high quality is more expensive than the cost of natural diamonds.

GLOSSARY

Associative Sublimation: Atoms of a solid join together to form molecules before entering the vapor phase.

Chemical Vapor Transport: Reversible transfer of a solid as a volatile compound through reaction with a gas.

Dendrite: Needlelike, often with branches, fast-growing crystal.

Devitrification: Transformation of glass into crystalline state.

Dissociative Sublimation: Decomposition of molecules of a solid when entering the vapor phase.

Dopant: A small defined quantity of substance added to the crystal.

Cluster: A group of like atoms or molecules forming an unstable condensate.

Nucleus: The smallest group of like atoms or molecules forming a stable condensate.

Peritectic Reaction: Formation of a solid phase β and liquid phase l from a solid phase α by heating of α, i.e., $\alpha \rightarrow \beta + l$.

Peritectic Temperature: The temperature at which the three phases α, β, and l coexist.

Segregation: Change of solute concentration during crystallization.

Stefan Problem: Problem of solving the heat-flow equation with a moving boundary.

Striations: Narrow bands of nearly constant solute concentration in crystals.

Substrate: A thin plate (in most cases a single crystal) onto which a thin solid layer is deposited from a vapor or liquid phase.

Supersaturation: State of vapor (or solute concentration) at pressures (concentrations) greater than that in equilibrium with the crystal.

Undercooling: Supercooling, state of melt at temperature below the melting point.

INTRODUCTION: CRYSTALLINE AND NONCRYSTALLINE SOLIDS

Historically, we have categorized solids as either crystalline or glassy (often referred to as amorphous solids) as illustrated in Fig. 1. A simple operational definition of crystallinity, which will be expanded upon in detail below, is the state of matter characterized by long-range positional order of its constituent atoms. That is, there is a set of well-defined rules that may be used to specify the positions of all atoms in the solid. In general, the task of describing the various crystalline structures is simplified by the presence of periodic translational order. Once the local arrangement of atoms in one region of the crystal is described, this basic structural unit may be translated through some set of well-defined vectors to construct the entire solid. For glassy materials, on the other hand, no such set of rules or relations exists beyond an average local structure enforced by the forces that bind atoms together. This means that although local short-range positional order may exist in glassy solids, there is no corresponding long-range positional order. A third class of structures which, though well-ordered, are not periodic crystals includes incommensurate structures and quasicrystals. These are solids which possess long-range positional order which is aperiodic. Although our primary purpose here

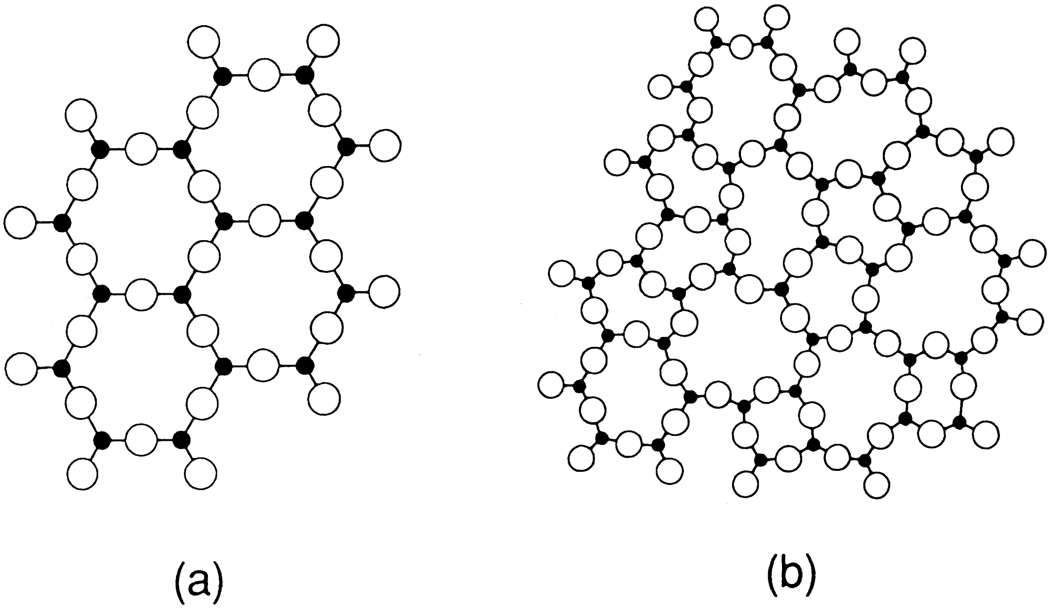

FIG. 1. Crystalline (a) and glassy (b) networks of atoms. (After Kittel, 1986.)

is the description of periodic crystalline solids, the latter two classes of structures will also be discussed where appropriate.

1. CRYSTAL STRUCTURES

This section deals with the definition and details of periodic crystal structures. In particular, we consider what restrictions periodicity places on the symmetries of crystal structures and the placement of atoms within these structures. We first develop the language of crystallography by considering two-dimensional crystal lattices and then move on to three-dimensional structures.

1.1 Two-Dimensional Crystal Lattices

1.1.1 Bravais Lattices and Translational Symmetry. Consider the two-dimensional array of points shown in Fig. 2. These points are said to belong to a *Bravais lattice* if the arrangement and orientation of lattice points, as viewed from one particular point, is identical to that viewed from all other points in the lattice. All points in Fig. 2 satisfy this condition. The hexagonal net of Fig. 3, however, clearly does not satisfy this requirement since points *X* and *Y* are not equivalent. A more formal definition of a two-dimensional Bra-

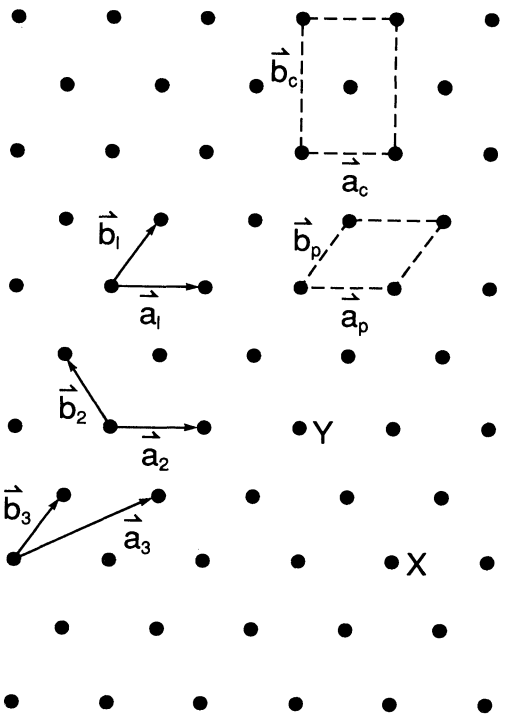

FIG. 2. The centered rectangular Bravais lattice. Primitive translation vectors and primitive and conventional unit cells are illustrated.

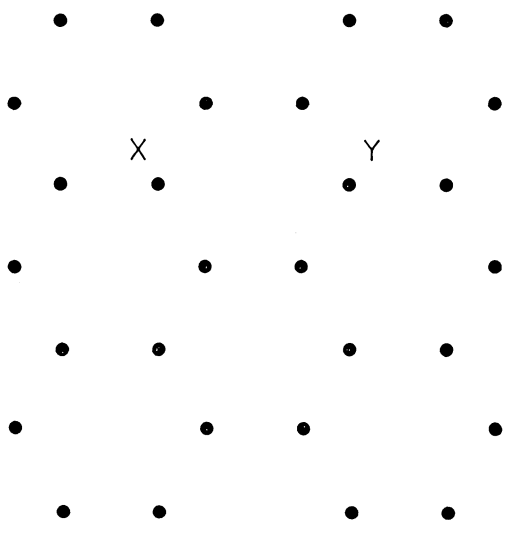

FIG. 3. Two-dimensional hexagonal net. Points X and Y are not equivalent.

vais lattice is that all points may be reached by a translation of the form

$$\mathbf{R}=n_1\mathbf{a}+n_2\mathbf{b},$$

where n_1 and n_2 are integers, and **a** and **b** are referred to as the *primitive translation vectors*. In three dimensions this definition must be modified to include translations out of the plane along a third primitive translation vector, **c**. A general translation in three dimensions is then described by the vector

$$\mathbf{R}=n_1\mathbf{a}+n_2\mathbf{b}+n_3\mathbf{c}.$$

For the two-dimensional Bravais lattice in Fig. 2, we can see that there are many possible choices for **a** and **b**. In terms of the three sets of primitive vectors illustrated in Fig. 2, a translation from point X to point Y can be represented by $-2\mathbf{a}_1+2\mathbf{b}_1$ or $-2\mathbf{b}_2$ or $-2\mathbf{a}_3+4\mathbf{b}_3$.

In the same way that we chose primitive translation for a Bravais lattice, we can define a *primitive unit cell* as the minimum-volume cell that will completely tile the plane. Note that the particular choice of this cell is also nonunique. One example of a primitive unit cell for the Bravais lattice of Fig. 2 is illustrated by the parallelogram spanned by vectors $\mathbf{a}_p$ ($\mathbf{a}_1$) and $\mathbf{b}_p$ ($\mathbf{b}_1$). If we now take this parallelogram and translate it through all linear combinations of $n_1\mathbf{a}_p+n_2\mathbf{b}_p$, for integer n_1 and n_2, we can tile the entire plane without overlap or gaps. It is often more useful, however, to define a second type of unit cell, termed a *conventional unit cell*, as depicted by the rectangle in Fig. 2. The reason for this is that the rectangular unit cell more clearly illustrates the underlying rectangular symmetry of the lattice. Note that while the primitive unit cell contains one lattice point, the conventional unit cell in this figure contains two lattice points. The four lattice points at the corners are shared by four unit cells while the lattice point at the center is completely within the domain of a single cell. Again, if we translate the rectangle by integer combinations of $\mathbf{a}_c$ and $\mathbf{b}_c$, we can tile the entire plane without overlap or gaps.

Before going on to describe the symmetries of lattices, we complete the picture by pointing out that the crystal structure is then fully determined by associating a set of atoms with each lattice point or unit cell. Clearly, if we decorate each unit cell with atoms in an identical manner, the same translation vectors used to move between points on a Bravais lattice can be used to move between identical atoms in all unit cells. In other words, the atomic arrangement is also periodic.

1.1.2 Point Groups and Space Groups.

Although there are an unlimited number of possible lattices in two dimensions, there are only five distinct two dimensional Bravais lattices, as shown in Fig. 4. The most general Bravais lattice is the oblique lattice since it places no restrictions on **a**, **b**, or the angle (γ) between them.

The symmetries of a crystal are defined by the kinds of operations that leave the structure invariant. In addition to the translations described above, there are also *point-group operations* to consider. The point group is the

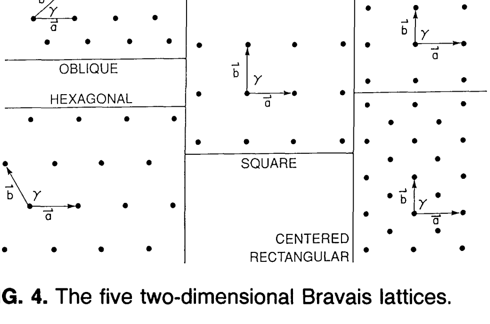

FIG. 4. The five two-dimensional Bravais lattices.

set of all operations which leave one point fixed. In two dimensions these operations include rotations about a fixed point and reflection across a line. The group of such actions which leave the lattice invariant (map the lattice points back onto themselves) defines the point symmetry of the lattice. The oblique lattice, for instance, may be left invariant only under rotations of π (180°) or 2π (360°). If we rotate the lattice points about one fixed point by these values, the rotated lattice is again coincident with the unrotated lattice. By further restricting the possible values of **a**, **b**, and γ, we obtain the special lattice types in Fig. 4. For instance, by restricting $a=b$ and $\gamma=90°$, we see (Fig. 5) that the square Bravais lattice is invariant under rotations of $\pi/4$, as well as reflections across lines x, y, x', and y'. Similarly, one can place constraints on **a**, **b**, and γ that lead to hexagonal Bravais lattices which are invariant under rotations of $2\pi/3$ and $2\pi/6$.

It should be pointed out here that the requirement of periodic translational order restricts the allowed rotational symmetries of two- and three-dimensional lattices to rotations by 2π, $2\pi/2$, $2\pi/3$, $2\pi/4$, and $2\pi/6$. In other words, in addition to a simple rotation by 2π (360°), periodic crystals may have twofold, threefold, fourfold, and sixfold rotation axes, but not five-fold or seven-fold or higher rotational symmetry. The reason for this is illustrated in Fig. 6 for the case of fivefold rotational symmetry. Consider two nearest-neighbor lattice points **A** and **B** separated by some minimum distance d. If we rotate **B** by an angle of $2\pi/4$ about **A** to get **B**′, and rotate **A** about **B** by the same angle to get **A**′, then both **A**′ and **B**′ are also lattice points of a square lattice with a minimum separation distance of d. If we perform the same set of operations on **A** and **B**, now specifying the rotation angle to be $2\pi/5$, the new lattice points **A**′ and **B**′ are now separated by less than d, contradicting the original assumption that d is the minimum distance. The conclusion from all of this is that periodic lattices may not have fivefold rotation axes.

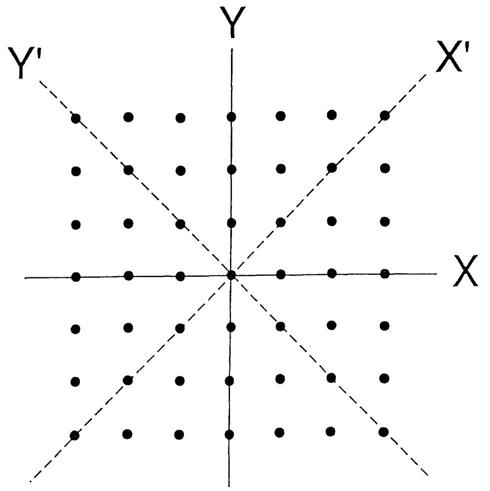

FIG. 5. Square Bravais lattice showing reflection symmetry across the lines x, y, x', and y'.

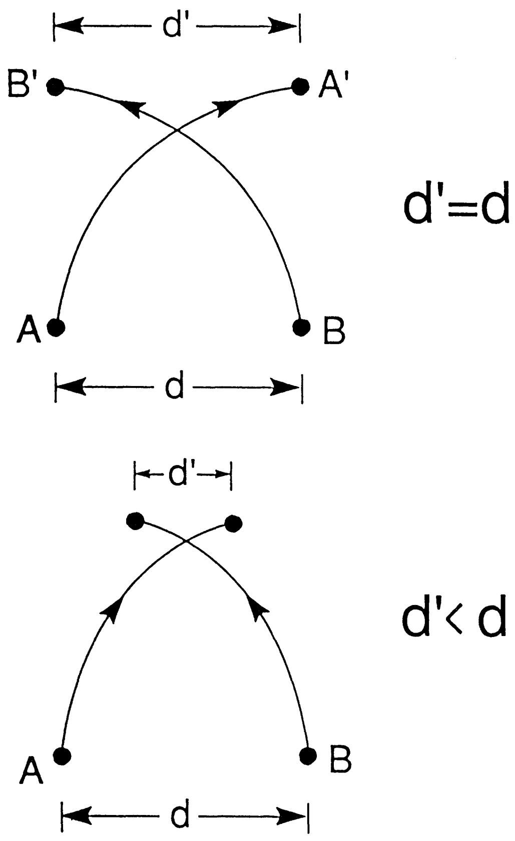

FIG. 6. An illustration of why fivefold rotation axes are not permitted for periodic structures.

The combined actions of all point-group operations (rotations and reflections) result in a total of ten two-dimensional point groups which are illustrated in Fig. 7. The oblong, triangular, square, and hexagonal filled symbols represent twofold, threefold, fourfold, and sixfold rotation axes, respectively. The heavy lines denote *mirror lines*. The presence

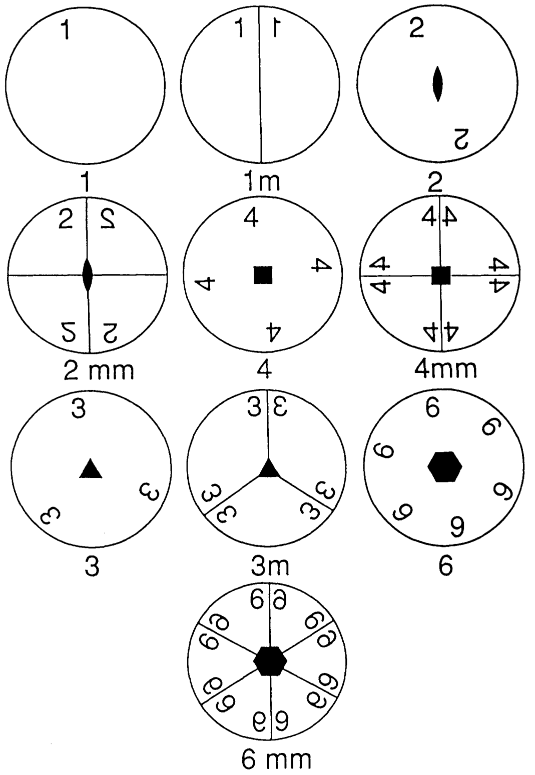

FIG. 7. The ten two-dimensional point group operations. The oblong, triangular, square, and hexagonal symbols denote twofold, threefold, fourfold, and sixfold rotation axes. The heavy lines represent mirror lines. (After the *International Tables for X-ray Crystallography.*)

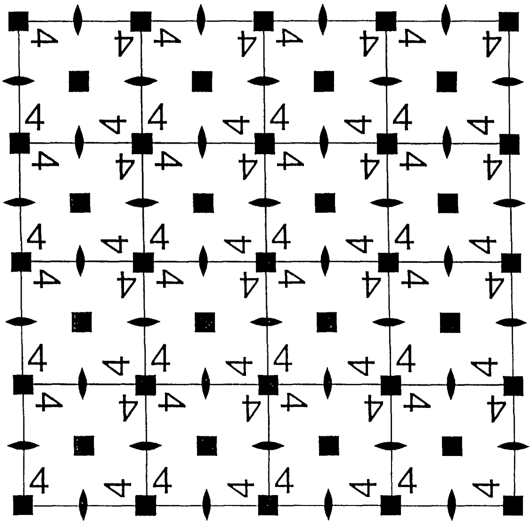

FIG. 8. The point group 4 translated through the vectors of a square lattice.

of a mirror lines indicates that reflection across that line leaves the pattern invariant. It is interesting to note that the combination of certain point-symmetry elements lead to others. For example, for the group 2*mm* in Fig. 7, the combination of a twofold rotation axis and a mirror line results in a second mirror line perpendicular to the first.

New symmetries appear when we consider the effect of compounding point-group and translational symmetries. For example, the point group 4 translated through the vectors of a square lattice results in a set of twofold axes midway between the lattice points and fourfold axes at the center of each unit cell (Fig. 8). Another operation, termed a *glide,* is composed of a reflection across the glide line and a translation of one-half the repeat distance along that line (see Fig. 12). Taken together, the combinations of point-group operations with translations, and glides, yield 17 two-dimensional *space groups.* In other words, there are 17 ways of arranging a set of identical objects periodically in two dimensions. All two-dimensional periodic structures belong to one of these space groups.

The three two-dimensional space groups of fourfold (square) symmetry are shown in Fig. 9 along with the diagram of spatially distributed symmetry operations found in the *International Tables for X-ray Crystallography.*

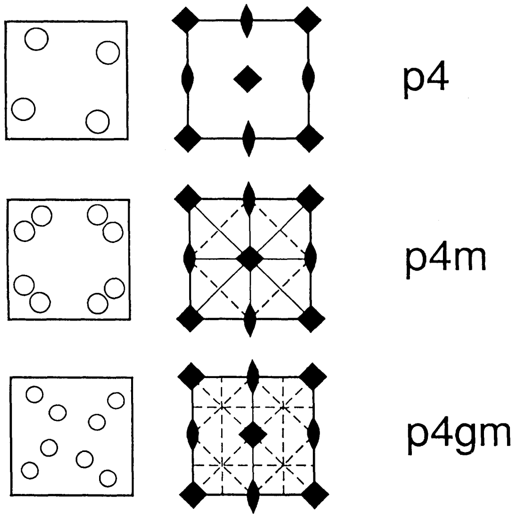

FIG. 9. The three two-dimensional space groups derived from the square space lattice and point-group operations. (After *The International Tables for X-ray Crystallography.*)

The left-hand figure illustrates an important point concerning the demands that various symmetry operations place upon the distribution of atoms in the unit cell. The space group label $p4$ indicates that the group is primitive (one lattice point per unit cell) and has fourfold rotational symmetry. If we place an atom at some *general position* (x,y) within the unit cell (where x and y are some fraction of the repeat distance a along the two orthogonal axes), three other atoms must be placed at $(-x,-y)$, $(y,-x)$, and $(-y,x)$ to satisfy the requirement of fourfold rotational symmetry. Likewise, the other space groups associated with the square lattice, which include additional mirror and glide symmetries, pose their own requirements for the symmetric placement of atoms. Note that there are also *special positions* such as (0,0), which only require one atom per unit cell.

1.2 Crystallography in Three Dimensions

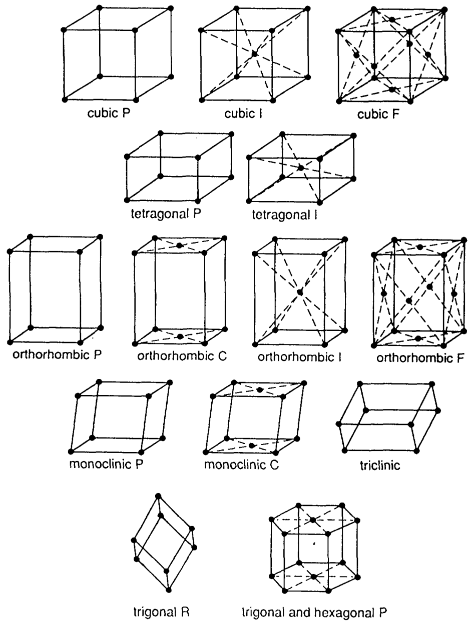

FIG. 10. Conventional unit cells of the 14 three-dimensional Bravais lattices. (After Kittel, 1986.)

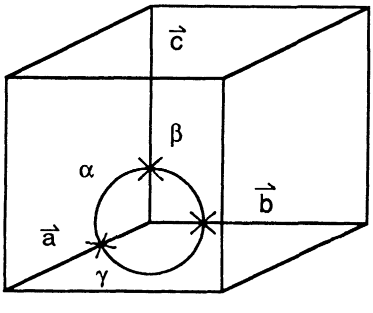
TABLE 1. The seven crystal systems in three dimensions.

System	Conventional cell edge lengths	Restrictions on angles
Cubic	$a=b=c$	$\alpha=\beta=\gamma=90°$
Tetragonal	$a=b\neq c$	$\alpha=\beta=\gamma=90°$
Orthorhombic	$a\neq b\neq c$	$\alpha=\beta=\gamma=90°$
Hexagonal	$a=b\neq c$	$\alpha=\beta=90°$ $\gamma=120°$
Trigonal	$a=b=c$	$\alpha=\beta=\gamma\neq 90°$ but less than 120°
Monoclinic	$a\neq b\neq c$	$\alpha=\gamma=90°$ $\beta\neq 90°$
Triclinic	$a\neq b\neq c$	$\alpha\neq\beta\neq\gamma$



All of the language that we developed in the last two sections carries over to the description of three-dimensional periodic crystalline lattices. In three dimensions there are 7 crystal systems (summarized in Table 1) and 14 Bravais lattices with conventional unit cells as shown in Fig. 10. Each Bravais lattice may also be described by a minimum-volume primitive unit cell as described in Sec. 1.1.1. For instance, the primitive unit cell of the face-centered-cubic (fcc) structure is a 60° rhombohedron defined by the vectors connecting a corner of the conventional unit cell with the lattice points at the centers of the three faces. The primitive unit cell of the fcc (cubic F-type) lattice contains one lattice point, while the conventional unit cell contains four (each of the corners is shared by eight unit cells, while each of the six faces connects two unit cells). As before, the conventional unit cell is preferred since it more closely reflects the symmetry of the underlying lattice.

Including the 10 two-dimensional point groups, which remain valid operations, there are 32 three-dimensional point groups which include new symmetry operations such as mirror planes perpendicular to the axis of rotation, rotary-inversion axes (where a rotation about an axis of $2\pi/n$ is accompanied by a reflection across a plane perpendicular to the line), and inversion through a point [where points $(x,y,z) \rightarrow (-x,-y,-z)$].

There are two additional operations which are required to enumerate the 230 three-dimensional space groups completely. First, a *screw axis* is defined by a rotation accompanied by a translation along the rotation axis by a vector which is some rational fraction of a Bravais lattice vector. Figure 11, for instance, shows examples of right-handed and left-handed screw tetrads. In this case, equivalent sites are related by a 90° rotation and a translation by $c/4$, where c is the repeat distance along the screw axis. One can similarly define screw diads, triads, and hexads. The second operation defines a *glide plane*, and consists of a translation through a vector which is not in the Bravais lattice and a reflection across a plane containing that vector. A glide plane consisting of a translation by $c/2$ is illustrated in Fig. 12.

For further details on space groups and point groups in crystallography, we refer the reader to the first volume of *The International Tables of X-ray Crystallography.*

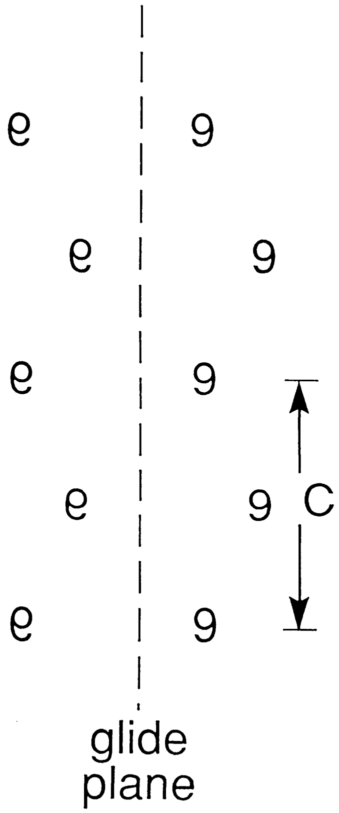


FIG. 12. A glide plane. The arrangement to the right of the plane is obtained by translating the assembly on the left by $c/2$ and reflecting across the plane.

1.3 Describing Planes and Directions

Quite often we are concerned with the arrangement of atoms in a particular plane of a three-dimensional crystal or the direction of the normal to that plane. Lattice planes in the cubic system are shown in Fig. 13. The plane itself is specified by a set of three *Miller indices* (h,k,l) which are defined as a set of integers which are inversely proportional to the intercepts of the plane along the crystal axes. For example, the (2,1,1) plane in Fig. 13 intercepts the a, b, and c axes at points $a/2$, b, and c. Similarly, the $(-1,1,1)$ or $(\bar{1},1,1)$ planes lies along the body diagonal of the cube and has intercepts of $-a$, b, and c. We may also group symmetry-related planes in a crystal into a family denoted by $\{h,k,l\}$. For instance, in the cubic system the planes (1,0,0), (0,1,0), (0,0,1), $(\bar{1},0,0)$, $(0,\bar{1},0)$, and $(0,0,\bar{1})$ all belong to the {1,0,0} family of planes. In contrast, for a crystal with tetragonal symmetry the (0,0,1) and $(0,0,\bar{1})$ planes do not belong to the {1,0,0} family. The direction of the plane is defined by the normal to the lattice plane of interest, and denoted by the same set of Miller indices enclosed in square brackets, $[h,k,l]$. The [2,1,1] direction in Fig. 13 is therefore normal to the (2,1,1) plane.

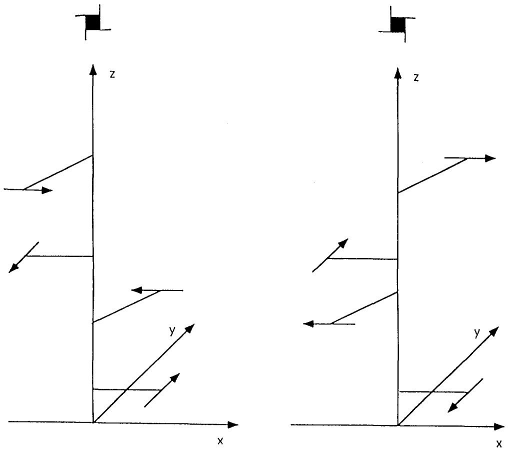

FIG. 11. Right-handed and left-handed screw tetrads. The arrangements in planes displaced by $c/4$ are related by a 90° rotation about the line.

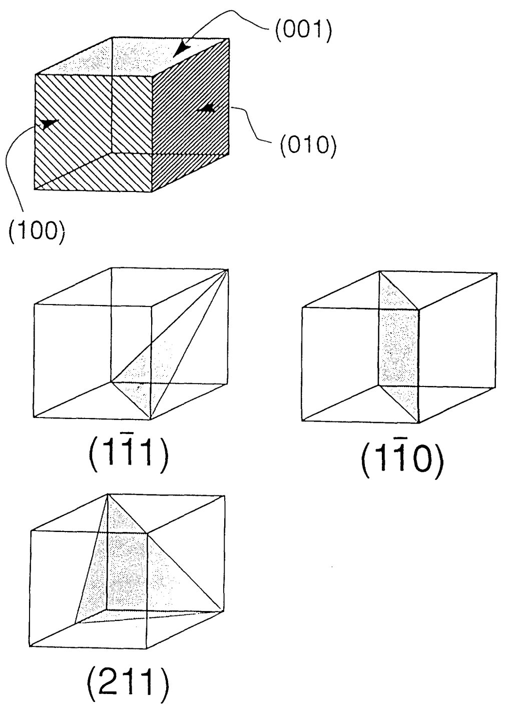

FIG. 13. Lattice planes in a cubic crystal. Directions are specified by the outward normals to these planes.

1.4 Examples of Crystal Structures

1.4.1 Close-Packed Structures. With few exceptions, metals crystallize into highly symmetric, densely packed structures of the cubic and hexagonal lattices shown in Fig. 14. As described below in Sec. 2.4, this arises from the nondirectionality of metallic bonding.

The *face-centered-cubic* (fcc) close-packed structure [Fig. 14(a)] may be described in terms of a cubic conventional unit cell with four atoms at positions (0,0,0), $(0,\frac{1}{2},\frac{1}{2})$, $(\frac{1}{2},0,\frac{1}{2})$, and $(\frac{1}{2},\frac{1}{2},0)$. Each atom is in contact with 12 nearest neighbors along the face diagonals of the unit cell at a center-to-center separation of $a/\sqrt{2}$, where a is the edge length of the unit cell. The density of the fcc structure may be calculated as follows: The volume of the cubic unit cell is a^3, and the total volume occupied by the four atoms per unit cell is $4\times 4\pi R^3/3$. If we take the radius of each atom as half the nearest- neighbor distance the packing fraction of the fcc close-packed structure is 74%.

The *hexagonal-close-packed* (hcp) structure itself is not a Bravais lattice, but may be viewed as two interpenetrating hexagonal lattices displaced from each other by $\mathbf{a}/3$, $2\mathbf{b}/3$, and $\mathbf{c}/2$. The atomic positions of the two atoms per hexagonal unit cell are then (0,0,0) and $(\frac{1}{3},\frac{2}{3},\frac{1}{2})$. Each atom is again coordinated by 12 nearest neighbors (six in the plane and two sets of three from the planes above and below). For the ideal close packing of hard spheres, the ratio of the c-axis lattice constant to the in-plane (a axis) lattice constants is $c/a = \sqrt{8/3}$.

There is a close similarity between the fcc close packing and hexagonal close-packing schemes. This is most clearly seen if we consider the packing of atoms in the planes perpendicular to the [111] directions of the fcc lattice or the [001] axis of the hcp structure. As illustrated in Fig. 15, the closest packing of atoms (equal sized spheres) in a plane is

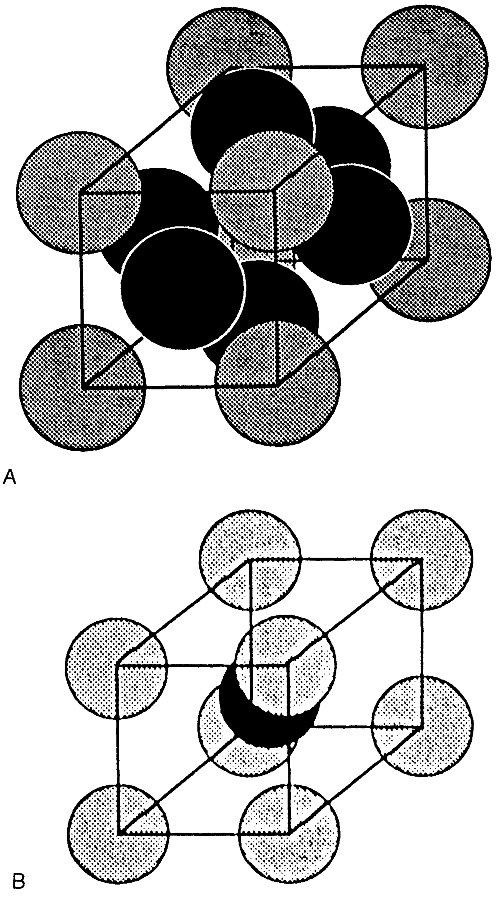

FIG. 14. Packing of equal-size spheres in the (a) fcc and (b) bcc structures. The light and dark shaded spheres represent atoms at the corners and faces of the fcc lattice, respectively, and the corners and body center of the bcc lattice.

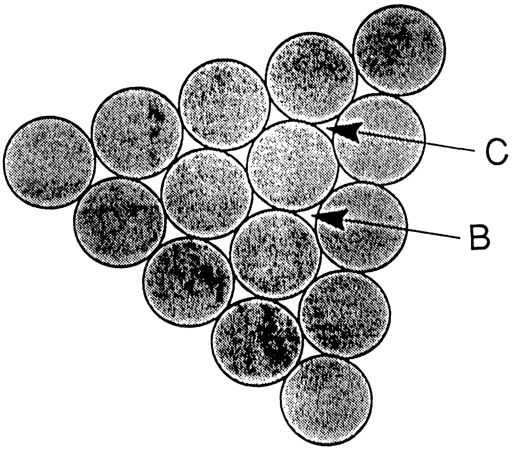

FIG. 15. Atomic packing in the (111) or (001) planes of the fcc or hcp structures. Interstices *B* and *C* denote sites available for atoms in the next layer.

accomplished by sixfold coordination of each atom. The pattern of atoms is precisely analogous to the two-dimensional hexagonal Bravais lattice that has threefold and sixfold symmetry. The voids between the atoms in this plane define the set of positions available for atoms in the next plane. Note that once one of the voids labeled *B* or *C* is chosen as the site for an atom in the next layer, all atoms in that layer sit in the *B* sites. If we continue up one more layer, there is a choice. The next layer of atoms may be situated either in the interstices labeled *C*, or directly over the atoms in layer *A*. If the packing proceeds in a sequence *ABCABCABCABC*,..., the fcc close-packed structure results, with the normals to these planes defining the [111] direction in the cubic lattice. On the other hand, if the stacking sequence is *ABABABABABAB*,..., the layers correspond to the planes perpendicular to the [001] direction of the hcp structure. A third stacking sequence, observed in some rare-earth metals, is *ABACABACABACABAC*,..., corresponding to the double hexagonal close-packed arrangement (dhcp).

The *body-centered-cubic* (bcc) close-packing arrangement [Fig. 14(b)] consists of two atoms per cubic unit cell at (0,0,0) and $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. Each atom is coordinated by eight nearest neighbors along the body-diagonal directions at a separation of $\sqrt{3}a/2$, and six atoms along the cube edge directions at a separation of a. The packing fraction of this structure is somewhat lower than the fcc structure (67%). The closest-packed planes are the (110) layers where the atoms are arranged in a square rather than the triangular network of the fcc (111) layers.

1.4.2 The Diamond, Cubic Zinc-blende, and Hexagonal Wurtzite Structures. The *diamond* structure is commonly found for covalently bonded semiconductors such as silicon and germanium. The structure (Fig. 16) is based upon a fcc space lattice with a two atom basis in the unit cell at (0,0,0) and $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$. The unit cell, therefore, contains eight atoms. The resulting structure may be viewed as two equal-sized, interpenetrating fcc sublattices with a relative displacement of one-quarter of the distance along the body diagonal. Each atom is tetrahedrally coordinated by four nearest neighbors at a separation of $\sqrt{3}a/4$, and the packing fraction of these structures is quite low (34%). The *zinc-blende* structure (Fig. 17) of many other structures with covalent or partially covalent bonding is a simple modification of the diamond structure. In ZnS, e.g., the Zn atoms are situated on one of the fcc sublattices while the S atoms sit on the other. Each atom is tetrahedrally coordinated by atoms of the other species.

The relationship between the hexagonal *wurtzite* and zinc-blende structures is analogous to that between the fcc and hcp structures described in Sec. 1.4.1. Viewing along the [111] direction of the zinc-blende struc-

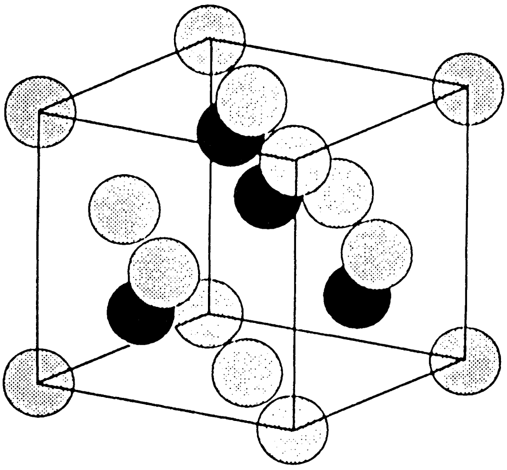

FIG. 16. Atomic packing in the diamond lattice. The light and dark shaded spheres represent atoms on the two fcc sublattices which are displaced along a body diagonal by $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$.

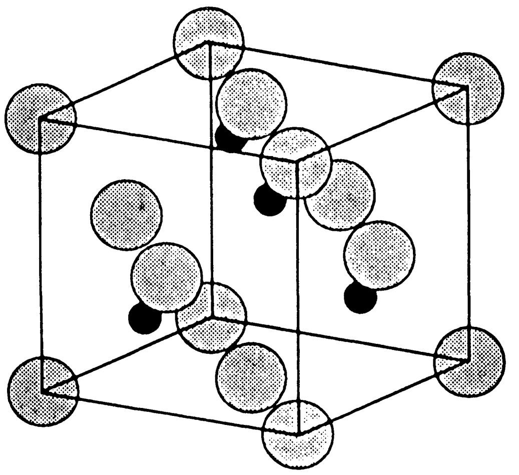

FIG. 17. Packing of different size atoms in the cubic ZnS lattice. The large spheres represent Zn while the small spheres represent the S atoms. Note the similarity to the diamond structure.

ture, we see planes of atoms of the same species stacked in the *ABCABCABC...* sequence. These same planes, stacked in the *ABABABAB...* sequence along the [001] direction, are the basal planes of the wurtzite structure. The space lattice of the wurtzite compounds is hexagonal with four atoms per unit cell. One species is situated at the position (0,0,0) and $(\frac{1}{3},\frac{2}{3},\frac{1}{2})$, while the other is found at $(0,0,u)$ and $(\frac{1}{3},\frac{2}{3},\frac{1}{2}+u)$. The offset u depends upon the compound but is close to $\frac{3}{8}$.

1.4.3 The Sodium Chloride and Cesium Chloride Structures. Many ionic solids crystallize into the NaCl or CsCl structures (Fig. 18). In the *sodium chloride* arrangement, each ion is coordinated by six oppositely charged ions in an octohedron. The space lattice is face-centered cubic with the halogen at positions (0,0,0) and the alkali atom at $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. The *cesium chloride* structure is simple cubic with the alkali ion at (0,0,0) and the halogen at $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. Each ion is coordinated by a cube of eight ions of opposite charge.

1.4.4 The Calcium Fluoride Structure. Many compounds of the form AB_2 crystallize in the CaF_2 structure (Fig. 19). The space lattice is fcc with a two-point basis and eight atoms per unit cell. The structure may be viewed as three interpenetrating fcc sublattices. Atoms of type A, and half of the B atoms, are found in the ZnS arrangement described

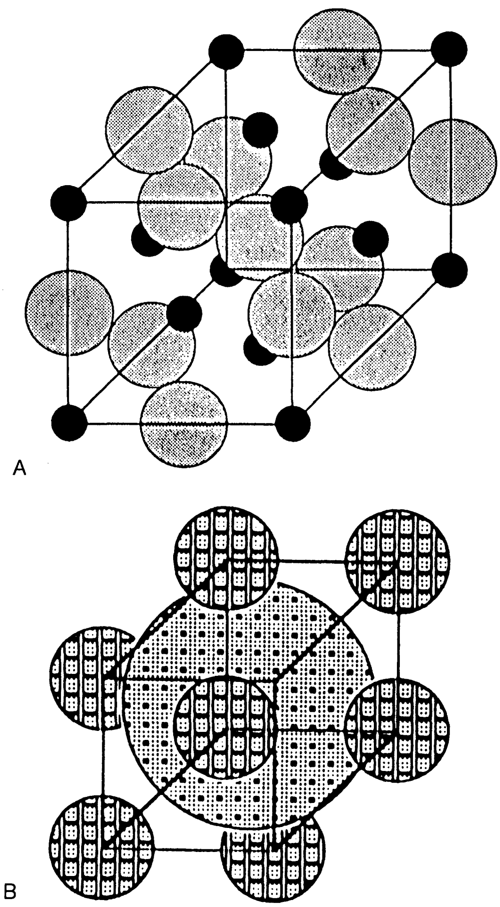

FIG. 18. The (a) sodium chloride and (b) cesium chloride structures.

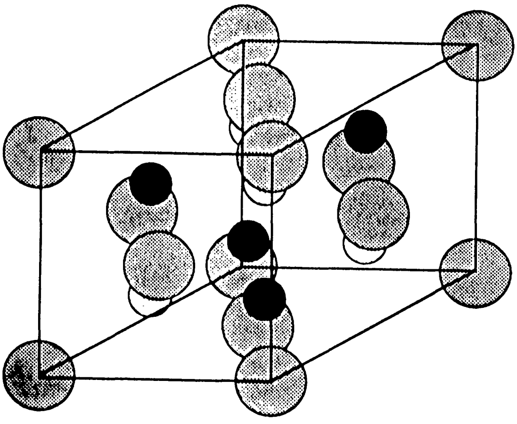

FIG. 19. The CaF_2 structure. Ca atoms are found at the corners of the cubic cell. Half of the F atoms (lightly shaded) are found at the *S* sites of the ZnS arrangement,and the remaining F (darkly shaded) are located on the third fcc sublattice as described in the text.

in Sec. 1.4.2. The remaining B atoms are found at positions $(-\frac{1}{4},-\frac{1}{4},-\frac{1}{4})$ plus face-centered translations. Each A atom is coordinated by a cube of eight B atoms, and each B atom is found within a tetrahedron of A atoms.

1.5 More Complicated Crystal Structures

All of the crystalline structures described in the last few sections are relatively simple, involving only a few atoms per unit cell. It is important to realize that this is not the general case. Unit cells with tens, hundreds, or even thousands of atoms are not uncommon and a description of the local environment of a particular component may be quite difficult. As an example, consider the structure of Al_6Li_3Cu illustrated in Fig. 20. The space lattice is bcc ($a = 13.9$ Å) with 160 atoms in the unit cell. The structure may be more simply described as a bcc packing of clusters of atoms centered at the corners and body center positions. Each cluster contains 105 atoms and has the shape of a truncated icosahedron.

1.6 Surface Structures

The surface of a crystal contains only a very small fraction of the total number of atoms in the solid, but is of importance since it represents the interface between the bulk crystal and its external environment. The structure of the surface layers may be essentially unchanged from that of the bulk crystal except for some modification in layer spacing due to the absence of atomic layers above the surface. On the other hand, there may be significant *reconstruction* of the surface, so that the top layer is out of registry with lower lying layers.

The structure of the surface layer may be cast in terms of one of the 17 space groups detailed in Sec. 1.1.2. Figure 21 shows three possible configurations, or *nets*, for the fcc (111) or hcp (001) surfaces. Here we imagine that the surface atoms are placed at the intersections of the net. The $p(1\times1)$ net is an unreconstructed surface. The $p(2\times2)$ net represents a reconstructed surface with primitive translation vectors twice as long as those of the unreconstructed $p(1\times1)$ net. The $(\sqrt{3}\times\sqrt{3})R30°$ net is also a reconstruction with translation vectors $\sqrt{3}$ times longer than the $p(1\times1)$ net, and rotated 30° with respect to the in-plane translation vectors of the bulk.

1.7 Incommensurate Crystals and Quasicrystals

While the crystal structures of the vast majority of elements, compounds, and alloys we encounter may be classified in terms of one of the 230 three-dimensional space groups, these do not exhaust all of the possibilities.

Incommensurate solids are materials which do not have periodic translational order but exhibit only the crystallography allowed rotational symmetries. As the term implies, incommensurability is derived from a periodic crystalline structure through the modulation of some property of that solid. The modulation itself often results from interactions which have a periodicity that is different from that of the basic lattice. In metals, e.g., instabilities can arise from interactions between the conduction electrons resulting in a modulation of the density of electrons in the solid (a charge density wave). The charged ion cores are also driven to readjust their position through their interaction with the electron gas. Therefore, as illustrated schematically in Fig. 22, the positions of like atoms in neighboring unit

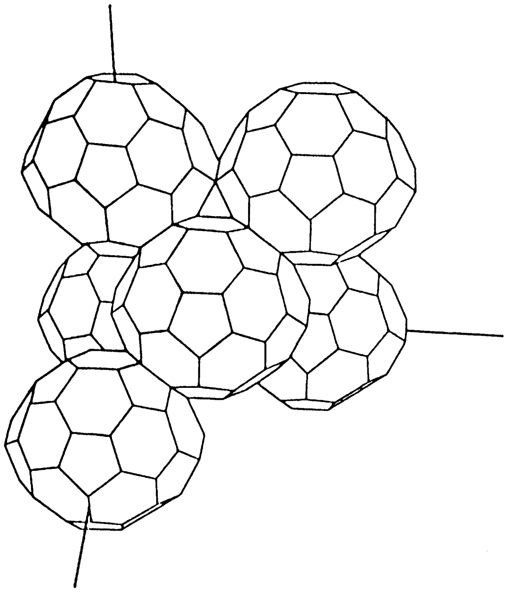

FIG. 20. The cubic phase of Al_6Li_3Cu may be viewed as a bcc packing of clusters of 105 atoms in the shape of a truncated icosahedron. Only the overall shape of the clusters is shown.

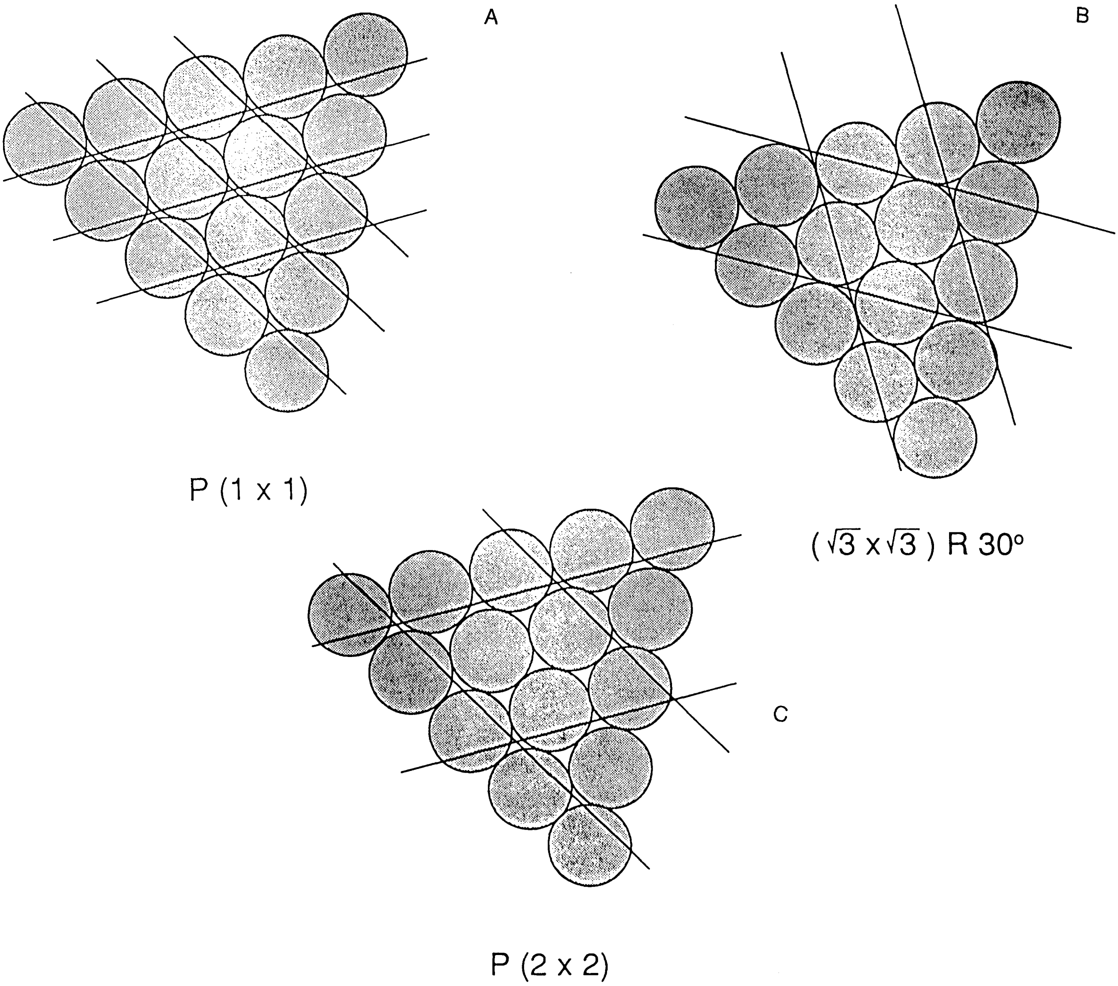

FIG. 21. Two-dimensional nets on the surface of the (111) planes of an fcc structure or (001) planes of an hcp structure.

cells are no longer connected by a simple translation vector, but by a translation plus a displacement from the average position. This displacement is also periodic, but may not have a period that is some rational multiple of the underlying lattice. In general, the incommensurability of the structure varies as a function of temperature and may exhibit "lock-in" transformations to a commensurate structure at particular temperatures.

Quasicrystalline solids not only lack periodic translational order, but exhibit rotational symmetries (e.g., five-fold rotation axes) which are crystallographically forbidden. The first quasiperiodic solid was discovered in 1984 in an alloy of aluminum and manganese with icosahedral symmetry (see Fig. 23). Since the icosahedral group admits rotations of $\pi/5$, the structure is inconsistent with any of the 230 periodic space groups discussed in Sec. 2.2. It is important to note, however, that the lack of periodic translational order does not imply that these materials are disordered glassy solids. For example, Fig. 24 shows a one-dimensional quasiperiodic Fibonacci sequence of atoms separated by two distances, $L(=\tau)$ and $S(=1)$. The sequence of atomic positions, R_n, from some origin may be defined by the rule

$$R_n=\frac{n}{1+1/\tau^2}-\frac{1}{\tau}\{n\tau\},$$

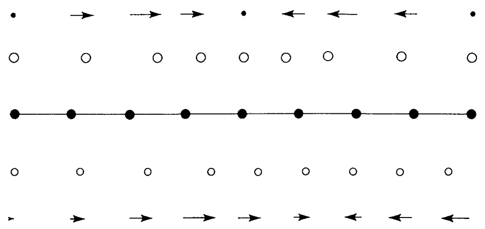

FIG. 22. One-dimensional modulated structures. The filled circles represent the atomic positions in the absence of a modulation, while the open circles denote the modulated structure. Top: The period of the modulation is a rational multiple of the underlying lattice. Bottom: The modulation is incommensurate with the underlying lattice.

where $\tau=\frac{1}{2}(\sqrt{5}+1)$ is known as the golden mean, n is an integer, and the curly braces denote the fractional part of the enclosed expression. The very existence of a rule specifying the atomic positions means that the structure is well-ordered, albeit aperiodic. Since our example here is one dimensional, the idea of forbidden rotational symmetries does not enter the discussion. Therefore, the Fibonacci sequence is perhaps more correctly described as an incommensurate structure. In two dimensions, however, one can construct a quasiperiodic tiling of the plane which is closely related to the one-dimensional Fibonacci sequence, using two rhombic "unit cells." The *Penrose tiling* shown in Fig. 25, or rather its three-dimensional cousin, is one of the candidate structures for the icosahedral alloys.

2. BINDING FORCES AND COHESIVE ENERGY

Having described and discussed the various classifications of crystalline solids, we now turn to a description of the interactions which bind atoms together into these structures. Binding forces act to lower the free energy of the solid with respect to an assembly of isolated atoms. The *cohesive energy* (*q.v.*) of a solid is, in fact, defined as the difference in total energy between the solid and its isolated constituents.

2.1 The Van der Waals–London Interaction

The weakest of the crystal binding forces is found in the inert-gas solids such as krypton, neon, xenon, and argon. These atoms have closed-shell configurations and are highly stable. When two atoms closely approach each other, however, an attractive interaction can result from induced dipole moments. This attractive interaction is a strongly decreasing function of interatomic separation (R), falling off as R^{-7}. There is also, of course, an even shorter-range repulsive interaction which results from electron overlap at very small separations. Taken together, the two terms combine to yield a total energy for the solid which is usually written as

$$U(r)=2\epsilon\left[A_{12}\left(\frac{\sigma}{R}\right)^{12}-A_6\left(\frac{\sigma}{R}\right)^{6}\right],$$

and is known as the Lennard-Jones 6-12 potential. Here σ and ϵ are parameters derived from the gaseous state data, and the constants A_{12} and A_6 depend upon the crystal structure. It should be pointed out that the $1/R^{12}$ dependence of the repulsive energy is introduced for calculational convenience and because it seem to work well for the description of binding energies in the inert-gas crystals. In fact, we only require that the repulsive interaction be much shorter-ranged than the attractive forces, and other forms for this term have been used.

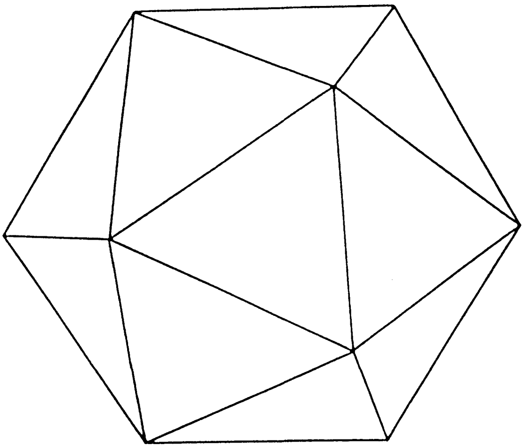

FIG. 23. An icosahedron is characterized by 12 vertices (fivefold axes), 20 triangular faces (threefold axes), and 30 edges (twofold axes).

FIG. 24. A one-dimensional quasiperiodic Fibonnaci sequence. Atoms are separated by either a long (τ) or short (1) distance. The ratio of the number of L to S separations approaches τ as the length of the sequence increases.

All of the inert-gas solids crystallize into the fcc structure, and are characterized by binding energies on the order of 0.01 eV per atom. Since the binding is weak, solidification takes place only at low temperatures (< 10 K) and zero-point fluctuations play an important role in the stability of these structures. Since there are no free electrons in these solids, they are extremely good insulators.

2.2 Ionic Bonding

For ionic crystals, the dominant contribution to the binding energy is the interionic Coulomb attraction. NaCl is an example of a purely ionic solid; a Na 3s electron is transferred to fill the 3p shell of Cl, resulting in a positively charged Na^+ and negatively charged Cl^-. The stability of the structure is owed to the fact that the total energy decrease due to the interionic electrostatic attraction is greater than the energy required to transfer electrons between isolated neutral atoms. The electrostatic interaction is much stronger than the dipole interaction, and is longer ranged (the electrostatic force decreases like $1/R^2$). The total cohesive energy, including a term for the repulsive interaction between ion cores at small separation, can be written as

$$U(R)=C/R^n-\alpha q^2/R.$$

Here, C is a constant that can be determined from the known equilibrium separation of the ions and q is the net charge of the ions. The *Madelung constant* α essentially sums the contributions to the electrostatic potential between an ion and all of its neighbors (both near and distant).

In contrast to the weakly bound inert-gas crystals discussed above, ionic crystals are usually hard and have high melting points. Since the excess charge is highly localized around the negative ion, there are no free electrons to carry charge. Ionic crystals, in the absence of defects such as vacancies, are therefore poor conductors.

Alkali halide ionic solids crystallize into either the sodium chloride or cesium chloride cubic lattice (see Sec. 1.4.3). Although most crystallize into the NaCl structure, it is interesting that the electrostatic contribution to the cohesive energy is actually a bit larger (by about 1%) for the CsCl structure. The repulsive interaction between ions, however, increases with increasing coordination number and slightly favors the NaCl arrangement. The particular choice of structure is largely governed by the relative sizes of the ions.

2.3 Covalent Bonding

Covalent bonding in crystals is characterized by the sharing of electrons between constituent atoms. For instance, the 2p orbital of carbon, the 3p orbital of silicon, and the 4p orbital of germanium are all four electrons short of being filled. The energy of an assembly of carbon atoms, e.g., can be lowered by overlap between the unfilled orbitals, thereby sharing the valence electrons. Because of this sharing, the charge distribution is not completely localized around each ion as is found

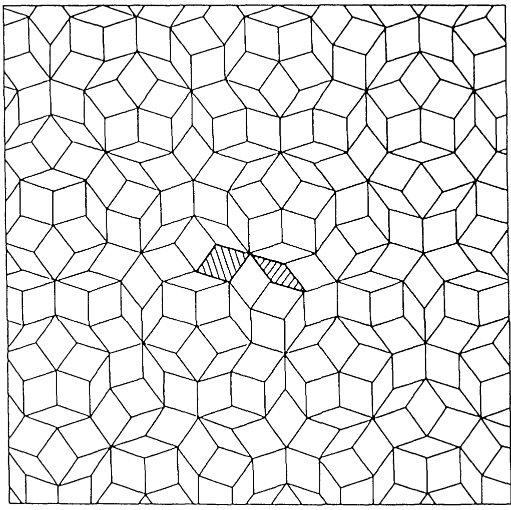

FIG. 25. A two-dimensional Penrose tiling of "fat" and "skinny" rhombuses. Note the presence of local regions with clear fivefold rotational symmetry. The three-dimensional analog of this tiling is one model for the icosahedral phase alloys.

for the ionic crystals. In particular, substantial electron density is found in the interstitial region between atoms. Covalent bonds are highly directional, forming tetrahedrally coordinated structures of the diamond lattice type (see Sec. 1.4.2), and very strong, making them hard and difficult to deform. Since the electron distribution is at least partially delocalized in covalent bonding, covalent crystals are not as good insulators as the ionic or inert-gas crystals. All semiconductors (i.e., Ge, Si, GaAs, etc.) are fully, or nearly, covalent.

For some other compounds, the cohesive forces may best be described as mixed ionic and covalent bonding. The bonding in systems such as ZnO, ZnTe, BeO, ZnSe, CdS, and CdTe, e.g., is characterized as $\approx$60%–70% ionic. The first three crystallize into the hexagonal wurtzite structure and the latter three are found in the cubic zinc-blende structure (see Sec. 1.4.2). At the other end, the bonds between atoms in semiconductors such as InAs, GaAs, and GaSb are described as mostly covalent with some ionic character.

2.4 Metallic Bonding

Metallic bonds differ from the covalent bonds of semiconductors in that the valence electrons are shared among all atoms in the crystal and are relatively free to wander through the crystal lattice. This accounts for the good conductivity of metals. The mechanisms which give rise to metallic bonding are complex and must account for the interaction between the ion cores and the electron gas, as well as the interaction between the electrons themselves. Since the electrons are not assigned to any particular ion core, or pair of ions, metallic bonds are nondirectional. Therefore, metals tend to crystallize into the dense, highly symmetric arrangements—the close-packed structures described in Sec. 1.4.1.

3. DEFECTS IN CRYSTALS

The Gibbs free energy of a system at some temperature, T, may be written as $G=H-TS$. At $T=0$ K an ideal crystal, free of defects, is the state of minimum free energy. Defects increase both the enthalpy H and the entropy S of a system. Consequently, the free energy can be a minimum for a crystal with defects at finite temperature. Even for cases in which G is not a minimum, however, defects in crystals may be stabilized for kinetic reasons since their removal usually requires the diffusion of atoms.

All real crystals contain defects. One must keep in mind, though, that in many cases the presence of defects is not undesirable. For instance, pure semiconducting crystals of Si require the intentional addition of certain impurities to become useful solid-state devices. The presence of dislocations at the surface of a crystallite generally enhances the rate of growth at the solid–liquid interface.

3.1 Vacancies, Interstitials, and Impurities

The simplest defect is a *vacancy*. As illustrated in Fig. 26, a vacancy corresponds to an empty site in the structure which is normally occupied in the ideal crystal. Another simple point defect corresponds to an atom situated at an *interstitial position,* not normally occupied in the ideal crystal.

The concentration of isolated defects in thermal equilibrium may be calculated if we know the energy E required for their formation. For N atoms in the crystal, the number n of defects of some particular type is given by

$$n=Ne^{-E/k_BT},$$

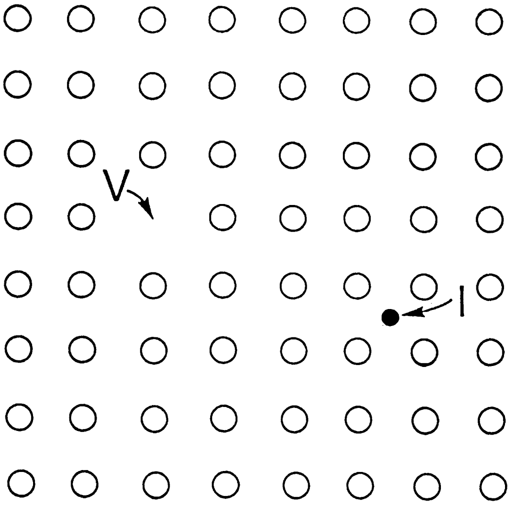

FIG. 26. A schematic illustration of simple defects in a monatomic Bravais lattice. The absence of a circle denotes a vacancy, while the filled circle represents an interstitial atom.

where k_B is the Boltzmann constant and T is the temperature. Similar calculations for clusters of defects are more complicated since the presence of one defect may influence the energy required to form another nearby. There may be other constraints placed on the number and type of simple defects in crystals. For instance, the relative number of positive-, or negative-ion vacancies of interstitials in ionic crystals is regulated by the requirement of charge neutrality.

Chemical impurities can play a crucial role in modifying the physical properties of materials, even in minute concentrations. The electrical properties of semiconductors, e.g., depend largely upon the number of electrons that can be excited across the narrow energy gap separating the valence band from the conduction band. Electrons can be excited across this gap thermally (so that the conductivity of semiconductor increases with temperature), or by an applied electric field. The intentional addition of certain chemical impurities can introduce energy levels within the gap close to either the valence or conduction band, thereby reducing the temperature or applied potential required to populate the conduction band, or alternatively, depopulate the valence band. Chemical impurities may be either *substitutional*, sitting at a site normally occupied by an atom of the pure crystal (e.g., an arsenic impurity at a germanium site in a germanium crystal), or interstitial.

3.2 Chemical Disorder in Alloy Systems

In *ordered alloy* systems, specific sites are assigned to the constituent elements (Fig. 27). For instance, at low temperature, the equiatomic alloy of CuZn (brass) is chemically ordered and may be described as simple cubic with the copper atoms situated at the corners of the cube and Zn atoms at the body center (the CsCl structure). As the temperature of this system is raised above some critical temperature, T_C, there is an *order–disorder transformation* (see ORDER–DISORDER TRANSITIONS) which results in a mixing of the Cu and Zn sites. That is, both the corner and body center sites are occupied by copper or zinc with equal probabilities. The structure is then more correctly described as body-centered cubic. If this alloy is cooled rapidly from some temperature above T_C, the high-temperature phase may be "frozen in," resulting in a metastable disordered phase with some degree of *site-exchange disorder*.

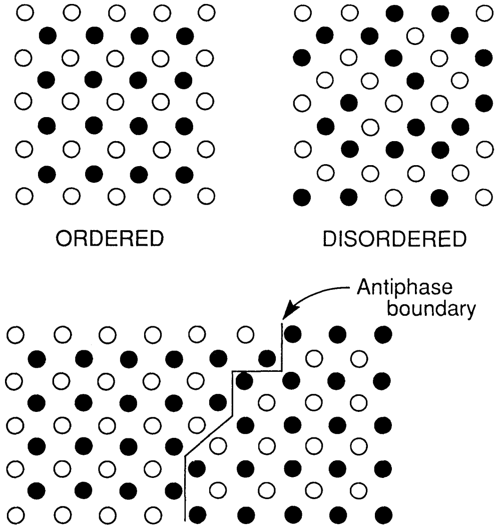

FIG. 27. Ordered (left) and disordered (right) alloys of A (open circles) and B (closed circles) atoms. The full line in the bottom panel represent an antiphase domain boundary between two ordered domains.

Antiphase domains may also occur in chemically ordered alloys. The sites of A and B atoms within any given domain are well-defined, but the A sites in one domain become the B sites in the adjacent domain (Fig. 27).

3.3 Stacking Faults and Line Defects

In contrast to the situation for point defects, extended defects in crystals are metastable since the energy required for their formation is not fully compensated by the increased entropic contribution to the free energy. Therefore, most extended defects may be removed by appropriate heat treatment or *annealing*.

A common defect found in fcc and hcp metals is the *stacking fault*. As described in Sec. 1.4.1, both structures may be viewed as a stacking of close-packed atomic planes. The layer sequence *ABCABCABC...* corresponds to the stacking of planes along the [111] direction of the fcc lattice, while the sequence *ABABABAB...* corresponds to layers stacked along the [001] direction of the hcp lattice. There are, in fact, an infinite number of such possible sequences which correspond to the intermixture of local fcc or hcp order. For instance, the sequence *ABCABABCABCABC...* corresponds to an fcc crystal with a stacking

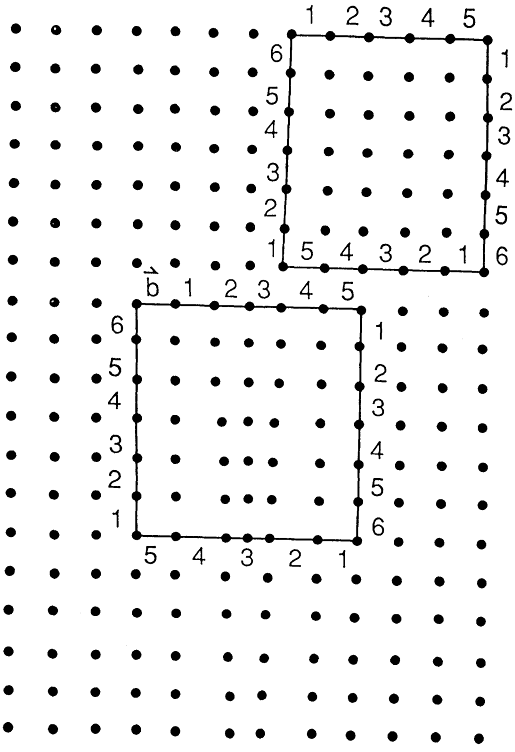

FIG. 28. An edge dislocation. The solid line at the upper right shows a Burgers loop around a defect-free region of the crystal. The solid line in the middle describes the same set of translations around the edge dislocation. The Burgers vector of the dislocation is indicated by the arrow which closes the loop.

fault (a missing *C* layer in the sixth position), which produces a local region of hexagonal order.

These sequences may be used to describe another type of planar defect commonly seen in crystals, termed a *twin*. Consider the sequence of layers *ABCABCACBACBA*..., where the ordering of the layers reverses after the seventh layer. The sequences on either side of this *twin boundary* are mirror images.

Line defects, also termed *dislocations*, have a profound effect upon the mechanical properties of crystals. An *edge dislocation*, depicted in Fig. 28, may be constructed by removing a plane of atoms from one-half of the crystal, leaving the other half unmolested. Alternatively, one may view an edge dislocation as arising from the insertion of a half-plane of atoms. The *dislocation line* runs parallel to the end of the half-plane, out of the plane of Fig. 28. Note that in order to maintain long-range order throughout the entire crystal, the two halves of the crystal must be rejoined so that, near the dislocation line, atoms are crowded together on one side and pushed apart on the other. The presence of edge dislocations greatly reduces the crystal's resistance to shear deformation since the mobility of this defect is quite high. Dislocations may be pinned, however, by impurities.

If we cut partway through a crystal, and then shear the two halves of the cut as shown in Fig. 29, the resulting defect is termed a *screw dislocation*, defined by the dashed line in the figure. At the surface of the crystal, a screw dislocation produces a ledge. Sites immediately adjacent to the ledge on the surface are particularly favorable for the addition of new atoms. Therefore, screw dislocations perform the important function of providing nucleation sites for the next layer of surface atoms during the growth of a crystal from the melt (see Sec. 4). The surface of the crystal grows in a spiral fashion around the dislocation line.

Other extended defects may be formed from combinations of edge and screw dislocations, and may be described by a *Burgers vector*. The Burgers vector is defined by constructing a closed path around the region of the dislocation. In a perfect crystal, a closed loop may be accomplished by a series of translations through the Bravais lattice vectors as shown in Fig. 28. If a dislocation is present within this region, the same sequence of translations will not yield a closed loop. The vector joining the end of the sequence to

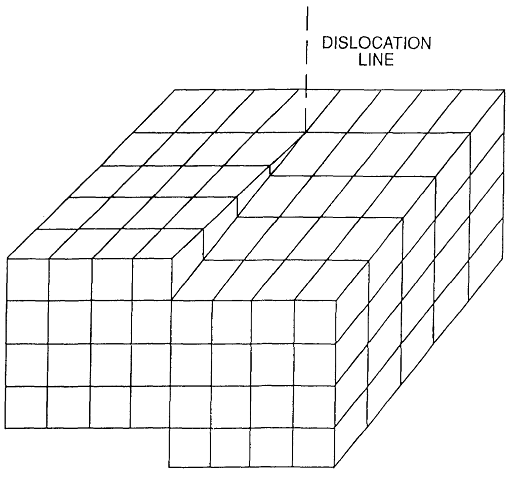

FIG. 29. A screw dislocation. The dislocation line is indicated by the dashed line.

the beginning is the Burgers vector of the dislocation. The Burgers vector is perpendicular (parallel) to the dislocation line characterizing an edge (screw) dislocation.

Low-angle *grain boundaries* are extended defects that separate crystallites, and may be constructed from arrays of edge dislocations. The relative orientation of the two crystallites depends upon the Burgers vector and spacing of the array of dislocations. The presence of grain boundaries often enhances reactions in solids since they provide easy pathways for the diffusion of atoms.

4. CRYSTALLIZATION

In this section, we are primarily concerned with the growth of crystals via a first-order transformation from a liquid phase (see PHASE TRANSITIONS). Below the melting point, the free energy of the well-ordered crystalline phase is lower than that of the liquid, favoring crystallization.

In the next sections, we consider only the case of transformations between a single-phase liquid and a single-phase solid at the same composition. More complex transformations, such as the solidification of eutectic alloys, will not be addressed here.

4.1 Nucleation

There are two distinct stages in the crystallization process: nucleation and growth. For the case of *homogeneous nucleation*, seeds of the new crystalline solid are dispersed uniformly throughout the volume of the melt. The formation of these nuclei is a dynamic process where microscopic regions of crystalline order form and then dissolve through thermal fluctuations. The growth of atomic clusters of the crystalline phase is favored by its lower bulk free energy, but inhibited by the unfavorable positive free energy associated with the surface of the cluster. Since the surface-to-volume ratio decreases with increasing cluster size, clusters larger than some critical radius are stable and can grow; they become the nuclei of the solid phase.

The nucleation process can be enhanced by the presence of interfaces or foreign particles in the liquid. *Heterogeneous nucleation* occurs when the seeds of the solid phase form about these defects, offsetting the positive surface energy of the cluster with the decrease in free energy associated with removing the defect. This process is analogous to "seeding" a cloud with foreign particles to nucleate rain drops.

4.2 Growth

Once nuclei are formed, their growth is controlled by a complex array of processes at the interface between the nuclei and liquid. These include the success of atoms in finding the proper sites on the surface of the crystallite; the probability that atoms will "stick" to this site; and the rate at which excess energy, released in the form of heat once the atom joins the cluster, is removed from the region of the interface.

For some period of time after nucleation, the crystallites grow independently at a rate controlled by the factors mentioned above. As the size of the crystallites increases, neighboring crystallites of different orientations will come in contact. At low enough temperatures (e.g., relatively fast cooling rates), polycrystalline material results. At a high temperature, however, the larger grains can grow at the expense of smaller grains yielding a finite number of single crystals. Certain techniques can be used to promote the growth of large single crystals.

The morphology of grain growth in a liquid medium depends largely upon the rate of cooling. For strong departures from equilibrium conditions, such as large undercooling, grains can be highly irregular or *dendritic*, consisting of tree-like projections into the melt (Fig. 30). These dendrites have a preferred orientation, with their axes along the direction of fastest growth (e.g., the [100] direction in fcc metals).

Under conditions closer to equilibrium, the grain often develops into a well-defined polyhedron closely related to the symmetry of the underlying crystal lattice. *Faceted interfaces* occur along directions of slow growth (Fig.

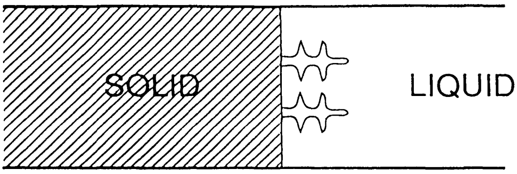

FIG. 30. Dendritic growth at a solid–liquid interface.

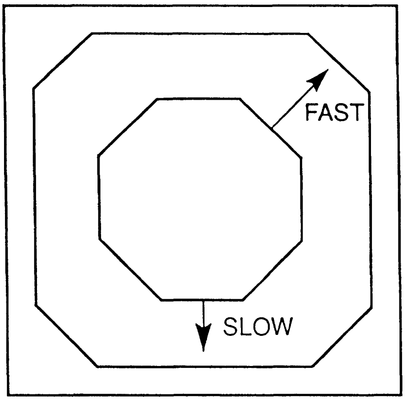

FIG. 31. The development of facets during the equilibrium growth of crystals. Note that the faces perpendicular to the slow growth directions dominate the shape of the crystal at later stages of growth.

31) which generally correspond to directions normal to the most dense planes of the structure. In an fcc metal, e.g., faceting is most likely to occur along the [111] directions.

4.3 The Recrystallization of Glasses

If the rate of undercooling is extremely large, the liquid can solidify into a glassy structure. The recrystallization of glasses often proceeds in a manner analogous to the nucleation and growth process described above. At temperatures far below the melting point, the free energy of the crystalline phase is significantly lower than that of the glass. Crystallization is inhibited, however, by slow kinetics (atoms have to move some distance to effect the transformation). As we heat the system above the glass transition temperature T_g, seeds of the crystalline phase nucleate and grow. Since the difference in free energy between the glass and crystal is so large, the rate of homogeneous nucleation in the glass phase is much larger than that found for liquids; the critical size for nuclei is much smaller. Recrystallized glasses, therefore, are generally much finer-grained than crystals grown from the melt.

5. SUMMARY

In this article, some of the basic features and language of crystalline solids including crystal structure, binding forces, defects, and growth have been introduced. All of these topics have been the subject of intense investigation over the past century which has led to the development of important new technologies such as semiconductor devices. Given the brevity of this article, many interesting and important topics could not be covered in any detail. The reader is referred to the list below for a more comprehensive treatment of the subject.

INTRODUCTION

Crystallography is the science of crystals and crystalline materials, which include most terrestrial and industrial solids. The science includes the study of crystal structure on an atomic scale and also the shapes, forms, defects, growth, transitions, and properties of crystals. Chemical analysis to determine the elemental composition of a substance and the determination of its crystal structure are the important experiments of the solid state. Principally, x-ray- or neutron-diffraction experiments are used to determine crystal structures, that is to say, the crystal symmetry, the relative positions, and the elemental nature and arrangement of the atoms in the structure. X-ray diffraction by a crystal was first demonstrated in 1912, following the discovery of x rays by Röntgen in 1896. Nevertheless, using earlier mathematical developments and measurements of the angles between the faces of crystals, all of the rudiments of three-dimensional crystal symmetry had been worked out by this time and were at hand to be applied to the new atomic-scale crystallography. Prominent among these early developments were observations on crystal form by René Haüy (1784), Wollaston's (1809) construction of the optical goniometer, Hessel's (1830) demonstration of the 32 symmetry classes, Bravais's (1848) demonstration of the 14 lattices, Sohncke's (1867) discovery of new symmetry elements, and finally, the derivation of the 230 space groups independently by Schoenflies (1891) and Fedorov (1891).

Thus, when in 1912 von Laue, Friedrich, and Knipping demonstrated the diffraction of x rays by crystals, the door was opened to the possibility of gaining exact information on the

arrangement of atoms within a crystal. This discovery was rapidly followed by the Braggs' (1913) interpretations of their experiments on rocksalt and other crystals; however, the wavelengths of characteristic x radiations still had to be determined. So began a science of the most fundamental significance. The history of crystallography is complicated and enlightening, and a short description thereof can be found in *Fifty Years of X-Ray Diffraction* by Ewald (1962). Over the years the subject became so important that in 1947–48 the International Union of Crystallography (I.U.Cr.) was created to be concerned with all viable aspects of crystallography through its Commissions, its triennial General Assembly and convention, and its publishing activities.

Much of the realm of crystallography is covered in specific articles elsewhere in the *Encyclopedia,* and some of these articles are cross-referenced in the text. Therefore this article introduces crystallography to the general reader, providing an overview, yet without sacrificing physical and mathematical precision to simplicity. With very many known crystal structures at hand, we can only illustrate this article with information on a few simple types, upon the basic structural principles of which many more complex types are formed.

Finally, it is observed that the rate at which the current technological and medical revolutions are proceeding results in no small degree from the information provided by crystallographic studies.

1. THE CRYSTALLINE STATE

A crystal is characterized by a long-range order. That is to say, the atomic arrangement is periodic in a three-dimensional space throughout the crystal (see CRYSTALLINE STATE). Other solid material may be amorphous, so that there is only short-range order that extends merely for a few shells of atoms in the surroundings of any given atom (see AMORPHOUS MATERIALS, STRUCTURE OF).

Any solid that one views is likely to be made up of crystals and/or amorphous material, and of crystals of more than one type and chemical composition. A compound may exist in the form of gas, liquid, or several forms of solids. Each of these has been conventionally called a *phase,* which is a homogeneous portion separated by a boundary from other portions in a multicomponent system. Thus, the term *crystal* here is the solid of a *single phase,* and the term *crystal structure* refers to the geometry, symmetry, and the arrangement of atoms or molecules of the phase. The solid of a single phase generally is composed of many independent crystals, variously oriented with respect to their symmetry axes, the whole being joined solidly together. Such a state is referred to as *polycrystalline* (see GRAIN BOUNDARIES). In general, solids may also contain crystals of several compounds with quite different chemical compositions and crystal structures or several types of crystals of the same compound. When an element or chemical compound, e.g., SiO_2, exists in several different structural arrangements, this is known as *polymorphism* (see PHASE EQUILIBRIA and PHASE TRANSITIONS). A phase is stable at some temperatures and pressures, and a metastable phase stays indefinitely at temperatures and pressures in which it is energetically unfavorable. Phase transitions take place by changing either the temperature or the pressure or both (see HIGH-PRESSURE EFFECTS IN SOLIDS). For example, diamond, the metastable phase at room temperature and pressure, must be synthesized at high temperature and pressure.

When one sets out to determine the atomic arrangement of a crystal, one not only seeks a sample of the solid that is pure (i.e., that does not also contain crystals of other compounds), but one that is a single crystal, wherein one crystal orientation extends throughout the solid. This is a practical requirement (see CRYSTAL GROWTH), as the diffraction patterns from polycrystalline samples confuse the data analysis since crystal orientation is random, thus limiting the useful information obtainable.

A crystalline arrangement of atoms is described by the laws of symmetry, which include the translation operations. Theoretical consideration of crystal symmetry verified 230 *space groups* (see Sec. 1.4), to one of which the crystal structure must belong. Although the number of space groups is limited, the number of different crystalline arrangements is essentially unbounded. This is because these laws permit continuously variable atom positions to be assumed, although they are fixed in any particular crystal structure.

Furthermore, the positions can be occupied by any combinations of about 100 natural and manmade elements.

A periodic crystalline arrangement gives rise to well-developed crystal faces of single crystals that are independently grown. These faces display the symmetry elements inherent in the crystal type. Sometimes such crystals exhibit a phenomenon known as *twinning,* where, for example, two different orientations are related by a *mirror plane,* whereon they unite coherently.

A crystal may contain organized coherent defects such as twinning, or a given crystal structure may be composed, e.g., of layers of two simple structural types that join coherently and repeat in regular sequence (see IMPERFECTIONS IN CRYSTALS). It may also exhibit irregular or random defects; indeed a polycrystalline material exhibits such defects along the boundaries of the crystallites of different orientations. In other crystals where the atoms occupy ordered sites, the ordering may "get out of step," e.g., be displaced in one region of the crystal compared to another, either on a random or regular basis. Regular ordering sequences or regular atom-displacement sequences may cause a *superstructure,* where a new unit cell that recognizes the regular ordering or displacements relative to the basic unit cell (see Sec. 1.1) may require multiplication of the edges by 2, 3, etc., along the axes **a**, **b**, or **c** concerned. Thus the ordered tetragonal Al_3Ti is an F_{112} superstructure (multiplication $2\times\mathbf{c}$) of the cubic copper structure, *F* (see Sec. 1.2 and HETEROSTRUCTURES AND SUPERLATTICES, METALLIC; HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR).

Liquid crystals are ordered fluids. The ordering in one, two, and three directions gives rise to phases called *nematic, smectic,* and *cholesteric* liquid crystals, but they are not considered solid states (see LIQUID CRYSTALS). On the other hand, the recently discovered *quasicrystals* are solids, but their symmetry and geometry do not follow those observed for crystals. Nevertheless, their existence was confirmed by diffractions, which proclaimed the presence of noncrystallographic fivefold symmetry (see Sec. 1.3) axes in these solids (see QUASICRYSTALS).

1.1 Unit Cells and Crystal Systems

Since a single crystal is an aggregate of millions of atoms periodically arranged in space, systematic methods of description have been devised. The first thereof is the *unit cell,* which is (generally) the smallest parallelepiped that stacked repetitively in three dimensions generates the structure of the crystal, regardless of the atomic content within the parallelepiped. This unit cell is defined by three noncoplanar vectors of magnitudes a, b, and c and three angles between them, α, β, and γ (Fig. 1). Such unit cells must belong to one of seven *crystal classes* that are defined purely by symmetry, although they also have metrical constraints as indicated in Table 1. Thus even though a unit cell may have $a=b=c$ and $\alpha=\beta=\lambda=90°$, if the atomic arrangement does not exhibit at least the minimum symmetry of a cubic system (*point group* 23, see Sec. 1.3), the unit cell must belong to a class lower than cubic. Further remarks on the choice of unit cells are made in the next section.

1.2 Lattices

The concept of a *lattice* is essential to the study of crystal structure. A lattice is an infinite periodic array of points at the termini of the vectors $\mathbf{L}_{uvw}=u\mathbf{a}+v\mathbf{b}+w\mathbf{c}$, where **a**,**b**,**c** are the three noncoplanar vectors defining a primitive unit cell and u,v,w are integers. Thus the integers $[uvw]$ are used to define a lattice direction (note the use of [ ] to define directions, whereas ( ) are used to define lattice planes (see Sec. 1.5)).

There are seven primitive lattices (one lattice point per cell) corresponding to the seven crystal classes. However, because of

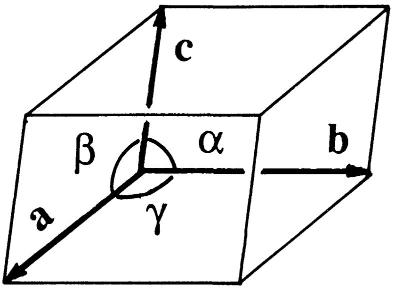

FIG. 1. Quantities a, b, c, α, β, and γ used in defining a unit cell. A right-handed coordinate system is always used.

Table 1. Axial and angular relationships, characteristic symmetry, and the 14 Bravais lattice types of the seven crystal systems.

System	Axial and angular relationships	Min. symmetry and (point group)[a]	Lattice type and symbol[b]
Triclinic	$a \neq b \neq c$; $\alpha \neq \beta \neq \gamma \neq 90°$	$1(\bar{1})$	P
Monoclinic	$a \neq b \neq c$; $\alpha = \gamma = 90° \neq \beta$	$2(2/m)$	P,C[c]
Orthorhombic	$a \neq b \neq c$; $\alpha = \beta = \gamma = 90°$	$222\ (mmm)$	P,I,F,C[d]
Tetragonal	$a = b \neq c$; $\alpha = \beta = \gamma = 90°$	$4(4/mmm)$	P,I
Cubic	$a = b = c$; $\alpha = \beta = \gamma = 90°$	23[e] $(m3m)$	P,I,F
Trigonal	$a = b = c$; $\alpha = \beta = \gamma$	$3(\bar{3})$	R
Hexagonal	$a = b \neq c$; $\alpha = \beta = 90°$, $\gamma = 120°$	$6(6/mmm)$	P

---

[a] The point group is the maximum symmetry.

[b] Lattice symbols: *P*, primitive; *C*, *ab*-face centered; *I*, body centered; *F*, all-face centered; *R*, rhombohedral.

[c] Lattice type *C* is for *b*-axis unique or *A* for *c*-axis unique.

[d] Depending on the choice of axes, lattice type *A* (*bc*-face centered) or *B* (*ca*-face centered) may also be assigned.

[e] The twofold and threefold axes for cubic are along the face and body diagonals, respectively. The angle of intersection is 35.26°.

symmetries permitted in some of these lattices, it is more convenient for structural description to choose the face-centered lattices *A*, *B*, or *C*, the body-centered lattice *I* (all with two lattice points per cell), and the all-face-centered lattice *F* (four lattice points per cell), rather than the primitive lattices. This was already recognized by Bravais (1848), who saw that there were 14 such lattices; they now bear his name (Table 1 and Fig. 2). Although some crystal structures such as that of copper do have atoms only at lattice points, so that it is correct to refer to either the *Cu lattice* or the *Cu structure*, in general this is not so, and it is incorrect to use *crystal lattice* as a synonym for *crystal structure.*

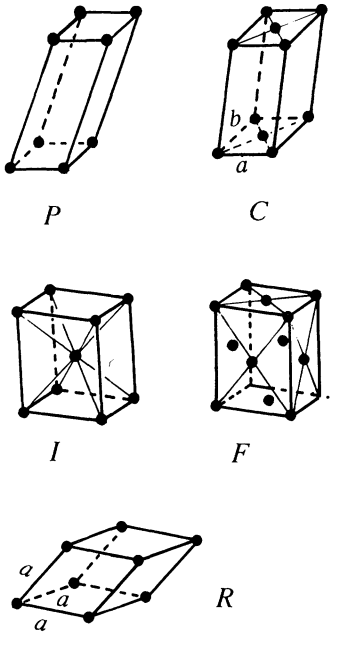

FIG. 2. Primitive *P*, *ab*-face-centered *C*, body-centered *I*, all-face-centered *F*, and rhombohedral *R* (trigonal) lattices (see Table 1).

1.3 Point-Group Symmetry

The manifestation of crystal symmetry is present both in the exterior forms and in the atomic arrangement within the crystals. This is how all of the elements of the crystal symmetry could be determined before any of the internal arrangements of atoms therein were discovered. Thus early morphological and mathematical studies led to the correct conclusion that there are 32 symmetry types that are called *point groups.* The morphology of crystals led to the recognition of *n*-fold rotation axes (where $n = 1, 2, 3, 4$, or 6, but not 5), mirror planes *m*, and a possible center of inversion *i* or $\bar{1}$. Combinations of these symmetry elements, which leave at least one point fixed, give rise to the 32 point groups. It is worth noting that some texts include *axes of rotary inversion* $\bar{n}$ or *improper rotation axes* as symmetry elements, but they result from combining rotation axes with a center of inversion or with a mirror plane.

Notations for describing point groups make use of some characteristic symmetry operation in the group, but they do not give all symmetry elements. Sometimes symmetry elements n or m in three directions are involved. When a mirror plane perpendicular to the n-fold axis is a major feature, it is represented by n/m. A twofold axis, if present, is often perpendicular to another major n-fold axis, and mirror planes can contain the major axis; these symmetry elements are placed side by side. For example, the symmetry point group of a cube with equal parts cut off from the corners is 432, representing the fourfold, threefold, and twofold rotation axes as major features. The pyramidal arrangement of H and N atoms in NH_3 gives rise to a threefold axis and mirror planes, its point group being $3m$. The planar benzene molecule C_6H_6 has a mirror perpendicular to the sixfold axis and two other types of mirror planes; its symmetry belongs to the point group $6/mmm$. Whereas these symbols of the Hermann–Mauguin notation are popular with crystallographers, the Schoenflies symbols are used more often by spectroscopists. The Schoenflies notations of the above point groups are $D_{6h}=6/mmm$, $C_{3v}=3m$, and $O=432$. Schoenflies symbols stress the nature of the group, being dihedral (D), cyclic (C), or octahedral (O). Although point groups were of interest to mineralogists at some time in the past, they do not play a key function in crystal structure descriptions today; however, they are still significant in crystallography as they provide an easy classification of crystals. A regular tetrahedron belongs to the point group 23 (Schoenflies symbol T), where the twofold axes go through the midpoints of opposite edges and the threefold axes go through the vertices and the geometric center. The relationship between a regular tetrahedron and a cube illustrates that 23 is a point group of the cubic crystal system.

1.4 Space Groups

Crystallographic lattices are generated from a point by translations, which are thus a symmetry operation. Hence it is apparent that a complete description of crystal symmetries must include translations as well as those present in point groups. Again the study is executed by the techniques of group theory. Combination of crystallographic point-group symmetry operations with translations gives new symmetry elements such as *screw axes* (2_1, 3_1, 4_1, and 6_1) and *glide planes* (axial glides a,b,c, diagonal glide n, and diamond glide d). The theory showed that there are 230, and only 230, distinct combinations of symmetry elements in three-dimensional space, which are known as the 230 *space groups.* These are each described in the Hermann–Mauguin notation to show essential symmetry elements, e.g., $P6_3/mmc$. The *International Tables for Crystallography* (Hahn, 1983) of the International Union of Crystallography, the *vade mecum* of crystallographers, give essential data for all space groups such as the possible sets of symmetry-equivalent positions therein, their multiplicity (number of equivalent positions), Wyckoff notation (see the Glossary), and point symmetry, and their coordinates. The space group to which a crystal belongs is an essential piece of information, without which the description cannot be completed from the published set of crystal data.

A space-group symbol consists of two parts: a letter depicting the lattice type and some essential symmetry elements. The triclinic system has two primitive space groups, $P1$ and $P\bar{1}$. Crystal structures belonging to the latter have a center of inversion, i.e., if there is an atom located at a point x,y,z, there is also one at $-x,-y,-z$; thus only half of the atomic coordinates in the unit cell needs to be given, as the other half is implicit or equivalent by symmetry. By way of illustration, the 13 space groups of the monoclinic system are listed in Table 2 with a remark about the symmetry features. Space groups with the same symmetry feature, but of different lattice type, are given on the same line. Table 2 also illustrates the relationship between space-group and point-group symmetry. The translation component of the former is absent in the latter.

Table 2. The 13 space groups of the monoclinic system.

Space group	Symmetry feature	Point group
$P2$, $C2$	Twofold axis	2
$P2_1$	2_1 screw axis	2
Pm, Cm	$m \perp$ the unique axis[a]	m
Pc, Cc	c glide	m
$P2/m$, $C2/m$	$m \perp 2$	$2/m$
$P2_1/m$	$m \perp 2_1$	$2/m$
$P2/c$, $C2/c$	c glide $\perp 2$	$2/m$
$P2_1/c$	c glide $\perp 2_1$	$2/m$

---

[a] $\perp$ means perpendicular to.

Therefore screw axes in space groups become simple n-fold rotation axes in point groups. Similarly, glide planes of space groups become mirror planes of point groups.

A symmetry element or operation will transform a set of coordinates x,y,z to a new location. For example, a twofold axis, if parallel to the b axis, gives $-x,y,-z$, and a 2_1 screw gives $-x,\frac{1}{2}+y,-z$. A c glide gives a new location at $x,-y,\frac{1}{2}+z$. Symmetry operations in each space group can be specified by a set of coordinates, which generate all atomic positions in a unit cell. For the space group of common occurrence, $P\,2_1/c$, the set of general coordinates (b axis unique) is: x,y,z; $-x,\frac{1}{2}+y,\frac{1}{2}-z$; $-x,-y,-z$; $x,\frac{1}{2}-y,\frac{1}{2}+z$. A diagram depicting these points is given in Fig. 3. However, if x, y, or z have values such as 0 or $\frac{1}{2}$, the set of four points degenerates into a set of two points only. These are called *special positions*. The special values give rise to several distinct sets, each with its own number of positions or multiplicity, and site symmetry. The sets are denoted by Wyckoff notations. A complete list of all Wyckoff sites for the space group $P\,2_1/c$ mentioned above is given in Table 3. Obviously, the origin for the coordinate system given in this example is at the center of inversion. The choice of origin and setting complicates matters for the comparison and classification of structure types.

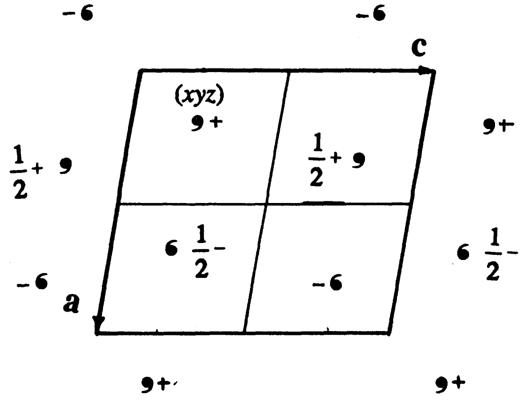

FIG. 3. Symmetry-equivalent images of a pattern represented by a comma at x,y,z (fractional coordinates with respect to a,b,c) in the space group $P2_1/c$. The + signs beside the comma indicate a point below the page. The coordinates $\frac{1}{2}\pm y$ of the points are represented by $\frac{1}{2}\pm$. Depending on the value for y, these points can be above or below the page. Inverted commas are due to mirror planes or centers of inversion.

1.5 Lattice Planes and Crystal Faces

For use in crystal diffraction and for morphological studies, it is necessary to consider a set of parallel planes so constructed that every lattice point lies on some member of it. These are called lattice planes, rational planes, or simply *planes*. When such planes cut an axis of the unit cell, they always divide it into an integer number of equal parts. If we start with some lattice point on a plane as the origin and proceed from it along the axes to the first member of the same set of planes, the equation for the first member plane can be expressed in terms of the intercepts. If the intercepts along the three axes are a/h, b/k, and c/l, respectively, the (h,k,l) are referred to as the Miller indices of the set of planes. The commas may be omitted if the integers or h, k, and l lead to no ambiguity. For example, referred to a lattice point as the origin, the first member of planes (321) intercepts the three axes at $a/3$, $b/2$, and c, respectively; see Fig. 4. The set of planes (100) is parallel to the bc plane. It should be noted, however, that the distance d_{100} between (100) planes is not a, except in orthorhombic, tetragonal, and cubic systems, which have orthogonal axes. The interplanar distance d_{hkl} for the general triclinic system is rather complicated, but for structures with orthogonal axes it is easily recognized.

Miller indices may be used in many ways: to designate a set of lattice planes, a particular member of the set, or a crystal face parallel to the set. The plane (100) intersects at unit length on the axis [100], which represents a lattice point and a direction (see Sec. 1.2). The direction [100] is not perpendicular to the plane (100) except in crystal systems with orthogonal axes, but [100]* referred to a direction in reciprocal space is perpendicular to (100).

The Miller indices are sometimes used to represent a *form* $\{hkl\}$ which represents a set of symmetry-equivalent planes. For example, $\{100\}$ includes (100), $(\bar{1}00)$, (010), $(0\bar{1}0)$, (001), and $(00\bar{1})$, which generate a cube for a cubic crystal. For a triclinic crystal, $\{100\}$ represents only (100) and its symmetry-equivalent plane $(\bar{1}00)$; $\{010\}$ represents (010) and $(0\bar{1}0)$, and $\{001\}$ represents (001) and $(00\bar{1})$. The faces or planes represented by the form $\{hkl\}$ depend on the crystal system.

Table 3. Multiplicity, Wyckoff notation, site symmetry, and coordinates of symmetry-equivalent sites in the space group $P\,2_1/c$.

Multiplicity	Wyckoff notation	Site symmetry	Coordinates of equivalent points
4	*e*	1	$x,y,z;\ \bar{x},\bar{y},\bar{z};\ \bar{x},\frac{1}{2}+y,\frac{1}{2}-z;\ x,\frac{1}{2}-y,\frac{1}{2}+z$
2	*d*	$\bar{1}$	$\frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0$
2	*c*	$\bar{1}$	$0,0,\frac{1}{2};\ 0,\frac{1}{2},0$
2	*b*	$\bar{1}$	$\frac{1}{2},0,0;\ \frac{1}{2},\frac{1}{2},\frac{1}{2}$
2	*a*	$\bar{1}$	$0,0,0;\ 0,\frac{1}{2},\frac{1}{2}$

All ($hk0$) planes are parallel to **c** or [001], and all ($hk0$) faces have one direction [001] in common. If the crystal is elongated in [001], these faces make it appear as a prism. Thus these are called *zonal planes* or *zonal faces*. The *zones* formed by these faces are convenient in the description of morphology and diffraction patterns. Diffracted beams from zonal planes form a cone with the apex at the crystal.

1.6 The Reciprocal Lattice

A crystal is an identity in a three-dimensional space, and its repeating lattice is called a *direct lattice*, for which a *reciprocal lattice* can be defined either for the convenience of diffraction studies or for other applications. A reciprocal-lattice point is defined to be lying on the normal of a crystal plane (hkl) at a distance K/d_{hkl}, K being a constant. The three reciprocal-lattice vectors **a***, **b***, and **c*** are normals to the planes (100), (010), and (001) with magnitudes of K/d_{100}, K/d_{010}, and K/d_{001}, respectively. Note that since $2/d_{100} = 1/d_{200}$, the reciprocal point corresponding to (200) is twice the distance from the origin as that of (100) or **a***. By the same token, other points in the reciprocal space can be deduced, generating the reciprocal lattice using the basic set of vectors **a***, **b***, and **c***.

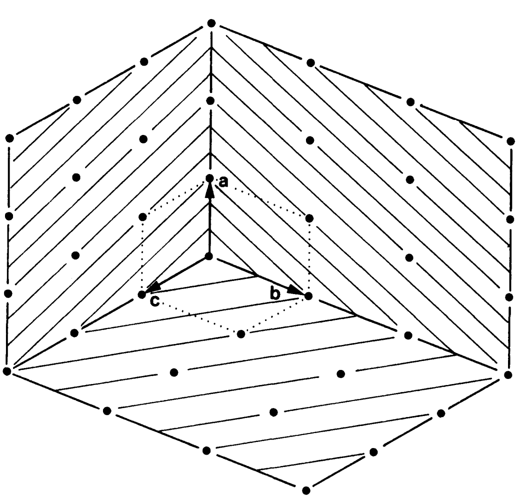

FIG. 4. A set of planes with Miller indices (321) showing the intercepts on axes *a*, *b*, and *c*. Every lattice point lies on some member of the set. The diagram includes three unit cells (one outlined by dashed lines) in each of the three directions.

When applied to x-ray diffraction studies, the constant K can be taken as λ (wavelength of the x rays used); in this case **a*** ($=\lambda/d_{100}$), **b***, and **c*** are unitless pure vectors. The convenience for such a choice has a direct connection with the Bragg equation written in the form $2\sin\theta=\lambda/d_{hkl}$ (see Sec. 2.2). Alternatively, K may be taken as 1, and the reciprocal-lattice space has a unit of reciprocal length. Using vector notation, the relationships between reciprocal and direct lattice vectors are

$$\mathbf{a}^*=\frac{\mathbf{b}\times\mathbf{c}}{V},\quad \mathbf{b}^*=\frac{\mathbf{c}\times\mathbf{a}}{V},\quad \mathbf{c}^*=\frac{\mathbf{a}\times\mathbf{b}}{V},$$

where V is the volume of the unit cell in direct space, and it has the expression

$$V=abc(1+2\cos\alpha\cos\beta\cos\gamma-\cos^2\alpha-\cos^2\beta-\cos^2\gamma)^{1/2}.$$

The reciprocal-lattice angles α^*, β^*, and γ^* bear the following relationships:

$$\cos\alpha^*=\frac{\cos\beta\cos\gamma-\cos\alpha}{\sin\beta\sin\gamma},$$

$$\cos\beta^* = \frac{\cos\gamma\,\cos\alpha - \cos\beta}{\sin\gamma\,\sin\alpha},$$

$$\cos\gamma^* = \frac{\cos\alpha\,\cos\beta - \cos\gamma}{\sin\alpha\,\sin\beta}.$$

Of course, the above relationships are simple for orthogonal systems, in which $\alpha = \beta = \gamma = 90°$.

2. CRYSTAL STRUCTURE DETERMINATION

Although determination of chemical composition and crystal structure are the first two steps in the characterization of a substance, they are but a component in the investigation of its chemical, physical, and other properties. Crystal structure determination provides a three-dimensional map of the atoms in the solid. Thus it gives information on the crystal symmetries involved in the atomic arrangement, on the dimensions and crystal class of the repeat volume or unit cell, and on what atoms occupy which crystal sites fully, partially, and in ordered or random fashion, as well as giving the values of the atomic coordinates. Thus information is obtained about the surroundings of each atom in the structure and the distances and angles between it and its neighboring atoms.

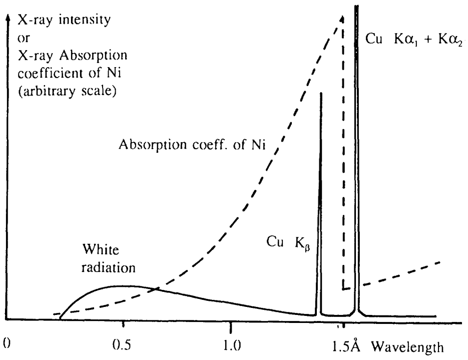

FIG. 5. A typical x-ray spectrum generated by bombarding a copper target with high-energy electrons; also shown are the absorption coefficients of nickel. The sharp drop in absorption coefficients at wavelength between *Kβ* and *Kα* is called the absorption edge.

2.1 Radiations for Crystallography

X-ray, neutron, and electron beams are the major radiations used for crystal structure determination. Each radiation has a unique characteristic and diffraction mechanism.

2.1.1 X-Ray Emission Spectra. Figure 5 shows a typical low-wavelength x-ray intensity spectrum, here generated by 50-kV electrons from a copper target. It is characterized by relatively low-intensity *white* or continuous radiation above a certain wavelength that is made use of in Laue photographs (see Sec. 2.2.1) and by the relatively intense $K\beta$ and $K\alpha_1$ and $K\alpha_2$ peaks at specific wavelengths, with intensities $K\alpha_1 > K\alpha_2 \gg K\beta$. Wavelength separation between $K\alpha_1$ and $K\alpha_2$ is small, and both are used for single-crystal and powder-diffraction photographs and diffractometer data. To simplify the data, the $K\beta$ radiation can be removed by placing a thin nickel foil in the path of the entrant beam, since it strongly absorbs $K\beta$ but not $K\alpha_1$ and $K\alpha_2$. The sharp difference in absorption coefficients within a short range of wavelength is called the ***absorption edge.*** The absorption edge of nickel falls between $K\beta$ and $K\alpha$ of copper x rays, i.e., nickel strongly absorbs $K\beta$ but absorbs little $K\alpha$ (Fig. 5). If the $K\alpha_1$ and $K\alpha_2$ frequencies have to be separated, it requires very careful setting of a *bent-crystal* monochromator, but generally this refinement is considered unnecessary. The principles outlined here are generally applied appropriately to x radiation from molybdenum or other metal targets. Of course, each target metal has characteristic radiations of some unique wavelengths with high intensities and corresponding filter material. The intensity of the x radiation is a function of the accelerating potential and intensity of the electron-generating beam. The potential and intensity are limited by the probability of "burning through" the water-cooled metal target. Stronger x-ray beams can be generated by a rotating-target generator, and very much more intense x-ray sources have now become available at specific *synchrotron radiation* (SR) locations. These are pulsed (intermittent) x-ray beams of continuous wavelength generated when electrons are accelerated to an energy of the order of 10^9 eV or 1 GeV (see SYNCHROTRON RADIATION).

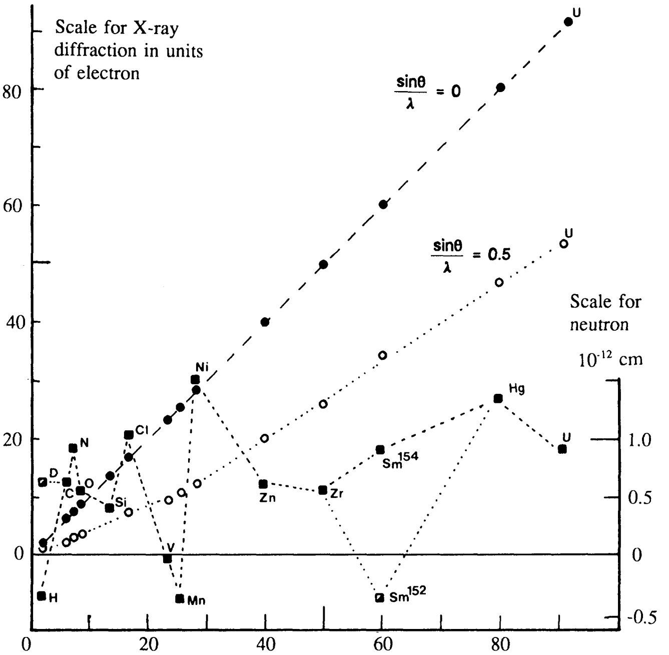

FIG. 6. Comparison of atomic-scattering factors for x rays and for neutrons. Two sets of values are given for x rays, filled circles for $\sin\theta/\lambda = 0$ and open circles for $\sin\theta/\lambda = 0.5$. Corresponding neutron data of the most abundant isotope are represented by filled squares. Isotopes of H and Sm are given for contrasting their difference. Units for the factors are electrons for x rays, and 10^{-14} m for neutrons.

2.1.2 X-Ray Atomic-Scattering Factors. X rays are scattered by the shells of electrons surrounding the atomic nuclei; the amplitudes of x rays scattered by an element, defined as the *atomic-scattering factors*, are positive and increase monotonically with the number of electrons or atomic number (Fig. 6). This has several important consequences in structural analysis.

1. *Location of atoms.* Since for hydrogen, particularly, the scattering factor is very small, very little electron density will appear in Fourier syntheses (see Sec. 2.2) at the locations of the hydrogen atoms, especially if the substance contains other atoms of much greater scattering power. This is why locations for hydrogen atoms cannot be determined with confidence.
2. *Assignments of elements to crystal sites.* When the atoms in a structure have scattering powers that differ little from the average value, it is difficult to assign elements to specific crystal sites. Furthermore, superstructure reflections that might be expected due to atomic ordering will be very weak and probably not detectable. In special cases this situation may be improved by judicious choice of x radiation and making use of the anomalous scattering factor, which is pronounced in the vicinity of an element's absorption edge.
3. *Phase-angle determination.* If a heavy atom is introduced in organic compounds that contain elements H, C, N, and O, its dominant atomic-scattering factor can be used to assist phase-angle determination (see Sec. 2.2).

Finally, since x rays are scattered by the electrons surrounding an atomic nucleus, interpretation of x-ray-diffraction experiments gives information not on the locations of the atomic nuclei but on the electron densities surrounding the nuclear sites.

2.1.3 Neutron Atomic-Scattering Factors. Neutrons, discovered in 1935, are particles emitted from the nuclei of atoms in nuclear reactions such as the fission of heavy atoms in reactors. The wave properties of neutrons make them suitable for diffraction studies. First, whereas x rays are scattered by electrons, neutrons are scattered by the atomic nuclei, whose radii are about $\frac{1}{100\,000}$ of those of atoms. Furthermore, the combined effect of nuclear scattering and magnetic scattering due to intrinsic spin and magnetic moment of the neutrons and of atomic nuclei gives rise to a phase-angle shift of the diffracted neutrons.

An out-of-phase (angle) shift results in a negative neutron-scattering factor. Therefore neutron atomic-scattering factors can have positive or negative values, or indeed have a value approximating zero (Fig. 6). They may even differ appreciably between atomic isotopes, as between hydrogen and deuterium. Indeed, with respect to other elements, the hydrogen and deuterium neutron-scattering factors are relatively much larger than their x-ray-scattering factors, which generally makes neutron-diffraction experiments more effective than x-ray experiments for locating the positions of these atoms in structures. Second, the particular values of neutron-scattering factors can be used with judicious advantage in structure determinations. For example, in the case of an ordered Ni-V alloy, neutron-diffraction experiments can well be combined with x-ray-diffraction experiments to locate the sites of the atoms, since the neutron atomic-scattering factor for vanadium is approximately 0. Finally, since neutrons have intrinsic spin and magnetic moment, diffraction experiments can be used to gain information on atomic moments and their orientations for magnetic atoms in structures by separating from the observed scattering that which is normally expected, thus revealing the *magnetic* scattering, which then may be interpreted.

2.2 X-Ray Crystal Structure Analysis with Single Crystals

W. L. Bragg's interpretation of the x-ray-diffraction patterns from NaCl, KCl, KBr, KI, and ZnS laid the foundation for x-ray structure analysis. A simple illustration of the principle of x-ray diffraction is the Bragg equation: $2d_{hkl}\sin\theta=\lambda$, where d_{hkl} is the interplanar spacing for (hkl), θ the angle of inclination of the x-ray beam to the crystal plane, and λ the wavelength of radiation used (Fig. 7). Thus a constructive beam results when both the wavelength and orientation of the crystal with respect to the beam are proper. Note that the diffracted x-ray beam or *reflection* [of plane (hkl)] deviates by an angle of 2θ from the incident beam (see X-RAY DIFFRACTION).

Bragg's law gives the condition for a reflection to develop, while the intensity I_{hkl} of the diffracted x-ray beam is related to the arrangement of atoms in the crystal. In short, I_{hkl} is proportional to the square of a quantity known as the *structure factor* F_{hkl}, which can be expressed as

$$F_{hkl}=\sum_{j=1}^{j=n} f_j \exp[2\pi i(hx_j+ky_j+lz_j)],$$

where $i=\sqrt{(-1)}$; x_j,y_j,z_j are the coordinates of the atom j expressed as fractions of the unit-cell lengths; f_j is the atomic scattering factor; and the summation is taken over all atoms (number n) in the unit cell. Generally, the higher the atomic number of the atom, the larger the f_j value, which decreases as θ increases. When a reflection develops, the path difference of x rays scattered from neighboring planes (hkl) is one wavelength, or a complete cycle of 2π (Fig. 7). The atom j with atomic scattering factor f_j located away from the origin at x_j,y_j,z_j will have a phase-angle difference of $2\pi(hx_j+ky_j+lz_j)$ relative to that from the origin. X-ray diffraction is the superposition of waves from all atoms, and thus the sum is the structure factor, which when squared is proportional to the intensity of the reflection. Thus structure determination involves the investigation of diffraction patterns, measurements of the angles 2θ and intensities of the reflections, and comparisons of the structure factors calculated for the proposed structural arrangement with those derived from experiment. However, to derive the structure from x-ray measurements is not

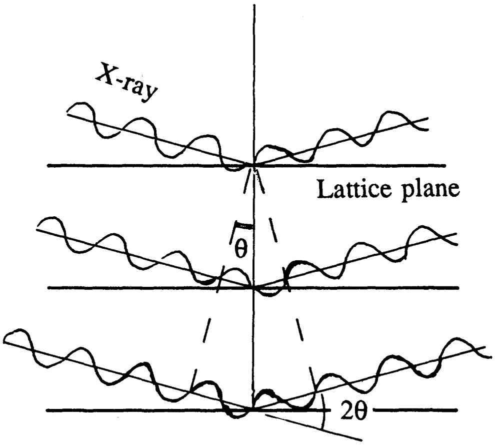

FIG. 7. A simple illustration of the principle of x-ray diffraction, showing the path-length difference of one wavelength for reflected x rays from adjacent lattice planes.

a trivial matter. If the structure factors are known, the electron density $\rho(x,y,z)$, the peaks of which correspond to the positions of atoms, can be calculated from the Fourier series (see FOURIER AND OTHER MATHEMATICAL TRANSFORMS)

$$\rho(x,y,z)=\frac{1}{V}\sum_{-h}^{h}\sum_{-k}^{k}\sum_{-l}^{l}F_{hkl}\exp[2\pi i(hx+ky+lz)],$$

where x,y,z is a point in the unit cell. Unfortunately, the diffraction experiments only provide the magnitudes $|F_{hkl}|$, but not the phase angles α_{hkl}, of F_{hkl} $[=|F_{hkl}|\exp(2\pi i\alpha_{hkl})]$. Thus, the diffraction pattern is analogous to only half of a holographic image. Therefore, solving a crystal structure is essentially a matter of solving the *phase-angle problem* or what crystallographers call the *phase problem*. Various methods have been devised for solving this problem, and the Patterson method invented in 1934 dominated until the 1980s (Glusker *et al.*, 1987). The Patterson function employs the square of the structure factors in a Fourier synthesis,

$$P(xyz)=\frac{1}{V^2}\sum_{-h}^{h}\sum_{-k}^{k}\sum_{-l}^{l}|F_{hkl}|^2\cos[2\pi(hx+ky+lz)],$$

where $P(xyz)$ is the Patterson density at the coordinates x,y,z, and its peak positions correspond to the interatomic vectors transferred to a common origin. Analysis of the Patterson map often reveals relative pairs of atoms. Since heavy atoms, such as chlorine or iron, say, in an organic substance, dominate the x-ray scattering, vectors between them in the crystal are commanding features of the Patterson map, from which locations of heavy atoms can easily be determined. Once the locations of the heavy atoms are found, structure factor calculations using them give phase angles that approximate those using all atoms. Thus borrowing the phase angles derived from the heavy atoms, but using the measured amplitudes for the Fourier synthesis, reveals the locations of the light atoms N, O, C, and H of most organic compounds. This is known as the *heavy-atom method* of Robertson (1953) for solving organic and protein crystal structures (see Sec. 2.3). However, the situation for metallic alloys is more difficult, since generally atomic-scattering factors of the different atoms may differ little from the average value [see Sec. 2.1.2, point **2**].

Hauptman and Karle (1953) applied statistics to the intensities of reflections, and their ideas led to wide success in solving the phase-angle problem during the 1970s. These are called *direct methods*, because the phase angles are derived directly from a mathematical treatment of the intensities themselves.

When phase angles for many reflections are derived from the locations of some atoms or by direct methods, these reflections can be used in the Fourier synthesis to reveal more atomic positions. Successive rounds of calculations generally lead to a satisfactory structure, and when all atoms are located with the help of chemical knowledge, better values of the atomic coordinates can be obtained by carrying out least-squares refinements. These minimize the factor R, which is the normalized difference between calculated and observed intensities of all reflections for a given structural arrangement:

$$R=\left(\frac{\Sigma^{hkl}(|F_{hkl}|_o-|F_{hkl}|)^2}{\Sigma^{hkl}|F_{hkl}|^2}\right)^{1/2}.$$

Early structure determinations from film methods gave R values of 10% or more, but modern data collected using diffractometers give R values between 9% and 2%.

Failure to obtain, after successive refinements, what would be considered a satisfactorily low R value should indicate possibly

1. a wrong choice of space group,
2. significant errors in phase-angle determination,
3. the incorrect positioning of some atoms in the structure,
4. incorrect assignment of elements to crystal sites or unrecognized random distribution of elements among the sites, or
5. any combination of points **1**–**4**.

A final check of the correctness of the structure can be obtained by calculation of a *difference Fourier synthesis*, $\Delta\rho$, which gives a three-dimensional map. Here the calculated electron-density map is subtracted from the observed one. Significant maxima or minima of electron density in the difference map indicate the possible presence of unplaced atoms, misplaced atoms, or incorrect assignment of atoms to crystal sites.

So far we have ignored two major factors that influence the observed intensities of x-ray reflections, compared to those calculated for a proposed structure:

1. *Thermal vibrations of the atoms.* This is taken into account by introducing into calculations a term known as the *temperature factor.*
2. *Absorption of x rays in the crystal studied.* To minimize the effects of x-ray absorption relative to crystal shape, ideally very small spherical single crystals should be examined.

When this is not possible, especially when the substance contains elements of high atomic number, estimates of the effects of absorption on the observed intensities of reflections relative to crystal shape, orientation, and dimensions must be made and taken into account.

Although modern crystal-structure analysis is now based on computer-controlled diffractometers and does not require much use of photographic techniques, many structures have been determined previously using various methods, so we give a general outline of these here.

2.2.1 The Laue Methods. The Laue methods (Amorós *et al.*, 1975) place a flat photographic film in a plane perpendicular to a beam of x rays of continuous wavelength to record the diffraction pattern from a stationary single crystal (Fig. 8). The film can be placed on either the same or the opposite side as the x-ray source, giving back-reflection or transmission Laue photographs, respectively. The Laue method is now used only to study crystal symmetry, perfection, or alignment for other experiments, although it is the easiest experiment to perform. Reflections from some zones appear on the film, and spots of each zone form ellipses on transmission and hyperbolas on back-reflection Laue patterns.

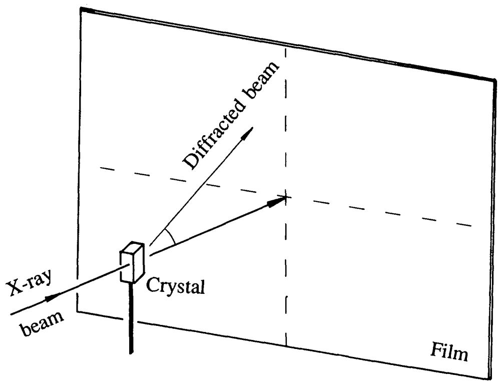

FIG. 8. A simple sketch showing the major arrangements in the Laue methods of x-ray diffraction.

2.2.2 Cylindrical-Film Methods. A flat film in the Laue method covers only a limited area for recording the reflections. More data can be collected when the film forms a cylinder coaxial with the rotation axis of the crystal. The axis is normal to the x-ray beam, giving rotation or oscillation photographs. Furthermore, if the film is allowed to translate while the crystal rotates, and if only one zone of reflection is allowed to be recorded at a time, a distorted reciprocal-lattice plane, e.g., (*hk*2), is recorded. This technique is called the Weissenberg method, which allows reflections from each set of planes (*hkl*) to be separated and their intensities measured. In the simple rotation methods, many reflections coincide in a single spot. Before 1970, the majority of intensity data for crystals was collected using the Weissenberg method, and the instrument, the Weissenberg camera, could also take cylindrical-film Laue, oscillation, and rotation photographs.

2.2.3 Precession Methods. In the precession method (Buerger, 1964), a simple direction, e.g., [100], of the crystal is aligned in the direction of the x-ray beam and is then tilted with respect to and caused to precess around it. This gives reflections of undistorted reciprocal-lattice planes for selected zones. Techniques used in aligning the crystal and selecting zones are useful in the study of crystal orientation as well as symmetry investigations. Careful study of such photographs is required to discover superstructures, especially if reflections due to the superstructure are weak. Precession cameras can also be used to take Laue photographs.

In summary, x-ray photographs reveal crystal symmetries and make possible the determination of cell dimensions, and generally of the space group. Estimation of the intensities of reflections from films was the major technique for crystal structure determination until the 1970s, when the use of automatic diffractometers that record intensities with scintillation detectors became common.

2.2.4 Diffractometers. A diffractometer is an instrument that rotates the crystal about three independent directions using three concentric circles. The angles on the circles are called ϕ, χ, and ω. The detector scans through the angle 2θ to measure the x-ray intensity. Thus the instruments are called four-circle diffractometers. The required orientations of the crystal for it to reflect the x-ray beam from (*hkl*) planes towards the scintillation detector used to measure the intensity are calculated from the unit-cell dimensions and orientation already determined. Computers are essential not only for these calculations, but also for controlling the angle driver and the detector. By the early 1980s, computer programs for solving the crystal structure had been integrated with those for diffractometer control to create complete operating packages.

2.3 Macromolecule Crystallography

Structure determination of proteins is a young science started in the 1930s, but its progress was slow at first, rapid growth only taking place since the 1970s. Compounds with large molecules include enzymes, redox proteins, carrier and storage proteins, hormones, antibodies, and viruses (see PROTEINS). Proteins are thousand-atom, chainlike, very large molecules, the building blocks of which are amino acids. The long chains of proteins are always folded into a globular shape (Blundell and Johnson, 1976).

Compared to small-molecule structural studies, the most difficult task in macromolecule crystallography has been the growth of suitable crystals and the preparation of heavy-atom derivatives. Nowadays, conditions for growing some protein crystals are well understood. Suitable methods have been found for growing an increasing number of proteins and enzymes. Growing crystals with heavy atoms inserted made the solution of the phase-angle problem easier.

Once the crystals are available, data collection, phase-angle determination, calculation of electron-density maps, interpretation of the maps, and least-squares refinements can follow, as in normal crystallography. However, because of the large molecular size, the unit cells of their crystals are very large, and many more reflections have to be collected, often using numerous crystals, since prolonged exposure to x rays may be destructive (see RADIATION DAMAGE OF CRYSTALS), and the calculation and interpretation of data are truly tedious. Many years of work used to be required for such a structure analysis; since faster data collection facilities and high-speed computing facilities have become available, this is no longer the case. When initially a small number of intensities is used, a low-resolution blurry image of the molecule may appear. When more reflections are added as time goes on, better resolution may reveal the backbone of the molecule and eventually even atomic sites. Thus the solution of protein and similar structures proceeds, as indeed do all structural solutions, by successive iterations whereby in the case of proteins, the resolution is successively increased, say from a scale of 10 to 5 to 2 Å, when individual major atom positions may appear in electron-density maps or sections. At 1 Å resolution, all atomic positions are accurately determined. Enzyme projects include the study of interactions between the protein and the *substrate* or between the protein and the *inhibitors*. These results lead to the understanding of biochemical reactions at the molecular level that are of great consequence in medicine and drug design. Furthermore, computer displays are used to model interactions between enzyme molecules, and these facilities enable biochemists and medical scientists to "see" biochemical reaction mechanisms and to facilitate the design of certain drugs.

Many countries have sites for macromolecular data collections, e.g., Cornell High Energy Synchrotron Source (CHESS), Stanford Synchrotron Radiation Laboratory (SSRL), National Synchrotron Light Source (NSLS) in the U.S.A.; Laboratoire d'Utilisation de Rayonnement Electromagnetique (LURE) in France; European Molecular Biology Laboratory (EMBL) in Germany; and Daresbury Laboratory in the United Kingdom.

Diffraction studies of synthetic and natural polymers usually give information about crystallinity and texture of the sample; low-angle scattering experiments are often employed. However, high-angle scattering experiments for polymeric molecules have lately been made possible by use of synchrotron radiations from which a suitable wavelength can be selected from a continuous spectrum of high intensity.

2.4 X-Ray Analysis of Polycrystalline Samples

Before 1960, many simple and even complex structures, particularly of metals and alloys, were solved by cylindrical-film powder methods, because single crystals could not be obtained. However, since crystal orientation is random in polycrystalline materials, reflections due to equivalent planes appear as arcs on the cylindrical film, and much information is lost compared to that obtainable from Weissenberg photographs of single crystals. More recently, computer-aided data analysis has increased the effectiveness of structure determination by powder methods when single crystals are unavailable.

Generally, powder-diffraction techniques are most useful for accurate determination of unit-cell dimensions and therefore for measurement of thermal expansion coefficients, since room-temperature films can be used to record reflections from samples cooled to as low as liquid-helium temperatures, or, enclosed in thin silica tubes, heated to high temperatures. However, diffractometer techniques are now used also for these purposes. Since most natural or industrial materials are polycrystalline, powder-diffraction methods are widely used for their identification, particularly in the metal and mineral realms. To this end, the Joint Powder Diffraction Commission (JPDC) maintains both printed and computerized indexes of powder-diffraction patterns of all known substances for their identification. Access to these can be had by various means but principally by the matching interplanar (*d*) spacings of the three most intense lines in the powder-diffraction pattern.

2.5 Other Diffraction Methods

X rays are electromagnetic waves, whereas neutrons and electrons are usually considered particles; however, a beam of each has the dual property that it can be treated either as a wave motion or as a beam of particles. In diffraction experiments, the former property is of interest. When just emitted from the nucleus of an atom during a nuclear reaction or fission, neutrons have an energy of 0.5 to 5 MeV, but are quickly slowed down when they collide with light atoms such as hydrogen in water, and become *thermal neutrons* of energy 0.025 eV at 293 K, with a de Broglie wavelength of $\lambda = h/mv = 18$ nm (1.8 Å). On the other hand, only high-energy electrons give a desirable wavelength for diffraction experiments.

2.5.1 Neutron Diffraction. The main thermal-neutron sources are nuclear reactors. Elaborate equipment is required to protect researchers and detectors from the harmful radiation; otherwise, the geometric requirements are similar to those for x-ray-diffraction experiments (see NEUTRON DIFFRACTION).

Since neutrons are scattered by the nuclei, rather than by the electrons, neutron-diffraction experiments give the locations of the nuclei in structures. Although neutron diffractions "see" time-averaged crystal structures, the inelastically scattered neutrons can also be measured by comparing the energies of neutrons before and after they interact with atoms in solids. Inelastic scattering experiments make possible the study of dynamic phenomena in the solid state. Thermal neutrons have velocities that are comparable to the thermal waves in solids; hence neutron-scattering experiments allow the observation of the Doppler shift of the scattered neutrons. This property makes possible the investigation of the dynamics (vibration spectrum) of atomic systems, by separating the inelastic and elastic scattering data (Bacon, 1975).

Compared to x-ray diffraction, neutron-diffraction experiments offer three distinct advantages:

1. Since neutron atomic-scattering factors can be either positive, negative, or approximately 0, judicious design of a neutron-diffraction experiment or comparison of the results of x-ray- and neutron-diffraction experiments can give specific information on the location of elemental species on crystal sites.
2. Since the atomic-scattering factor of hydrogen (and more so of its isotope deuterium) by neutrons is relatively much larger than that by x rays (Fig. 6), neutron-diffraction experiments are greatly favored over x-ray experiments for determining the location of hydrogen atoms in structures.
3. Since the neutron diffraction consists of "normal" and magnetic interactions, the two components of the scattering observed can be separated. Thus magnetic properties

associated with certain atoms and their specific sites in crystal structures can be studied (see MAGNETIC ORDERING IN SOLIDS).

2.5.2 Electron Diffraction. Electrons in a modern electron microscope operating at a potential of 50 000 to 10^6 V can penetrate thin materials of 0.1 μm thickness with a magnification power of 10^7 or more. For diffraction purposes, the effective de Broglie wavelengths range from 0.01 to 0.1 Å, so that the Bragg angles are about 1°. Nevertheless, diffraction patterns of very small crystals can be recorded photographically and used for structural investigation. However, because of the sensitivity of orientation, a small misalignment caused by crystal defects is observable in electron-diffraction patterns. The diffracted electron beam gives the image of the area irradiated by electrons; thus it is used for the study of crystal perfection so that the properties of the material can be correlated to sample treatment (see ELECTRON DIFFRACTION).

Because of the charge on the electron, an electron beam only penetrates slightly into the surface of a solid and can only pass through a very thin film of material. Therefore, the electron-diffraction pattern is essentially only two dimensional, although use of special techniques, such as slightly changing the orientation of the surface of the thin film or solid relative to the beam, may improve this situation when structure determination is necessary. Nevertheless, electron diffraction can well be used to identify small crystals settled in a thin-film metal matrix, and the shallow penetration is used with advantage to determine the arrangement of atoms on the surface of a crystal, a technique known as low-energy electron diffraction (LEED), although precise interpretation of the results of such experiments is subject to difficulties.

3. THE RESULTS OF CRYSTAL STRUCTURE DETERMINATIONS

Here we are able to provide only brief versions of atomic arrangements in the thousands of different crystal structures that have been determined. Broadly speaking, these fall into two classes:

1. structures in which single atoms can be considered bonded together, including metals and insulators/semiconductors, where the atoms either are covalently bonded together, or are charged ions;
2. molecular crystals in which groups of atoms forming molecules are covalently bonded together so that the peripheral atoms of the molecules exhibit filled valency subshells to those of neighboring molecules. Thus cohesion between the molecules in the crystals is very weak (van der Waals forces), and such crystals are generally soft, cleave easily if the geometry is appropriate, and have relatively low melting points.

3.1 Metals

The main characteristic of the crystal structures of metals and alloys is that the atoms generally, though not invariably, have high coordination numbers (CN) (see METALS AND ALLOYS, STRUCTURE OF). The "ideal" metallic arrangement is found in the close-packed face-centered cubic structure of copper in which each atom is surrounded by 12 neighbors in a cubo-octahedron (Fig. 9) or in the close-packed hexagonal structure of magnesium, where the surrounding is a twinned cubo-octahedron. This is because 12 is the maximum number of equal-sized spheres that can pack around a central sphere, all spheres being mutually in contact. This close-packed cubic arrangement is the basis of industrially used metals and alloys (see Sec. 4). When some atoms in an alloy have much greater diameters than others, coordination numbers up to 24, or even greater, may be found.

Another common metallic structure is the body-centered cubic type of wolfram (W), or the primitive β-CuZn type (two different components in ratio 1:1) in which each atom is considered to be surrounded by 8 atoms in a cube or 14 in a dodecahedron, depending on the relative sizes of the atoms (Fig. 10). Such alloys are of less use for industrial construction, but the basic arrangement may be of interest for magnetic and other properties. The close-packed and body-centered models are the basis of many more complex superstructural alloy structures.

Four convex coordination polyhedra that have triangulated surfaces are important in the structures of alloys. These are the CN12 icosahedron, the CN14 two-capped hexagonal

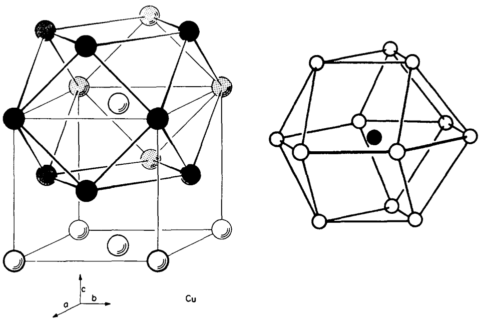

FIG. 9. The cubo-octahedron formed in all-face-centered cubic (fcc) crystals of copper (Cu), and the twinned cubo-octahedron in hexagonal-closest-packed (hcp) magnesium, which results when any one of the triangles is turned about its center by 60°.

antiprism, the CN15 three-capped truncated trigonal prism, and the CN16 four-capped truncated tetrahedron (Fig. 11). Also the trigonal prism, that may be capped by one, two, or three atoms, occurs frequently in the structures of alloys (Fig. 12).

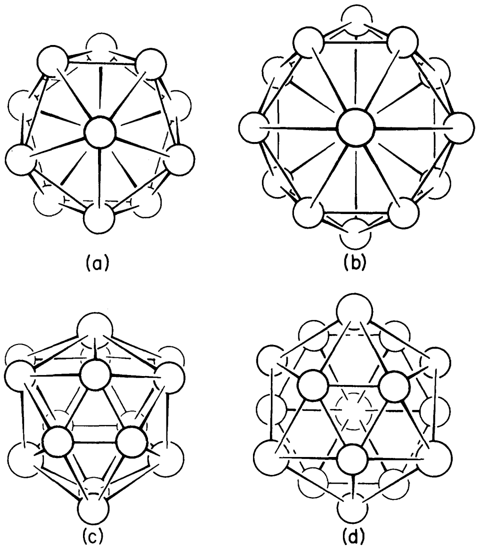

FIG. 11. Pictorial diagrams of CN12 (a) icosahedron, and (b)–(d) CN14, 15, and 16 coordination polyhedra of Frank and Kasper, central atom omitted (Frank and Kasper, 1958).

3.2 Insulators/Semiconductors

The tetrahedron and the octahedron are the most important CN polyhedra of the covalent and ionic insulators/semiconductors (see INSULATORS, STRUCTURE OF). Here the basic covalent structures are the cubic diamond and sphalerite (ZnS), or hexagonal wurtzite (ZnS) types of semiconductors, where each atom is surrounded by a tetrahedron of unlike neighbors so that adamantine arrays of covalent bonds run throughout the crystal in three dimensions (Fig. 13; see DIAMOND AND DIAMONDLIKE CARBON). Many more complex variants of these basic structural types are known. One of the basic ionic types is the rocksalt structure (NaCl), wherein each atom is surrounded by an octahedron of unlike ions

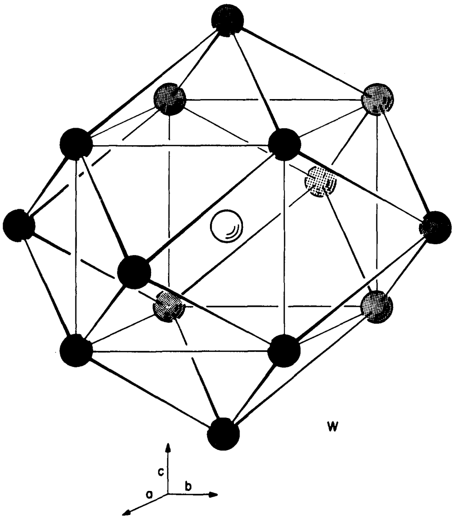

FIG. 10. The dodecahedron, CN14, in the body-centered-cubic (bcc) structure of tungsten (or wolfram W). The 14 neighbors are divided into sets of 8 (corners of cube) and 6 (body centers of neighboring cells).

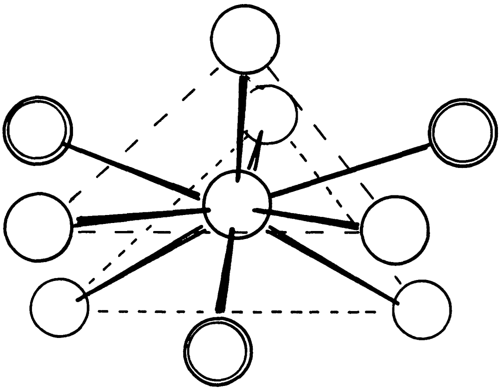

FIG. 12. A tricapped trigonal prism configuration.

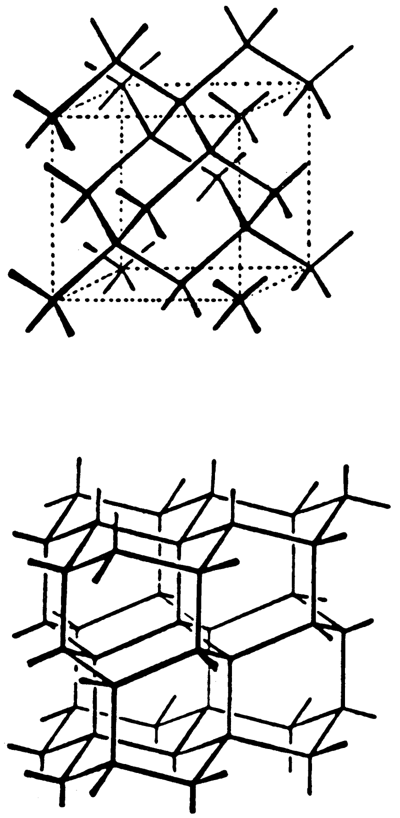

FIG. 13. The tetrahedral bonded framework of diamond or ZnS in the forms of cubic sphalerite (top) or hexagonal wurtzite type (bottom) (Wells, 1962).

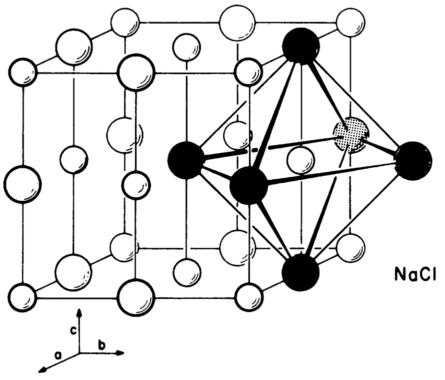

FIG. 14. The rocksalt structure as one of the basic structure types, with one octahedral coordination polyhedron outlined.

(Fig. 14). This arrangement satisfies the central forces of the predominantly ionic bonds. Many complex variants of this basic structure are also known, particularly in oxides, as are very many structures of inorganic compounds and minerals that embrace both tetrahedral and octahedral surroundings, such as spinels (Fig. 15), silicates, sulfosalts, etc. Another basic ionic structure of importance is the CsCl type (identical to the metallic β-CuZn mentioned above) in which each ion is surrounded by a cube of unlike ions. Finally, we draw attention to the frequent occurrence of trigonal prismatic coordination (Fig. 12) also in the structures of insulators/semiconductors.

3.3 Molecular Crystals

These mainly embrace organic materials (substances composed largely of C, H, O, and/or N), but they are also formed by covalent and ionic bonded inorganic materials. Thus the common elemental structures of Se and As form "infinite" molecules that run throughout the crystal in one and two dimensions, respectively (Figs. 16 and 17); the alloy GaTe forms an "infinite" two-dimensional molecule (Fig. 18). Many inorganic substances contain polyatomic anions or polyatomic cations in which a group of atoms is covalently bonded together to form a molecule that has an overall ionic charge, the charges being neutralized in the crystal by other ions of opposite charge: e.g., Na_2TaF_8 (Fig. 19) and $Mo[S_2CN(C_2H_5)_2]I_3$ (Fig. 20).

As well, metallic or insulator structures may contain uncentered clusters of atoms, the

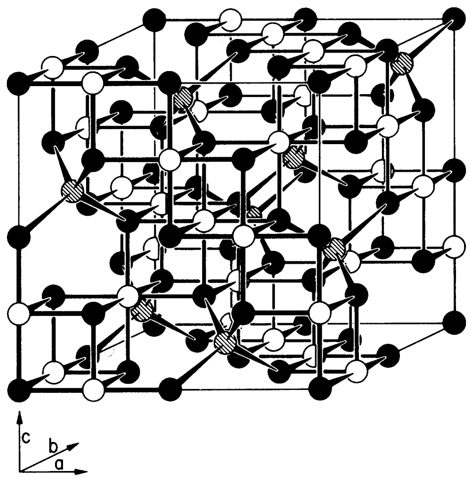

FIG. 15. The spinel crystal structure type.

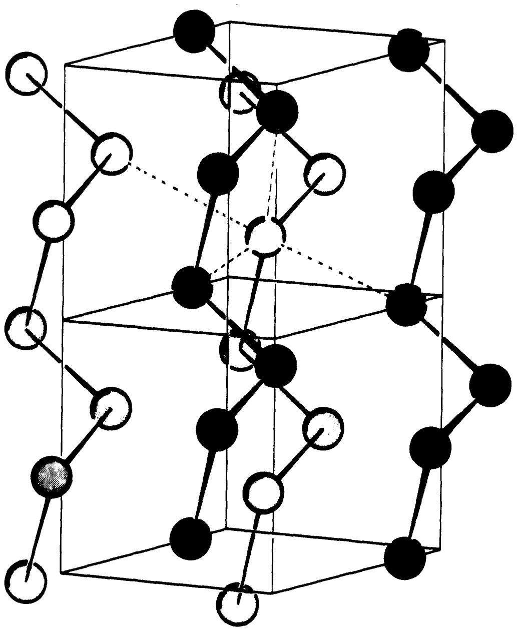

FIG. 16. The structure of Se and Te forming infinite chains in the crystal.

residual valency requirements of which are satisfied by forming occasional covalent bonds to neighboring clusters or intermediate atoms, or by the presence of charged ions in the spaces between the clusters—e.g., boron icosahedral clusters (Fig. 21) or Mo_3Se_4, CN14 (cube+octahedron clusters).

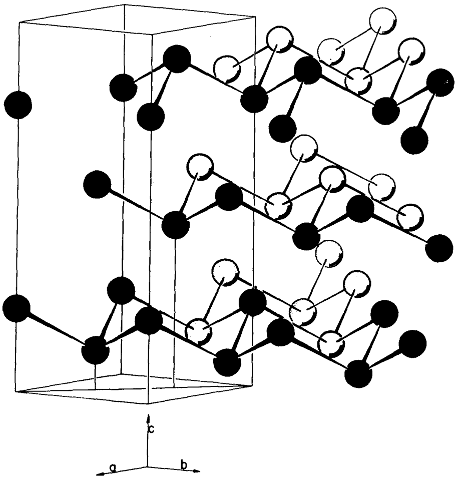

FIG. 17. The structure of sheets of the element arsenic, As.

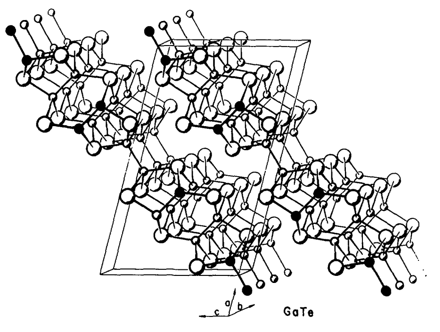

FIG. 18. The infinite-sheet structure of GaTe, with Ga and Te atoms represented by small and large spheres, respectively.

The crystallography of organic molecules is clearly a function of the most efficient packing together of the various molecular shapes as discussed by Kitaigorodski (1963) (see e.g., Fig. 22). However, ionic charges, polarity, and hydrogen bonding are some of the features that can greatly influence molecular packing and affect the cohesion between molecules. Atoms in some organic molecules called *zwitterions* are the sites of distinct positive or negative charges. Such molecules pack together, as far as shape permits, so that negative charges of one molecule attract positive charges of others. The separation of charges is never complete in a bond involving two different elements, and these bonds are said to be *polar*. Molecules usually pack in such a way that their polar branches are attracted to each other, whereas the nonpolar segments also tend to pack together (see Fig. 23). The —OH and —NH groups in a molecule tend to seek negative sites of polar bonds, and *hydrogen bonds* are formed via the positive

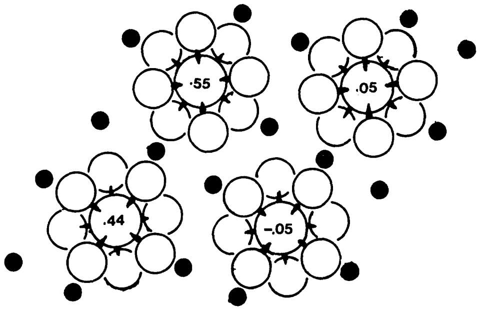

FIG. 19. The arrangement of Na^+ and $TaF_8{}^{2-}$ ions in Na_2TaF_8. Eight F atoms form a tetragonal antiprism. Fractional values in the centers of circles are the *y* coordinates along the *b* axis.

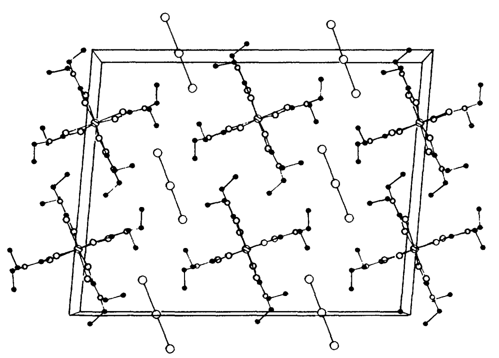

FIG. 20. Large cations $\mathrm{Mo[S_2CN(C_2H_5)_2]^+}$ and linear $\mathrm{I_3^-}$ anions in the crystal of $\mathrm{Mo[S_2CN(C_2H_5)_2]I_3}$.

nature of the H atoms in them. The electronegative atoms O and N in carboxyl —C(=O)OH, hydroxyl —OH, amine —NH and other groups or ions attract these hydrogen atoms. Since molecules may contain many of these groups, their packing together is arranged so as to permit the maximum number of intermolecular hydrogen bonds to form, thus considerably increasing the intermolecular cohesion (Fig. 24).

Finally, there are the structures of very large organic molecules such as proteins and viruses that can be (extracted and) grown in crystalline form for structural analysis. The crystals of these compounds fasten the molecules in rigid positions for x-ray studies. However, the features of their molecular structures are of prime interest. In Fig. 25, a picture of the structure of deoxyribonucleic acid (DNA) is shown.

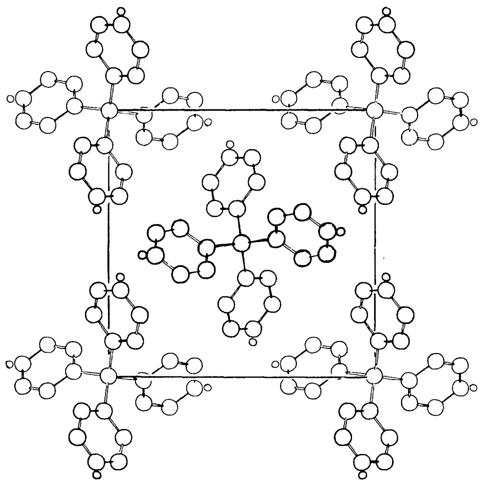

FIG. 22. The packing of tetraphenylmethane in a tetragonal system, a structure common to all tetraphenyl derivatives of the carbon group (C, Si, Ge, and Pb). The molecule in the center is located halfway up along **c**.

It should also be noted that the structures of inorganic polyionic molecules containing water of crystallization (see Fig. 24) can be greatly influenced by hydrogen-bond formation.

3.4 Assessment and Collation of Crystal Structure Data

With the number of determined crystal structures exceeding a hundred thousand, there is an obvious problem of recovering data when required, and perhaps more signifi-

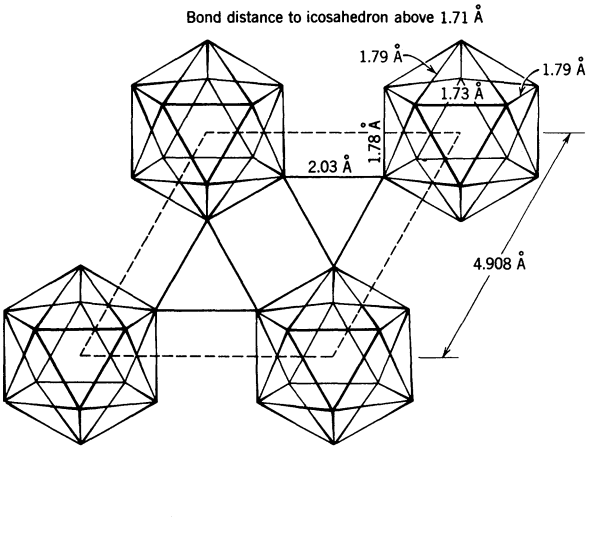

FIG. 21. Predominant icosahedral clusters of boron are the feature of the α-B structure (Decker and Kasper, 1959).

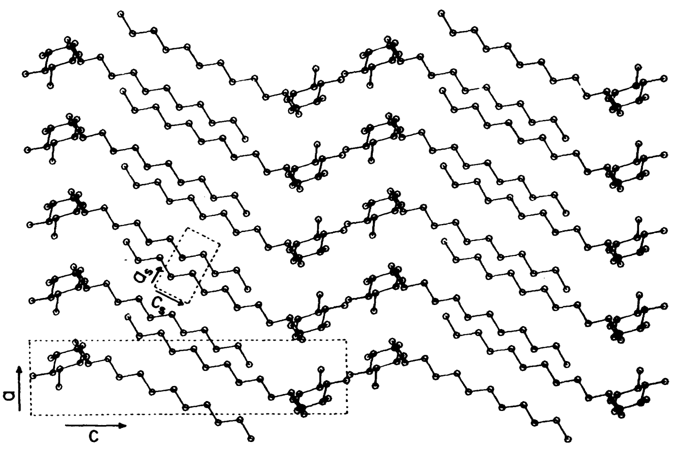

FIG. 23. Molecular packing of 1-decyl α-D-glucopyranoside, $C_{16}H_{32}O_6$, projected along *b*. The polar heads attract each other, leaving the nonpolar chains or tails staying together by themselves. The hydrocarbon subcell also appears in the projection (Moews and Knox, 1976).

cantly of usefully comparing and collating the data at hand. The first problem is now well served by computer data banks that permit retrieval of data under many headings. Of the many such private and public data banks, we shall mention only a few: Cambridge Structural Database (U.K.), organic; National Research Council Canada Metals Data Files (Canada); Gmelin/FIZ Inorganic Crystal Structure Database (Germany); Brookhaven Protein Databank (U.S.A.); and European Molecular Biology Laboratory Database (France).

The second problem of assessment and collation of data by the human mind is much more difficult, since even a mass of computer printouts is, by virtue of its very volume, likely to be intractable. However, in the metal (particularly) and inorganic realms, the concept of a *crystal structure type* developed over the years has proved useful. Although such a type, defined by the crystal's space group and the partially or fully occupied Wyckoff sites therein, may be unique to a single substance, generally it is adopted by several substances and occasionally by a hundred or even several hundred substances. Thus with this concept, the same structure type of many substances can be considered a single unit of information, and can be related to other structure types, and to the observed physical and other properties of its adherents. The advantage of this classification is that it groups together the structures of substances, regardless of their relative unit-cell sizes, relative ratios of the

lengths of the unit-cell edges, unit-cell angles, and relative values of variable atomic coordinates x,y,z. Its disadvantage is that it may asssemble together structures in which the coordination of the atoms differs. Generally this consequence is not serious compared to its simplicity and advantages, and it can be taken into account by noting the combinations of structural parameters at which changes of coordination occur.

The advantages of being able to interrelate many different structure types include

1. comparison of structures with similar atomic coordinations that may be significant in relation to particular physical or other properties, and
2. showing that a particular complex structure with a large unit cell is but a superstructure of a much simpler type, the superstructure being caused, e.g., by the ordering requirements of the atoms in the complex structure, or by atomic displacements from regular crystal sites caused by the particular chemical bonding needs of the atoms in the complex structure.

This concept has been basic to many famous books that have been written over the years; some of these are given in the Further Reading list.

4. CRYSTALLOGRAPHY IN INDUSTRY AND MEDICINE

Crystallographic knowledge is basic to the industrial use of materials, which is now known as *materials science.* For example, close-packed cubic metals and alloys are used for construction and mechanical devices because they are isotropic and because the close packing of the equilateral triangular networks of atoms to which the structure gives rise readily permits six active slip systems that facilitate plastic deformation (forming) of a polycrystalline material. Another mechanism for plastic deformation is mechanical twinning, in which the atomic planes slip through a definite fraction of the crystallographic repeat distance, in such a way as to produce a new crystal in twinned orientation relative to the original. Hardening generally results from precipitation of very small crystals of other symmetry in the cubic matrix as a result of suitable adjustment of composition by addition of minor quantities of other elements and annealing at elevated temperatures, followed by rapid cooling (quenching). Information on such precipitates derives from crystallographic studies, as does information on "textures" (crystal orientation) following forming operations. Metals are also important as electrical conductors, a property that arises from the unsaturated metallic bonding or partly filled overlapping energy bands, but which is influenced by interatomic distance, high purity, and perfect (not disordered) occupation of crystallographic sites in intermetallic compounds. Useful magnetic properties of alloys depend on composition ("magnetic" metallic elements present) and particularly on the crystallographic properties of atomic arrangement, coordination, and interatomic distances.

Superconductivity does not have its immediate origins in crystallographic arrangement, but it is interesting to note that all ordinary superconductors ($T_c < 23$ K) with high transition temperatures have one of some half-dozen structure types. Among the new superconductors with much higher transition temperatures, not only is composition important but also structural arrangement and the degree of order or disorder of the components on the crystal sites.

The important electrical properties of inorganic materials (insulators/semiconductors) and their practical use in devices depends not only on composition but also on crystallographic knowledge and crystal-growth techniques for the preparation of highly pure crystals and the creation of graded junctions, etc. Superionic conductivity is directly dependent on crystallographic knowledge, since the structures of such conductors must have linear channels of diameter sufficient for single conductor ions to move through unimpeded on application of an electric field. Magnetic properties of these materials (such as oxides) are, or were, exceedingly important to the recording industry, and structural information has played its part in the development of industrial magnets.

Crystallographic information has been a component in the pharmacological development of "drugs" that have so greatly influenced the modern practice of medicine. However, the greatest triumph of crystallography for modern medicine was Watson and Crick's (1953) determination of the structure of DNA, which resulted also from the concomitant work of many other able crystallographers. This, followed by the determination of the structures of proteins, has lead to the unravelling of the genetic code, the possible recognition of the causes of bodily malfunction that result from defects therein, etc. In addition, diffraction experiments have been used in examining the function of cells and cell membranes.

5. EPILOGUE

This article would not be complete without positive evidence of the importance attached to crystallography by the scientific community, and what better way is there than by listing the commanding number of Nobel Laureates who have been recognized for their achievements related to crystallography. Despite the inexhaustiveness, such a list marks the major milestones since the inauguration of the prize.

Physics:

1901	Wilhelm Röntgen, discovery of x rays
1914	Max von Laue, discovery of diffraction of x rays by crystals
1915	William Bragg and Lawrence Bragg, analysis of crystal structure by means of x rays
1929	Prince Louis de Broglie, discovery of the wave nature of electrons
1935	James Chadwick, discovery of the neutron
1937	Clinton Davisson and George Paget Thomson, discovery of electron diffraction by crystals.

Chemistry:

1936	Peter Debye, studies of dipole moments and the diffraction of x rays and electrons in gases
1946	James Sumner, discovery of enzyme crystallization
1954	Linus Pauling, study of the nature of the chemical bond
1962	John C. Kendrew and Max F. Perutz, determination of the structure of hemoproteins
1964	Dorothy M. C. Hodgkin, determination of the structure of vitamin B_{12}
1976	William N. Lipscomb, revelation of the structure of boranes
1980	Paul Berg, Walter Gilbert, and Frederick Sanger, studies of structure and biochemical function of DNA
1982	Aaron Klug, determination of the structures of viruses
1985	Herbert Aaron Hauptman and Jerome Karle, development of the procedures for the solution of the phase-angle problem in x-ray diffraction
1988	Johann Deisenhofer, Robert Huber, and Hartmut Michel, structure determination of a large (more than 10 000 atoms) bacterial protein complex responsible for photosynthesis.

Physiology and medicine:

1962 Francis H. C. Crick, James D. Watson, and Maurice H. F. Wilkins, elucidation of the structure of DNA.

GLOSSARY

Absorption Edge: The sharp difference in absorption coefficients of x rays within a short range of wavelength. The absorption edges are unique for each chemical element.
